The argon, of commercial grade, was obtained in small metal bombs at high pressure. It contained more impurities than either the helium or the neon, and was the most difficult of the three gases to purify, since, because of its absorption of argon, charcoal in liquid air could not be used. The argon was purified by maintaining an arc of about 2 amperes between a mischmetal and an iron electrode in the gas at a pressure of 10 to 15 cm. The arc was run continuously for from one to two days with the argon in one purifier, then the gas was transferred to another purifier and run under the same conditions for about a week. After this treatment it was still found to contain a very small trace of nitrogen. It was then stored in a reservoir containing well-degassed charcoal where it was allowed to stand for several days at room temperature. When admitted to the tube from this reservoir it was found to be very pure with the exception of a small trace of hydrogen. Most of this hydrogen was removed from the argon by admitting a very small amount of oxygen, generated by heating potassium permanganate, to the gas and circulating the mixture through the discharge tube and liquid air traps. The argon was again stored over well-degassed charcoal for several days, after which time it was found to be very pure.

PREPARATION OF THE TUBE

The electrodes were well-outgassed by heating with an induction furnace before being mounted in the tube. Before each set of experiments with mixtures of two of the gases the whole system was pumped for several hours and allowed to stand over night, evacuated and with liquid air on the traps, to

test for leaks. In case the system was tight the tube was baked at from 300 to 350°C for four hours while being pumped. At the same time the charcoal trap and the mischmetal getter trap, in the circulating system, were baked at 400°C. This part of the system, including the tube, was then pumped for about 4 hours while the tube and traps cooled. The whole system was allowed to stand over night, evacuated and with liquid air on the traps, to test again for leaks. After pumping again for about two hours the system was ready for use.

PROCEDURE

After the gases were purified and the tube prepared as described above, one of the gases to be used was admitted to the tube very slowly by means of a slow leak grooved stopcock, through the system of traps, Fig. 1, until the desired pressure was obtained and was then circulated for about 20 minutes through the discharge tube and traps with a discharge running at the desired current. The rate of circulation was then decreased to a very low value and the pressure adjusted accurately to the value desired. The current was kept constant, and voltage readings were taken at short time intervals in order to determine when conditions were constant for the taking of data as described below. Pressure measurements were taken at various intervals to see that the pressure and rate of circulation remained constant.

If a very small amount of another gas was to be mixed with the gas already in the tube, the gas in the tube was pumped out with the mercury circulating pump backed by a Toepler pump and stored in an empty reservoir or in a charcoal trap in liquid air. The tube was well pumped out with the mercury pump and a small amount of the other gas admitted to the tube to the pressure necessary to give the percentage mixture desired. The gas previously used was readmitted to the tube slowly in the same manner as before. The process described above of circulating the gases was repeated to insure a homogeneous mixture of the gases and the data were taken as described in the next section. For adding larger amounts of one gas to another, a separate system including a guage with its volume calibrated with respect to the tube volume was used. In this way by starting with one pure gas, mixtures with another gas could be studied in any proportions from very small percentages up to a 50 percent mixture. The results obtained were found to be repeatable within a few percent at any time. For each gas mixture studied a spectrogram of the light emitted from the positive column was taken in order to observe the change in excitation produced with changes of the gas mixture and to check the purity of the gas.

METHOD USED IN MEASURING THE POTENTIAL GRADIENT IN THE POSITIVE COLUMN

The method consisted in measuring the total drop in potential across the tube at various electrode distances, while the current was kept constant by varying the e.m.f. in the circuit. The anode was moved by magnetic control from outside the tube. Before any measurements were taken, the discharge was run with the maximum electrode distance for from one to two hours at

constant current until the maintaining voltage across the tube remained constant. The maximum electrode distance was 32 cm. The anode was moved from this point, 2 cm at a time, to within 10 cm of the cathode and back to 32 cm again. Readings of the total voltage across the tube were taken every two cm at intervals of one minute as the electrode distance was decreased and then increased again. The voltage readings for increasing electrode distance checked those for decreasing electrode distance to within less than one percent.

This method of measuring the field is applicable since a uniform cylindrical tube was used, and only the uniform positive column was studied. Since the current density and the concentration of ions and electrons remain constant throughout the length of the uniform positive column, the anode drop in potential does not change with the anode position along the column. The tube was run long enough before any data were taken so that the cathode drop in potential remained constant while observations were being made. The time required to take a complete set of observations was 24 minutes. The voltage readings, taken with decreasing electrode distance, when plotted against electrode distance, gave a straight line very accurately. The slope of this line gave the potential gradient or electric field in the positive column in volts/cm.

RESULTS

The results of the investigation are shown by the data given in Tables I and II and by the curves in Figs. 3 to 8 inclusive. The values of the electric field in the positive columns are given in Table I for the pure gases, helium, neon, argon and for mixtures of each of these gases with mercury vapor at

TABLE I. *Electric field in the positive column for the rare gases and mixtures of each with mercury vapor.* Current, 40.0 m.a. Pressure, 14.0 mm. Tube diameter, 4.4 cm.

Gas Positive column (Field in volts/cm)	pure He	He-Hg	pure Ne	Ne-Hg	pure A	A-Hg
	17.0	18.4	4.0	2.2	3.8	4.5

about 0.005 mm pressure. It can be seen from this table that mercury vapor added to neon causes a large decrease in the field but when added to either helium or argon causes a slight increase.

Table II gives the results of spectrograms taken from the positive column of the discharge in the various gas mixtures studied. It will be noted that a very small amount of argon added to either helium or neon completely subdues the helium or neon spectrum and only the argon is excited. Mercury has the same effect on either argon or neon; while with mixtures of small amounts of neon or of mercury with helium, the spectra of both gases appear. When argon, containing a trace of nitrogen, is added to neon in amounts up to 2.0 percent the neon spectrum disappears and the argon spectrum appears strong with the nitrogen spectrum weak. As more of the argon, containing a trace of nitrogen, is added to the neon the argon spectrum becomes weak and the nitrogen spectrum strong until with more than 5.0 percent only the nitrogen spectrum appears.

TABLE II. Results of spectrograms taken of radiation from the positive column of a glow discharge in the various mixtures of the rare gases and mercury vapor studied.

Gas mixtures	Percentage of added gas greater than the amount given below		Spectrum obtained
Helium—Neon	0.4%	Neon	Helium and Neon
Helium—Argon	0.2%	Argon	Argon only
Neon—Argon	0.15%	Argon	Argon only
Neon—{ Argon with a trace of nitrogen }	0.5% 2.0%	{ Argon with a trace of nitrogen }	Argon and Nitrogen
Neon—{ Argon with a trace of nitrogen }		{ Argon with a trace of nitrogen }	
Neon—{ Argon with a trace of nitrogen }	5.0%	Mercury	Nitrogen only
Helium—Mercury	0.03%	Mercury	Helium and Mercury
Neon—Mercury	0.03%	Mercury	Mercury only
Argon—Mercury	0.03%	Mercury	Mercury only

Fig. 3 shows the variation with pressure of the electric field in the positive column for pure helium and for a mixture of neon with helium. These curves show that the field varies directly as the pressure for both the pure gas and the mixture. They also show that the effect on the field produced by adding a small percentage of neon to helium does not change appreciably with the total pressure over a considerable range of pressure.

Fig. 3. Variation of electric field with pressure for pure helium A and a mixture of 99.0 percent helium and 1.0 percent of neon B. Current, 40 m.a.

Fig. 4. Variation of electric field with percent of neon added to helium. A, current 40 m.a., pressure 14 mm; B, 20 m.a., 7 mm; C, 40 m.a. 7 mm.

These curves of Fig. 4 show the variation of the electric field in the positive column with small amounts of neon added to helium under different conditions of pressure and current. The interesting point to note here is that the maximum field is a function only of the percent of neon in the helium and is independent of the pressure or of the current density. These curves also show that a large change in the field is produced by a very small amount of neon in helium.

Fig. 5, 6, and 7 show the variation of the field in the positive column with all possible mixtures of the three gases helium, neon, and argon taken only two together.

The curve of Fig. 5 shows that a small amount of neon in helium has a large effect on the field while a small amount of helium added to neon has very little effect on the field.

It can be seen from the curve of Fig. 6 that argon-helium mixtures have about the same characteristics as those of neon-helium except that a smaller amount of argon is more effective in helium than in neon in changing the field. The discontinuity in the curve is probably due to the difference in mobility and large difference in ionization potential of the two gases. For pure argon

and for mixtures of argon with small amounts of helium the discharge did not fill the tube completely but concentrated toward the axis of the tube. For from 2 to 7 percent helium in argon the discharge was unstable and could not be maintained at the current and pressure desired without changing the resistance of the circuit. For mixtures containing more than 7 percent helium the discharge filled the tube uniformly. The sudden increase in field produced is due to the change in the current density distribution over the cross section of the positive column. Where the current density is large at the tube axis

there is less diffusion of positive ions to the tube walls and therefore a smaller field, than in the case of a more nearly uniform distribution of current over a cross section of the column.

From Fig. 7 it can be seen that small amounts of argon have much less effect on the field in neon than of that in helium and that neon in small amounts has practically no effect on the field in argon.

Fig. 8 shows how the field in neon-argon mixtures is affected by a small trace of nitrogen in the argon.

DISCUSSION AND INTERPRETATION OF RESULTS

The interpretation of the electrical and spectral characteristics of the positive column in the gas mixtures studied is based principally upon collisions of the second kind between the excited metastable atoms or the ions of one gas and the neutral atoms of the other gas. The effect of limitation of electron velocities observed when a considerable amount of a gas of lower ionization and excitation potentials is added to another gas is insufficient to explain the large effects obtained with the very small percentages of the added gas. With a formula given by K. T. Compton,^{17,18} calculations were made of the number of collisions an electron would make with gas atoms in a mixture of helium with 0.1 percent neon under the discharge conditions which obtained. It was found that an electron would make in the order of 1000 collisions with gas atoms and hence, on the average, one collision with a neon atom while gaining the energy represented by the difference between the ionization potential of helium and the lowest excited state of neon. Since the probability of excitation by electron impact under these conditions is far from certainty, an increase in the field of 26 percent could hardly be attributed to limitation of electron velocities by collisions with neon atoms. With the mixture of less than 0.03 percent mercury vapor with neon the field is reduced by 45 percent which is entirely too large an effect to be explained by limitation of electron velocities. Therefore we must turn to collisions of the second kind for a satisfactory explanation of the observed results.

Collisions of the second kind. The following list of reactions, 1 to 6, inclusive, show the possible ways by which collisions of the second kind may take place between two gas atoms X_1 and X_2 where the energy of excitation is transferred from X_1 to X_2 . The resultant products of each of the first six reactions may be represented by any one of the expressions 7 to 10, depending upon the relative ionization and excitation potentials of X_1 and X_2 .

X' is an excited gas atom, X^+ a gas ion, $X^{+'}$ an excited gas ion, X^{++} a doubly ionized ion, and KE is kinetic energy.

The reactions represented by the initial conditions 1 or 2 resulting in 7, 8, or 9 are of most common occurrence in discharges in mixtures and are most important in explaining the effects observed.

Processes of ionization and excitation. The processes of ionization and excitation in the positive column in pure monatomic gases having metastable states can be represented by the following reactions.

Reactions by which ions are produced by electron impact.

where e_f is a fast moving electron with sufficient kinetic energy to ionize the neutral gas atom X , and e_s is a slow moving electron with sufficient kinetic energy to ionize an excited metastable atom X_m' .

Reactions by which metastable atoms are produced.

where X_m' is an excited metastable atom, and X' is an excited atom in a non-metastable state.

Reactions producing excitation of non-metastable states of atoms.

where e_{f1} is a fast moving electron with sufficient energy to excite a neutral atom, and e_{s1} is a slow moving electron with sufficient energy to excite a metastable atom.

In gas mixtures composed largely of one gas with a small amount of gas of lower ionization and excitation potentials than those of the main gas, other processes of ionization and excitation take place by collisions of the second kind.

Let X_1 = atoms of the main gas and X_2 = atoms of the gas present in small amounts.

Reactions of the second kind which produce ionization and affect the concentration of metastable atoms in a discharge in gas mixtures are the following.

A reaction of the second kind which decreases the concentration of metastable atoms of the main gas and therefore affects the ionization processes in a discharge in a gas mixture is the following

The reactions involving collisions of the second kind between ions of the main gas and excited or neutral atoms of the mixed gas, do not tend to increase the number of ions. Therefore, they will in general have very little effect on the field in the positive column. Reactions of this type will be discussed only in a few particular cases.

It was shown in the discussion of the theory of the positive column that the electric field gives a measure of the energy necessary to produce the concentration of ions required by the current passed through the tube and includes the energy lost in radiation as well as the heat conducted away by the tube walls. It was also shown that, for a pure gas, the electric field in the positive column is proportional to the ionization or excitation potentials of the gas. It can also be shown that the electric field in the positive column will be a function of the excitation potentials of the gas and proportional to the ratio of the energy emitted as radiation to that producing ionization.

If any process is introduced into the positive column which will change the ratio of the energy expended in radiation to that expended in ionization the field should change. A process which increases the efficiency of ionization will decrease the electric field in the positive column, since for a given current and pressure the concentration of ions remains constant. A process which decreases the efficiency of ionization or increases the energy expended in radiation will cause an increase in the electric field.

By adding a small amount of one gas to another gas the processes of ionization and excitation may be considerably changed. In case the added gas has lower ionization and radiating potentials than the main gas, very large changes in the field may be produced by very small amounts of added gas. When the added gas has higher ionization and excitation potentials than the main gas the field is only changed slightly, the change being proportional to the amount of gas added.

HELIUM-NEON MIXTURES

Consider the case of helium with a small amount of neon added. The variation of electric field in the positive column with the percent of neon added to helium is shown in Fig. 4, for amounts of neon up to 20 percent. The maximum of the field curve comes at 5 percent neon for different values of current and pressure. The amount of increase in the field over that for pure helium caused by the addition of 5 percent neon is 28.3 percent, for curve *A*; 60.8 percent for curve *B*; 61.8 percent for curve *C*. This shows that the effect of the neon on the field of helium is practically independent of the current, but varies with the pressure.

The following table gives the term values of the normal and metastable states, the ionization potentials and excitation potentials of the metastable states of the gases used in this investigation.

To explain the rise in the field produced by adding neon to helium the reactions producing ionization and excitation in the mixture must be considered.

TABLE III. *Metastable states and ionization potentials.*

Atom	Normal state (term in cm^{-1})	Ionization potential (volts)	Metastable (term in cm^{-1})	States excitation potential (Volts)
He	$1S_0$ 198298.0	24.47	2^3S_1 38454.7 2^1S_0 32032.5	19.73 20.51

Hg	$1S_0$ 84178.5	10.39	6^3P_2 40138.3 6^3P_0 46536.2	5.43 4.66

First consider the processes for production of ions occurring in pure helium.

The numbers represent the energy of the state in equivalent volts. Reactions producing the excitation of the arc spectrum of helium.

When a small amount of neon is added to helium the excitation of the helium arc spectrum is reduced to some extent while the neon arc spectrum is developed very strongly. Therefore the following reaction is considered to take place in the helium-neon mixture.

These results in Table IV show very close resonance between the metastable levels of helium and a large number of excited states of neon. The excess energy to become kinetic energy is very small for the excitation of a large number of the excited states of neon by impacts with metastable helium. Therefore, this reaction should have quite a high probability of occurrence in helium containing a small amount of neon.

This reaction (6) shows that the presence of a small amount of neon in helium will greatly reduce the concentration of metastable helium atoms, and practically eliminate the reaction (2), one of the processes of producing ions

TABLE IV. *Excitation of neon by metastable helium.*

in helium. Therefore, due to the presence of neon, a large amount of energy supplied by the field is transformed into radiation by reaction (6) which would have gone into ionization in the case of pure helium. Thus we see that the presence of a small amount of neon in helium greatly decreases the efficiency of ion production and therefore the field increases. The field decreases again when the concentration of neon atoms becomes large enough so that a considerable amount of the ionization is produced by direct electron impact with neon atoms. After the maximum in the field is reached at 5 percent neon the field gradually decreases to that of pure neon. A small amount of helium has no abnormal effect on the field in neon, as shown by Fig. 5. No collisions of the second kind take place between excited neon and neutral helium because the excited states of helium are all above the metastable states of neon. The spectrum of helium disappears between 10 percent and 5 percent helium in neon, for less than 5 percent helium in neon only the neon spectrum is obtained. This shows that when only a small amount of helium is present in neon, only very few helium atoms are excited by direct electron impact.

The phenomena at this end of the curve show the effect of limitation of electron velocities in mixtures but here the gas of the lower excitation potentials is present in the larger amount. The fact that the helium spectrum is developed quite strongly in mixtures containing as much as 85 percent neon shows that neon is not very effective in limiting the electron velocities even when present in more than 50 percent. Thus limitation of electron velocities sufficient to cause a 20 percent increase in field could not be considered to occur with less than 1 percent neon in helium. Therefore, the effect of the limitation of electron velocities is negligible as compared to collisions of the second kind where neon is present in only a few percent.

HELIUM-ARGON MIXTURES

Fig. 6 shows that the maximum value of the field for the mixture is produced with 1.5 percent argon which is less than the amount of neon required to produce the maximum effect in helium. However, the maximum increase in the field for the mixture over that of pure helium is only 17.6 percent for argon, as compared with an increase of 28.3 percent caused by the addition of 5 percent neon to helium. The results of spectrograms given in Table II show that with 0.2 percent argon in helium the arc spectrum of helium is completely suppressed and only the argon arc spectrum is developed. These facts would indicate that argon is more effective in removing metastable helium atoms than neon but that part of the energy of these metastable helium atoms is converted into ionization of argon and not entirely lost in radiation, as was the case of neon. These results are particularly interesting because neither the helium ion nor the metastable states of the helium atom are in close resonance with any of the known excited states of neutral argon or of the argon ion. The lowest excited state of argon II is the term $2s$ 108730 cm^{-1} or 13.41 volts above the normal state of argon II. The first ionization potential of argon is 15.69 volts. Thus to ionize and excite argon would require at least $15.69 + 13.41 = 29.10$ volts. The highest metastable state of helium is 2^1S_0 32032.5 cm^{-1} or 20.51 volts above the normal state, which is 8.59 volts too low to ionize and excite argon. The ionization potential of helium is 24.47 volts, which is 4.63 volts too low to ionize and excite argon.

Spectrograms taken of the positive column in mixtures of a small amount of argon in helium show that the spark spectrum of argon is not excited in mixtures with helium. The spectrogram of argon alone shows only the arc spectrum of argon. The spectrograms of helium-argon mixtures also show only the arc lines of argon and the strongest arc line of helium. However, there are a large number of strong argon spark lines in the region photographed which would have appeared if an appreciable amount of excitation of the argon ion had occurred. Therefore, the only possible reactions between metastable helium and neutral argon are the following:

TABLE V. Table for reaction (1).

Helium		Argon		Energy difference in equivalent (volts)
Term (cm^{-1})	Excitation potential of metastable state	Term	Ionization potential (volts)	
2^3S_1 38454.7	19.73	4^3P_0	15.69	4.04
2^1S_0 32032.5	20.51	4^3P_0	15.69	4.82
2^1S_0 32032.5	20.51	4^3P_1 1430.	15.87	4.64
2^3S_1 38454.7	19.73	4^3P_1 1430.	15.87	3.86

The amount of energy going into kinetic energy is too large to make reaction (1) very probable. However, the results indicate that this reaction does occur to some extent in helium-argon mixtures.

From the results obtained with mixtures of a small amount of argon with helium it would appear that reaction (2) has a high probability of occurrence. The outer electron configuration of argon is $3s^2, 3p^6$. It seems probable that two of the p electrons could be excited simultaneously by a collision of an argon atom with a metastable helium atom, which would excite negative terms in argon I. Negative terms have not been observed in the argon I spectrum, but there is no reason to expect negative terms to be excited under normal discharge conditions in argon when practically all of the excitation is by electron impact. However, if negative terms exist which are in close resonance with the metastable states of helium, reaction (2) should be highly probable in mixtures of a small amount of argon with helium. Reaction (2) will account for the strong excitation of the arc spectrum of argon in helium-argon mixtures and also will account for the increase of the field in helium produced by the addition of small amounts of argon. The negative terms which could be excited by reaction (2) would lie between three and four volts above the ionization potential of argon I. It would be interesting to make an extended spectroscopic study of the excitation of argon by metastable helium in the positive column to see if such negative terms could be observed.

NEON-ARGON MIXTURES

In this case the field in the positive column is small and nearly the same for each pure gas. Under the existing conditions of current, pressure, and tube diameter, the field in neon was 4.0 volts/cm; in argon 3.8 volts/cm. However, the curve in Fig. 7 shows that a small amount of argon added to neon causes a small increase in the field while neon in small amounts has practically no effect on the field in argon.

The possible reactions for argon mixtures are the following

Reaction (1) tends to decrease the field and (2) tends to increase the field. Reaction (1) would not have a high probability due to the large residual energy to be transformed to kinetic energy. The probability of transitions to the negative term states demanded by reaction (2) is also small. This is in agreement with the fact that argon has only a small effect on the field when added to neon.

The curve Fig. 7 shows that a maximum field is reached at about equal proportions of argon and neon due to the fact that there are more possible excited states in a mixture of the two gases than in either gas separately. Therefore, a greater part of the total energy of the field is expended in radia-

tion than would be the case for either gas separately. The fact that the field in pure argon is only slightly less than that in pure neon even though the ionization potential of argon is much less than that of neon must be due to a proportionally greater amount of the total energy supplied by the field going into radiation and heat in argon than in neon.

HELIUM-MERCURY MIXTURES

TABLE VI. *Excited states of mercury I and II which result from reactions with helium, neon and argon.*

Mercury II		Mercury I	
Term from normal state of Hg II (cm ⁻¹)	Equivalent volts from normal state of Hg II	Term from ionized state of Hg I (cm ⁻¹)	Equivalent volts from normal state of Hg I
² D ₃ 119695	14.75	⁶ P ₀ -7860	11.36
² D ₃ 134732	16.62	⁶ P ₁ -9798	11.60
² P ₁ 135666	16.71	⁶ P ₁ -9798	11.60
² P ₂ 144789	17.85	Ionization Potential	10.39
³ P ₂ 196151	24.20	⁶ S ₀ 84178.5	normal state
Hg ⁺⁺ 235461	29.06		

The possible reactions which can occur in helium-mercury mixtures are the following:

The probability of reaction (1) occurring is low since the residual kinetic energy is too high for close resonance. Reaction (2) has a higher probability of occurrence but will have very little effect on the ion concentration.

From the results of spectrograms of this mixture given in Table II it can be seen that both the spectra of helium and mercury are developed, which indicates that the mercury is not very effective in eliminating the metastable states of helium. The results given in Table I show that mercury has very little effect on the field in the positive column of helium. Both of these facts are in agreement with the low probability of the occurrence of reaction (1) in helium-mercury mixtures.

NEON-MERCURY MIXTURES

The case is quite different for neon and mercury mixtures. The only possible reaction for neon-mercury mixtures is the following.

This is the only reaction which can occur in neon-mercury mixtures that will affect the field in the positive column and which has a high enough probability of occurrence to be considered. This reaction has a very high prob-

ability due to the close resonance between the metastable states of neon and the excited states of the mercury ion.

Since most of the energy of the metastable neon atoms goes into ionization of mercury this reaction greatly increases the efficiency of the ionization processes in neon-mercury mixtures over those of pure neon. This is shown by the fact that the field in the positive column of neon is reduced to almost one half of its original value by the addition of less than 0.03 percent mercury vapor. The results of spectrograms of the neon-mercury mixture given in Table III show that the mercury arc spectrum is developed strongly while the neon arc spectrum is completely absent. This would be expected according to the above reaction which would greatly reduce the concentration of metastable neon atoms in the mixture over that for pure neon. If the results were attributed to the effect of limitation of electron velocities, mercury vapor would be expected to have the same effect on helium as it has on neon and possibly to a greater extent, but instead mercury vapor causes a slight increase in the field for helium. This fact is strong evidence that the observed effects, where one gas is present in a small percent of the total volume, are correctly attributed to the action of collisions of the second kind.

MIXTURE OF ARGON AND MERCURY

The possible reactions in argon containing a small amount of mercury are

Reaction (1) has a low probability of occurrence due to the rather high residual kinetic energy. Reaction (2) has a high probability due to the quite close resonance, the residual kinetic energy being small. This reaction corresponds to the excitation of negative terms of the mercury arc spectrum which have been observed with hollow cathode excitation of mercury by impacts of the second kind.¹⁹ Reaction (3) is not very probable and would not have much effect on the electric field in any case.

The results of spectrograms given in Table II show that the mercury spectrum is very much stronger than the argon spectrum in the mixture. This fact is in good agreement with the probability of reaction (2) being much greater than that of reaction (1). The fact that the field in the argon mercury mixture is higher than in pure argon shows that reaction (2) occurs with greater probability than reaction (1).

By comparing curves in Figs. 7 and 8 the effect of a trace of a diatomic gas as an impurity in one of the gases can be seen. Only a trace of nitrogen

¹⁹ F. Paschen, *Preuss Akad.* p. 3, 1928; also Naudé (reference 9).

was sufficient to more than double the field in pure argon. This large increase was due to the excitation of the nitrogen bands by collisions of the second kind with argon metastable atoms. In diatomic gases also a larger proportion of the energy of electron impacts goes into radiation than in monatomic gases and this causes an increase in the field. The spectrograms taken of these mixtures show that the nitrogen band spectrum begins to be developed strongly where the field in this mixture becomes larger than the corresponding mixture of pure argon and pure neon.

Birge and Hopfield²⁰ give the energy-level system for the positive bands of nitrogen. There are three states at 8.1, 8.5 and 9.4 volts, respectively. Each of the states have a large number of vibration levels. These vibrational levels extend from 8.1 to 14 volts. The ionization potential of nitrogen is given as 16.7 volts. The metastable states of argon at 11.50 and 11.67 volts will be in very close resonance with a large number of excited states of the nitrogen molecule. The metastable states of neon at 16.58 and 16.67 are in close resonance with the ionization potential of the nitrogen molecule. Therefore one would expect a very strong excitation of the positive bands of nitrogen in a mixture of neon and argon containing a trace of nitrogen, by impacts of the second kind between the metastable states of argon and neon and the neutral nitrogen molecules. From the curves in Figs. 7 and 8, it can be seen that the field in a mixture of neon and argon is greatly increased by the addition of a trace of nitrogen. This result is in good agreement with the fact that the metastable states of argon are in very close resonance with many excited states of the nitrogen molecule. Thus the concentration of metastable argon and neon atoms is very effectively decreased by the presence of only a trace of nitrogen.

CONCLUSION

The results show that the electrical and spectral characteristics of the uniform positive column in mixtures of monatomic gases can be explained principally in terms of collisions of the second kind between the ions or metastable atoms of one gas and the neutral atoms of the other. The effect of limitation of electron velocities is wholly inadequate to explain the results obtained for mixtures containing a fraction of 1 percent of one gas and is negligible as compared to the effect of collisions of the second kind. The limitation of electron velocities does occur in mixtures where both gases are present in large amounts and produces an appreciable effect.

The necessary condition for a large effect to be produced in the electrical and spectral characteristics of the positive column by a small percentage of one gas added to another is that there exists a close resonance between the metastable states of the main gas and the ionization potential or excited states of the added gas atom or ion.

RELATIVE INTENSITIES OF THE MAGNETIC AND ELECTROSTATIC ILLUMINATION COMPONENTS IN THE ELECTRODELESS DISCHARGE

BY CHARLES T. KNIPP

DEPARTMENT OF PHYSICS, UNIVERSITY OF ILLINOIS

(Received January 22, 1931)

ABSTRACT

Recent theory indicates that a considerable portion of the illumination in the electrodeless discharge is due to the electrostatic field. A discharge vessel was constructed to test this point experimentally. Obstructions were set in it with the idea that each type of discharge would cast its own shadow. Distinct shadows were obtained for both discharges when acting separately. When the magnetic field predominated and the ring discharge was fully formed no evidence was obtained of shadows due to electrostatic discharges, and conversely, as is shown by the photographs that accompany the article. The intensities of the two illuminations, as judged by the times of exposure, varied about as 1 to 50. The photographs seem to support the calculations of Sir J. J. Thomson.

RECENT theory indicates that a considerable portion of the illumination in the electrodeless discharge is due to the electrostatic field; that under favorable conditions of gas pressure and position of the energizing coil and electrodes this illumination may amount to a considerable part of the total. This result is in addition to the calculations made a few years back by Sir J. J. Thomson.¹

Fig. 1. Sketch of discharge vessel. Similar to a large Dewar vacuum test tube. Asbestos obstructions are shown. These appear in the four photographs that follow. A cylinder, MN, of black paper screened off high lights on opposite side. The position of energizing coil is shown.

A tube was designed by the writer with which it was hoped to test this point experimentally, at least qualitatively. In appearance the discharge ves-

¹ J. J. Thomson, *Phil. Mag.* 4, 1128 (1927).

sel was not unlike a wide-mouthed Dewar vacuum flask. Two Pyrex beakers of 1.5 and 2 liters capacity, respectively, were used in its construction. Its length when completed was 18 cm, its diameter 13 cm, and the interspace about 7 mm. Asbestos disks about 8 mm in diameter were placed at regular intervals throughout the interspace similarly to the spacing disks in a vacuum bottle. Fig. 1 shows a section through the vessel and coil.

The idea in mind was that these obstructions should cast shadows, similar to the Malteze cross experiment in a Crookes tube, and thus under proper conditions it was hoped that the direction of the discharge due to either field would be made visible.

The study was made with residual air at pressures of about 0.2 mm of mercury. The discharge vessel was energized by damped oscillations from a motor-generator high-voltage high-frequency set. The maximum voltage was about 25 kv operating on a frequency of about 800 kc.

Fig. 2. Electrodeless discharge completely formed by using 8 turns of energizing coil. Residual air, pressure about 0.2 mm Hg. Illumination intense white. Time of exposure 6 seconds, followed by a photoflash to get apparatus. Shadows are in plane of coil. No shadows due to electrostatic field are discernable.

Fig. 3. Electrodeless ring discharge completely formed when an energizing coil of 8 turns was placed inside of vessel. Illumination intense white. Time of exposure 6 seconds followed by a photoflash. Again shadows due to the asbestos obstructions plainly show the paths of the carriers. No electrostatic effects are visible.

To give prominence to the magnetic field the energizing coil should be compact and of comparatively few turns—6 or 8 in this instance. This may be placed either round the vessel as indicated in Fig. 2, or the coil may be replaced by one of smaller diameter and placed within the discharge vessel as shown in Fig. 3. If an outside coil of too large a diameter, or of too many turns, is employed the ring discharge will not form.

On the other hand to give prominence to the electrostatic field a long solenoid, as shown by the extended coil turns in Fig. 1, should be used. Better still is to place external electrodes consisting of a band conductor to the right

and to the left of the medial line as shown in Fig. 4. To prevent heavy sparking with the attending danger of disrupting the vessel a parallel coil of about 10 turns should be inserted. By adjusting the number of turns included in this parallel circuit a wide range of electric field intensities may be obtained.

The two fields may indeed be obtained simultaneously by simply using a long energizing coil of from 20 to 30 turns and of about 1 cm pitch. For the electrostatic field to predominate it is only necessary to make connections at the ends of this solenoid, Fig. 4. To localize the magnetic field (as is necessary in order to have the ring discharge form) the connecting leads should now be transferred to include 4 to 6 turns at the center of the solenoid, Fig. 2. Moving the leads from the ends to the center does not seem to reduce the resultant electrostatic field very greatly, but it does serve to localize the ring dis-

Fig. 4. Electrostatic discharge only. Electrostatic field obtained by using full length of energizing solenoid. Illumination faint (compared with that in the ring discharge). Time of exposure about 2 minutes. Overhead lights to get outline of apparatus. The direction of field is clearly shown by the streamers. Magnetic field not intense enough to form the ring discharge.

Fig. 5. Electrodeless discharge only. The band electrodes are looped across a coil of 8 turns (this coil was placed on the inside of vessel in Fig. 3). Illumination a faint purplish red glow. Time of exposure 130 seconds. The direction of field is clearly shown by the shadows cast. Overhead lights to finish exposure.

charge due to the magnetic field. It should be added that at no time, even with the electrodes most favorably placed, was it possible to get the characteristic ring discharge by means of the electrostatic field alone.

SUMMARY

1. To form an intense ring discharge required but a comparatively few turns of the energizing coil. Figs. 2, 3.
2. The paths of the carriers in the ring discharge were in the *plane* of the coil as is distinctly shown by the *shadows cast*. Figs. 2, 3.
3. The illumination was very intense. It required but 6 to 8 seconds to make an exposure.

4. The electrostatic discharge may be produced by either external electrodes, or by a long solenoid. Figs. 4, 5.

5. The paths of the carriers in this case, as one should expect, were parallel to the axis of figure as is distinctly shown by the *shadows cast*. Figs. 4, 5.

6. The illumination was very weak, a purplish red, as compared with the intense white of the ring discharge. It required 2 to 3 minutes to make an exposure of the density shown in Figs. 4 and 5.

7. At no time while the ring discharge was formed were the electrostatic effects visible. These, however, may have been masked by the greater intensity of the former.

SUPERSONIC INTERFEROMETERS*

BY ELIAS KLEIN AND W. D. HERSHBERGER
NAVAL RESEARCH LABORATORY, BELLEVUE, D.C.

(Received January 26, 1931)

ABSTRACT

The methods of applying high frequency sounds to small scale measurements are discussed. An interferometer was constructed and used to measure the velocity of sound in gases, liquids, and solids at frequencies ranging from about 10 to 700 kc. Three types of sources were tried, viz: quartz and Rochelle-salt crystals and magnetostrictive rods. The determination of the velocity of sound in solids is based upon: (1) optimum transmission of sound through a partition whose thickness is an integral number of half wave-lengths; (2) relative displacement of the nodal planes in a given liquid due to the immersion of a solid slab in the acoustical path. In the same manner, a small quantity of an unknown liquid is placed in a parallel walled cell and the latter is immersed in a liquid of known acoustic properties. Reactance and effective resistance of the interferometer (with a liquid medium) as a function of the reflector distance from the sound source were investigated. Approximate values of the impedance, power factor and watts dissipated in the instrument were thus computed. An improved circuit for use in absorption measurements in gases is described as well as the extended use of the interferometer employing two identical sound generators.

INTRODUCTION

CERTAIN physical and thermodynamic properties of various substances may be deduced from their sound transmission and absorption characteristics. The latter are usually determined experimentally by employing some form of standing wave system. The Kundt's tube and its diverse interesting modifications have provided a large amount of useful data relating to the velocities of sound in gases,¹ liquids² and solids.³ However, velocities measured by these so-called "tube methods" at audible frequencies require special corrections due to the yielding of the walls of the tube.⁴ The disturbing effects caused in this way may be eliminated by increasing the frequency of the source to the extent that the emitted waves within the tube are plane. Under such circumstances the velocity of sound in a confined fluid, when calculated from a standing wave system is independent of the size or shape of the container. Practically, these conditions obtain when the ratio of the diameter of the radiating surface to that of the emitted wave-length is greater than 12. Furthermore, to be reliable, the measurements should be taken at a considerable number of wave-lengths from the source, particularly if the radiator is

composed of many elements, such as a mosaic of piezoelectric crystals. In general, the energy radiated by a circular plate emitting longitudinal waves is confined mainly to a central beam, the width of which is found by the expression

$$\sin \theta = 1.22\lambda/D$$

where θ is the angle between the axis of the radiator and the boundary of zero intensity of the central beam, D is the diameter of the aperture or radiating surface; λ is the wave-length of the emitted wave.

Langevin⁵ was the first to make wide application of supersonic waves by utilizing the piezoelectric properties of quartz. In 1916 in an experimental water tank he demonstrated supersonic beam reflection at 100 kc. Since the original investigations of Langevin, Boyle⁶ and his collaborators have done a great deal of work in supersonics (or "ultrasonics" as they called it) by the aid of quartz-steel generators. Among their researches are measurements on the velocities of sound in a number of liquids and solids by the stationary wave method. A separate detector was required to indicate the nodal or antinodal planes in their standing wave system.

The present paper deals with supersonic stationary waves in which the source also detects the nodal and antinodal planes of the system. Therefore, an instrument in which stationary plane waves of high frequency sound are generated and detected shall be termed a *supersonic interferometer*.⁷

During the past few years several investigators have applied this type of interferometer to the study of sound in fluids. Pierce⁸ was the first to use it in his determination of the velocities of sound in air and CO₂ at high frequencies. His method employed an oscillating quartz crystal serving a three-fold purpose; namely, to control the frequency in a vacuum tube circuit; to generate sound waves from one face to a movable piston which is plane and parallel to the radiating face; and to detect the sound waves reflected from the piston. A stationary wave system is thus set up between the crystal and reflector. As the latter is moved through a series of nodal planes periodic maxima and minima are indicated on a microammeter suitably connected in the plate circuit. By these changes in the electrical circuit Pierce was able to measure the wave-length to a very high degree of precision. With this method, several other researches have been reported,⁹ in which the velocity as well as the absorption of supersonic waves in gases and vapors are measured.

⁷ This type of self-detecting interferometer has been variously described as a sonic interferometer by Wood and Loomis and an acoustic interferometer by Crandall and others. In the opinion of the authors, neither of these terms distinguishes the instrument from a tube resonator used at audio frequencies.

Hubbard and Loomis¹⁰ developed a compact interferometer with which they determined accurately the velocity of sound in various liquids. Their arrangement differs from that of Pierce in that the quartz crystal does not control the frequency of the oscillating circuit but is driven by an alternating e.m.f. whose frequency is far removed from that of the crystal. One surface of the quartz disk radiates sound directly into the liquid which is being studied. The production of stationary waves in the liquid and their measurements are effected by the aid of a plane reflector attached to a micrometer screw. Here also the nodal and antinodal planes are located by their reactions on the crystal source.

In all work with supersonic interferometers heretofore recorded quartz was used as the source of high frequency sound, and the investigations were limited to fluids. The present experiments deal with methods for using Rochelle-salt crystals or magnetostrictive rods as well as quartz for the interferometer source. It is further shown that the same interferometer can be used to determine the velocity of supersonic waves in solids and minute quantities of liquids.

APPARATUS

The interferometer employed in the present investigation is composed of three principal units as shown in Fig. 1. The upper part, (a), consists of a specially constructed micrometer screw whose spindle has a maximum movement of four inches and whose barrel is graduated every 0.025 inches for the entire travel of the spindle. The least count of the instrument is 0.001 inch. To the lower end of the spindle is attached a plane brass reflector which is accurately machined so that its reflecting surface always remains normal to the axis of the cylinder in which it is traveling. The lowest portion of (a) is a threaded cap to fit the various fluid containers.

The central section, (b), may be a cylindrical or rectangular fluid container, each end of which is threaded so as to fit the adjoining units, (a) and (c), interchangeably.

Part (c) represents one of several holders for the elements used as sources of supersonic waves. The side tube at the bottom accommodates the leads to the electrodes of the crystal or groups of crystals used. The dimensions of (b) and (c) differed according to the range of frequency and substance studied. The fluid containers, (b), varied from four to sixteen inches in length and from three to nine inches in diameter. Among the elements used as sources are: a single disk of quartz 2.5 inches in diameter and 0.25 inch thick; a similar disk of Rochelle-salt; several rectangular slabs of the above crystals about $1 \times 1 \times 3/16$ inches; a mosaic of quartz about four inches in diameter and one of Rochelle-salt 2.5 inches in diameter; several magnetostrictive rods 0.5 inch in diameter and 4 to 10 inches in length.

In the photographs of Fig. 1 may be seen an assembled interferometer with a rectangular container, one side removed; the three separate units; and three of the generating elements.

The circuit employed for impressing an alternating e.m.f. upon the source of the interferometer when the latter is used in conjunction with liquids and solids is shown in Fig. 2. A quartz crystal controls the driver frequency when extreme constancy is required. For work in which a continuously variable

Fig. 1. Diagram of interferometer.

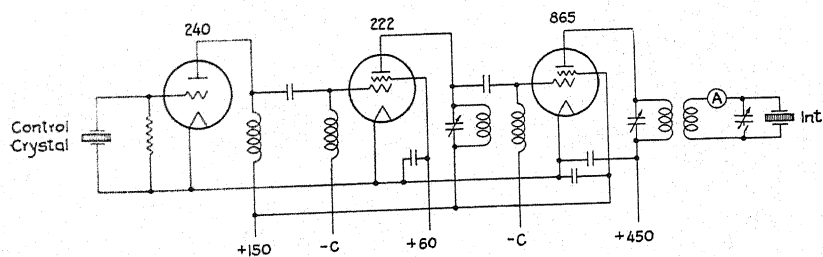

Fig. 2. Electrical driving circuit used with interferometer for work with liquids and solids.

frequency is desired a tuned-grid circuit is employed in the master oscillator stage. Extremely loose inductive coupling is used between the interferometer and the plate coil of the last tube. The circuit is designed to eliminate any effect of a variable load upon the frequency of the exciting e.m.f. The actual power drawn by the interferometer is a very small fraction of the available output power of the last tube.

METHODS OF DETECTION

There are numerous methods available for detecting the variations in impedance of the interferometer caused by changes in the position of the reflector. One of the simplest is to note changes in the series current. When the quartz disk is used as a sound source, it is essential to tune the output circuit sharply by means of the small variable capacity in parallel with the interferometer in order that the relatively small changes in impedance may become evident. The quartz interferometer at frequencies far removed from the resonant frequency of the disk reacts very nearly as a pure capacity which permits sharpness of tuning. On the other hand, when Rochelle-salt is employed the current through the instrument leads the voltage across its terminals by angles varying from 30° to 60° depending upon the reflector position, thus making sharp tuning impossible. The greatest fractional change in current observed with the quartz disk is about 15 percent, while if Rochelle-salt is used the fractional change in current ranges from 40 percent to 60 percent. To measure the series current, a vacuum thermocouple and microammeter with a full scale deflection of 200 microamperes was employed.

A novel method for detecting these impedance variations due to change in the reflector position is utilized by Hubbard and Loomis.¹⁰ They actually permit the variations in load on the last tube to affect the driving frequency, then readjust the tuning condenser which varies the frequency so as to compensate for this change. The curves obtained are condenser settings plotted against reflector position.

A number of alternative methods were tried. In one set of experiments not only was the series current through the interferometer measured, but simultaneously the potential difference across its terminals was determined with a thermionic voltmeter. Again, instead of employing inductive coupling between the driving circuit and the interferometer, resistance-capacity coupling was used. The reactions, though much feebler than those obtained with inductive coupling, were in entire agreement with them.

The exact nature of the impedance changes taking place as the reflector position is varied was examined in detail by bridge measurements of the effective capacity and resistance of the interferometer (with a liquid medium). The circuit of the bridge is shown in Fig. 3. Two of the arms were equal capacities of 500 micromicrofarads each. The Rochelle-salt interferometer was placed in one arm and a calibrated air capacity in series with a resistance in the remaining arm. A thermionic voltmeter indicated the state of balance of the bridge. Simultaneously, the series current through the interferometer was measured. No high degree of accuracy is claimed for these measurements,

due to the large phase angles encountered and due to difficulties with the shielding. The result of a set of observations at 122 kc is shown in Fig. 4. These curves show resistance, reactance, net impedance, power factor, phase angle, series current, potential difference across the interferometer terminals and milliwatts dissipated in it as a function of the position of the reflector.

Fig. 3. Circuit used in bridge measurements of effective capacity and resistance of interferometer.

Examining the curves in detail, it is noted that to a first approximation, the capacitive reactance may be expressed by the equation:

$$X = X_0 + A \sin \alpha$$

and the resistance by

$$R = R_0 + A \cos \alpha$$

where $\alpha = 4\pi(l-L)/\lambda$; l is the micrometer reading; L is a reference point on the micrometer scale, and λ is the wave-length of sound in the medium. Also, it may be shown that to a first approximation:

$$Z = Z_0 + A \cos (\alpha - \theta)$$

where $Z_0 = (X_0^2 + R_0^2)^{1/2}$ and $\theta = \tan^{-1}(X_0/R_0)$. That is, the impedance of the instrument may be represented by the vector sum of one impedance whose magnitude and direction is constant and a second impedance whose magnitude is very nearly constant but whose direction depends upon the position of the reflector. In general, the impedance of the interferometer may be expressed by the equation:

$$Z = Z_0 + \sum_{n=1}^{\infty} A_n \cos (n\alpha - \theta_n)$$

The impedance diagram obtained on plotting X against R possesses some similarities to those observed by Kennelly and Pierce¹¹ in their work on the motional impedance of telephone receivers and to those obtained by Black¹² in his work on magnetostrictive rods. However, in these particular cases the driving frequency is varied while the resonant frequency of the driven

¹¹ A. E. Kennelly and G. W. Pierce, Am. Acad. Proc. 48, 113 (1912).

¹² K. C. Black, Am. Acad. Proc. 63, 49 (1928).

remains constant. In the present case, the driving frequency is held constant, and the resonant frequency of the driven is varied by altering the length of the liquid column. Each time the length of this column is changed by a half wave-length, the set of observed points encircle the diagram once. By external mechanical means Kennelly, Pierce, and Black prevented any displacement on the part of the device whose motional impedance was being measured while here the motion of the crystals is never zero but is aided or impeded by sound reflected from the movable piston.

Fig. 4. Curves showing relationship between reflector position and resistance, reactance impedance, phase angle, and power factor of interferometer as well as current through it, e.m.f across its terminals, and watts dissipated in it.

Let ϕ denote the angle between the axis of resistance and the vector joining the center of the impedance diagram to any point on the perimeter. If the value of $d\phi/dl$ is constant around the diagram the simple set of resistance and reactance curves shown in Fig. 4 is obtained. In case $d\phi/dl$ varies around the diagram, the current curve no longer approximates a cosine function. It will be noted in Fig. 5 that the curves taken at 130 kc and 148 kc differ markedly from those taken at 122 kc. The constancy of $d\phi/dl$ and the shape of the curves are very closely dependent upon frequency. It is suspected that the sharpness of resonance in the liquid column is related to the selective transmission of the reflector.

EXPERIMENTAL PROCEDURE

Liquids.—The velocity of sound in a number of liquids was measured by means of this instrument using different types of generators. The set of curve shown in Fig. 5 are typical for the Rochelle-salt interferometer. The liquid used was a high grade of transformer oil. Half wave-lengths were determined with an accuracy of 0.1 percent. Frequencies were measured to 0.03 percent. Hence a relatively high degree of accuracy may be obtained in velocity calculations. Curves possessing "fine structure" may be obtained by driving the interferometer at lower frequencies and favoring higher harmonics by the selection of proper coupling coils. Such a curve is shown in Fig. 6. The driving frequency was 45 kc while the third harmonic was emphasized by tuning. This curve is of interest in showing particularly the complexity which may arise in the standing wave system.

Solids.—In order to measure the velocity of supersonic waves in solids a suitable liquid (oil) was chosen as the medium for the solid under considera-

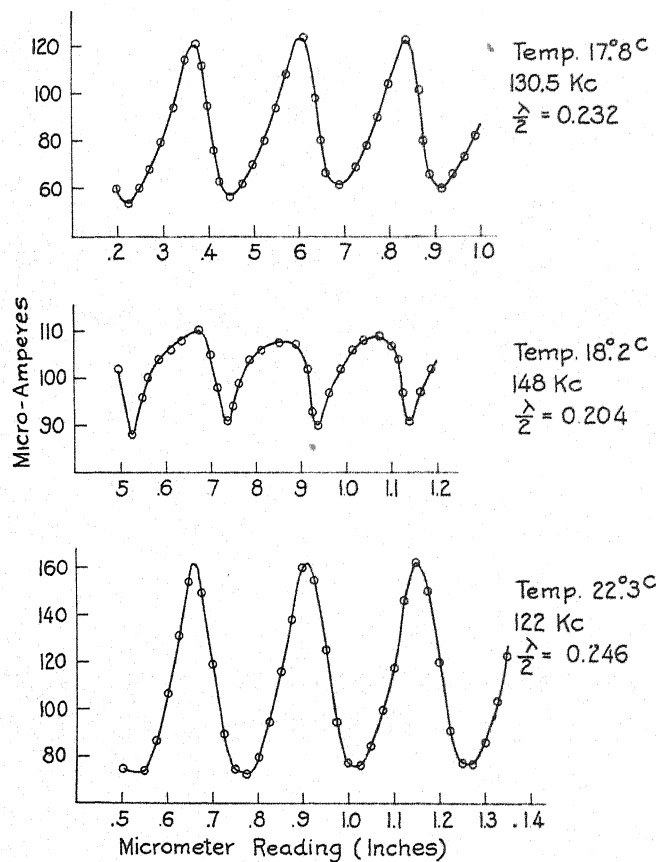

Fig. 5. Curves showing magnitude of series current variations obtained with interferometer and differences in general shape at various frequencies.

Fig. 6. "Fine Structure" curve. The standing wave system involves both a fundamental frequency and a third harmonic.

tion. The positions of the nodal and antinodal planes were accurately located in the liquid alone. Then with temperature and frequency unchanged a plane parallel slab of the solid was immersed in the sound beam and the relative displacements of the nodal and antinodal planes were ascertained. That is, the difference in acoustical path in the container when the liquid alone was present and when the solid was inserted in the beam was deduced from the micrometer readings, thus:

Let d = actual thickness of slab traversed by the beam

$$\mu = \frac{V_s}{V_l} = \frac{\text{Velocity of sound in solid}}{\text{Velocity of sound in liquid}}$$

Then the displacement of the nodal planes can be shown to be:

$$\Delta s = d(\mu - 1)/\mu$$

whence $\mu = d/(d - \Delta s)$.

This simple method works quite well when the product $V\rho$ for the solid is not greatly different from that product in the liquid, where V is the velocity of sound in the substance and ρ its density. This is the case in natural woods and wood compositions, in many varieties of bakelite and in rubber compounds. Table I illustrates the method for an amber bakelite of French manufacture.

TABLE I. *Illustration of measurement of velocity of sound in an amber bakelite of French manufacture.* Temperature 21°C. When micrometer reads zero reflector face is about 3 inches from source.

Micrometer Readings at Nodal Planes		Shift due to bakelite	Calculations
Oil alone	Amber bakelite in oil		
0.019	0.180 "	0.161	Measured thickness of slab = 0.412 in. Average shift = 0.161 in. $\mu = 0.412/0.251 = 1.64$ Known velocity in oil = 1.50×10^5 cm/sec $\therefore V_s = 1.50 \times 10^5 \times 1.64 = 2.46 \times 10^5$ cm/sec
0.318	0.479	0.161	
0.620	0.780	0.160	
0.922	1.083	0.161	
1.223	1.384	0.161	
1.526	1.687	0.161	
1.825	1.988	0.163	

However, if the two respective products mentioned above are very dissimilar, then it is necessary to choose such a thickness of material as will yield optimum transmission at a particular frequency. Generally, it is more convenient to use a slab of fixed thickness and then to find that frequency for which transmission of sound through the material is a maximum. This condition is realized when the slab thickness is an integral number of half wave-lengths. The theory of this method was suggested by Lord Rayleigh.¹³ Boyle and Rawlinson¹⁴ amplified Rayleigh's analytical treatment and applied it directly to supersonics. Later Boyle and Froman¹⁵ verified their

¹³ Rayleigh, *Theory of Sound*, Vol. II, p. 86.

¹⁴ Boyle and Rawlinson, *Roy. Soc. Canada, Trans.* 22, 55 (1928).

¹⁵ Boyle and Froman, *Canada Jour of Research* 1, 405 (1929).

theoretical conclusions by experiments in which they showed that at normal incidence transmission is a maximum when the thickness of the plate is an integral number of half wave-lengths. On the other hand, if the thickness is an integral odd number of quarter wave-lengths reflection is a maximum.

Fig. 7 is a sample curve showing the sharpness of selective transmission for a given thickness of commercial aluminum. As in the previous arrangement, the metal slab was immersed in oil at normal incidence. Series current through the interferometer source was observed at nodal and antinodal posi-

Fig. 7. Change in relative transmission with frequency for a slab of aluminum 0.825" thick.

tions of the reflector for the range of frequencies noted. The difference between maximum and minimum currents divided by their sum is the ratio $\Delta I/I$ used as ordinates in the curve. This ratio indicates the relative transmission of any substance assuming that no selective absorption or scattering is present. The frequency for which the specimen is an integral number of half wave-lengths is thus readily determined. In general, by varying the thickness of the material studied; or, by changing the frequency of the source sufficiently, the exact number of half wave-lengths included in a given sample can be ascertained. Quite often, the approximate number of half waves

in the substance may be calculated from a preliminary knowledge of some of its physical properties. The determination of the supersonic velocity in the solid from the measured wave-length in it and the frequency of the source is then easily verified by the nodal displacement method described above.

Example: Thickness of aluminum slab = 0.825 inches = $\lambda/2$. Best transmission frequency = 122 kc.

$$\therefore V = 122 \times 10^3 \times 0.825 \times 2 \times 2.54 = 5.11 \times 10^5 \text{ cm/sec.}$$

Displacement method in oil: Av. shift at 126 kc = 0.583 inches.

$$\mu = 0.825/0.242 = 3.31$$

$$\therefore V = 1.5 \times 10^5 \times 3.31 = 5.12 \times 10^5 \text{ cm/sec.}$$

Temperature 21°C.

One of the photographs shows slabs of brass, aluminum, and bakelite used in these measurements as well as a holder for the slab which permits other than perpendicular incidence to be used.

Small quantities of liquids.—When only small quantities of liquids are available, (say, less than 100 cc) the methods so far described are not readily applicable. In the first place the measurement of wave-length in the specimen must of necessity be made very close to the sound generator. And as was pointed out earlier, the phase relations close to the source are such as would tend to diminish the sharpness of nodal plane locations. Also the number of wave-lengths that are measurable in the liquid is small; hence the accuracy is reduced. Furthermore, it is often undesirable to have the liquid come in contact with the reflector and container, especially if these are not gold or platinum plated. Such difficulties were obviated in the present experiments by putting the small quantities of liquid to be tested in a parallel walled cell, which was immersed in a liquid medium of known acoustic properties. For example, the procedure for a specimen of turpentine was as follows: a bakelite cell was immersed in the oil previously studied. The cell was filled with the same oil. Micrometer readings for a series of nodal planes in the oil were recorded. Now with the turpentine in the cell, all other conditions remaining the same, the displacement of the nodal planes was measured. The supersonic velocity in the liquid was calculated by the same formula as in the experiment with the bakelite slab, thus:

$$\text{Shift due to 1 inch layer of turpentine} = -0.115 \text{ in. } \mu = 1/1.115 = 0.897.$$

$$\therefore V = 1.5 \times 10^5 \times 0.897 = 1.34 \times 10^5 \text{ cm/sec. Temperature } 21^\circ\text{C}$$

In Fig. 8, curve I was taken when transformer oil only separated the reflector from the source; curve II was taken after the parallel walled cell filled with the same oil had been interposed in the acoustic path; and curve III when turpentine had been substituted for the oil.

Gases.—For measuring supersonic velocities in gases the Pierce interferometer is perhaps the simplest method yet devised. Fig. 9 shows a curve obtained in air with a Rochelle-salt crystal instead of quartz in the Pierce circuit. At lower frequencies in air, magnetostrictive rods served admirably well

as sources of a stationary wave system. The driving circuit for the rods was similar to that described by Pierce.¹⁶ On the other hand, for the measurement of sound absorption in gases, the Pierce arrangement may lead to erroneous results. For it should be noted, that both the frequency and amplitude of the exciting e.m.f. are influenced by the resonant reaction of the gas column upon the crystal. The change in frequency is so small that only in cases of extreme accuracy need it be taken into account. However, it is the periodic fluctuation

Fig. 8. Shift in position of nodal¹⁶ planes illustrated.

in amplitude of the e.m.f. across the crystal that makes possible the location of the nodal and antinodal planes in the gas. That is, the vacuum tube acts as a rectifier and the changes in the rectified plate current, as the length of the gas column is altered, are a measure of variations in the e.m.f. across the crystal.

The experiments of Pielemeier, Reid, and others show that as the length of the acoustic path in the gas is increased, the changes in plate current di-

¹⁶ G. W. Pierce, *Am. Acad. Proc.* 63, 1st (1928).

minish. This diminution is due largely to absorption. Nevertheless, absorption coefficients calculated from this rate of diminution are inconclusive unless we possess an exact knowledge of the operating—not the static—characteristics of the tube and in addition how the emitted sound wave amplitude varies with that of the driving e.m.f., as well as what part the received sound wave amplitude plays in determining the net e.m.f. across the crystal. Observations made at 130 kc show that the rate of diminution of plate current variations, with increasing path length, may be altered at will by a factor of 80 percent merely by changing circuit constants.

In order to eliminate some of these difficulties Hubbard¹⁷ proposes to use two quartz crystals tuned approximately to the same frequency. One crystal is used in a master oscillator circuit which supplies an e.m.f. of constant frequency and amplitude, to the second crystal serving as a driven source of

Fig. 9. Air interferometer curve. The change in magnitude of the peaks with increasing path length is shown in pronounced fashion.

sound. This method should prove valuable if and when constant mechanical amplitude can be maintained in the second crystal during a complete cycle of changes introduced by the motion of the reflector in the gas. Inherently, a quartz crystal displays a rather narrow resonance curve, and the task of holding to a fixed point on this curve as the reflector is displaced is troublesome even though the temperature remains constant.

To attain the same end, we have developed a circuit which promises to be useful in absorption measurements. The schematic diagram is shown in Fig. 10. Three electrodes are used on the crystal plate, similar to an arrangement of Cady.¹⁸ The essential feature of this method is that it permits the amplitude of the exciting e.m.f. to be maintained constant, irrespective of the reaction of the gas column, by varying the resistance marked *P*. Moreover, since regeneration is employed, the difficulty in the two crystal system arising from the necessity of exact tuning is eliminated.

Another method for the determination of absorption coefficient of super-

LETTERS TO THE EDITOR

Prompt publication of brief reports of important discoveries in physics may be secured by addressing them to this department. Closing dates for this department are, for the first issue of the month, the twenty-eighth of the preceding month; for the second issue, the thirteenth of the month. The Board of Editors does not hold itself responsible for the opinions expressed by the correspondents.

Relations between Hall Effect and Resistance

Measurements of the Hall effect have been made on sputtered gold films, while the films were heated in air from room temperature to 110°C. These show a relation between the Hall e.m.f. and resistance like that obtained for tellurium films (Phys. Rev. 30, 673 (1927)). During the first heating after the film was sputtered, the Hall e.m.f. and resistance alike underwent a rapid decrease, in one case to values of both Hall e.m.f. and resistance only one-tenth that of the initial values. This relation is then a property of metals and not a peculiarity of tellurium. Wait and Mackeown have previously shown the Hall e.m.f. to be independent of resistance during aging of the film, and the tellurium films showed two types of aging; (1) a decrease in resistance independent of the Hall effect, and (2) a decrease in Hall e.m.f. in proportion to resistance, similar to the proportionality to resistance, (3) when the latter decreased with increase in temperature. This proportionality also held (4) when the resistance increased with increase in temperature. Processes (3) and (4) are reproducible.

Wait explained process (1) by showing that the measured e.m.f. should be the sum of the e.m.f.'s across the granules. This measured e.m.f. should be constant, while the decrease in resistance was due to the elimination of the interstices between the granules.

If we assume that the decrease in resistance on heating, in the case of metals and films which have a negative temperature coefficient of resistance, is due not to the increase in the number of so-called "free" electrons, but to the increase in the ease with which the electron passes from one atom to another, the pro-

portionality between Hall e.m.f. and resistance in processes (2), (3), and (4) is readily accounted for. In the initial non-reproducible decrease of resistance and Hall e.m.f. there is undoubtedly a coalescence of particles, decreasing the difficulty with which the electron can pass from atom to atom. The thermal agitation should occasionally bring an electron of one atom near to the orbit of another atom so that the electron in passing from atom to atom climbs over a smaller potential hill. Again, greater thermal agitation may cause greater obstruction to the drift of the electron from atom to atom in the current stream, giving the usual positive temperature coefficient of resistance. Since e.m.f. is work per electron, the Hall e.m.f., on this basis, should be proportional to the resistance in each of the three stages; (2) the initial decrease of Hall e.m.f. and resistance; (3) when the temperature coefficients of resistance and of Hall e.m.f. are negative; and (4) when the coefficients are positive.

With the increase in ease with which an electron passes from atom to atom there is probably also an increase in the number of electrons separating from atomic centers and taking part in conduction, giving the same result as above described in processes (3) and (4) but not accounting for process (2), if the number of "free" electrons depends only on temperature.

Note on the Structure of Groups in Crystals

In the February 15th number of the Physical Review, (37, 447, 1931) is published a letter to the Editor from Mr. M. L. Huggins,

which was based upon a short abstract of a paper given by me at the Chicago Meeting of American Physical Society last year. I find

it rather unfortunate that Mr. Huggins has based his letter on this abstract, as I am now preparing for publication a full account of the results I have obtained during my investigations of the last 3 years on groups $(\text{XO}_2)^{-m}$ in crystals. It seems necessary to me to give a few comments on Mr. Huggins' letter.

In the letter is stated that I, in agreement with earlier work on the crystal structure of NaClO_3 and NaBrO_3 (Kolkmeijer, Bijvoet, and Karssen,¹ Dickinson and Goodhue²) describe the XO_2 -group in these crystals as tetrahedral groups with one corner missing. This passage obviously must give the reader the false impression that these earlier investigators already had determined the structure of these interesting groups. This is not the case as every one familiar with the above papers can ascertain. I have shown that the structure proposed by the Dutch investigators for NaClO_3 and NaBrO_3 , as well as that proposed by Vegard,³ is incorrect.⁴ The structure given by Dickinson and Goodhue is inaccurate, and their results therefore do not allow conclusions to be drawn with regard to a possible non-planar XO_2 -group. Dickinson and Goodhue were as a matter of fact themselves aware of the inaccuracy, and only remark about the XO_2 -group that the halogen lies nearly in the plane of the oxygens, indicating that they are considering the XO_2 -group to be a coplanar group. There is thus a rather wide step from this conception of the XO_2 -group to mine. The first description of "tetrahedral" groups XO_2 in crystals was given by me in 1928,⁴ and has been dealt with also in other of my papers on these groups.⁵

It surprises me somewhat to learn that Mr. Huggins finds it necessary to point out the elementary fact that the two displaced electrons in the XO_2 -group can be correlated to a Lewis electron pair. I thought the interpretation of e.g. the ClO_2 -ion according to the

Lewis hypothesis was familiar to everyone. So far the application of the principles of shared electron pairs on the atomic arrangement in inorganic crystals has proved unsuccessful, while considerations of the crystal structure from point of view of ions, ionic dimensions, ionic polarizability, and crystal energy in the hands of such men as W. L. Bragg, K. Fajans, V. M. Goldschmidt, F. Hund, L. Pauling, A. E. van Arkel, J. A. Wasastjerna, and others have given very valuable and important results.

Until one is able to treat the quantization of the electrons in polyatomic groups completely on the basis of wave mechanics, we must be satisfied with rough approximations. It is obvious that one cannot consider such groups to be purely ionic in character. The point of view I have taken with regard to the groups XO_2 is the familiar one of considering the constituents primarily as ions, and then take into consideration the deformation taking place in the electron clouds. The final continuous distribution of electron density may then be regarded as an approximation to the statistical continuity of density one will get from a quantum mechanical treatment. Judging from the results already obtained by this point of view I see at present no advantage in introducing the conception of shared electron pairs in crystals of this kind.

The most important factor which is independent of the point of view one takes is, of course, the total number of valence electrons in the group. In my paper on the groups XO_2 soon to be submitted I have devoted a chapter to the relation between the number of valence electrons and the symmetry of molecules or groups XY_2 and XY_3 . If we limit ourselves to considering groups containing atoms of relatively low atomic number I have showed that the following rule holds for all observations hitherto obtained:

A group or molecule $\left\{ \begin{matrix} (\text{XY}_2)^{-m} \\ (\text{XY}_3)^{-m} \end{matrix} \right\}$ has a $\left\{ \begin{matrix} \text{co-} \\ \text{linear} \\ \text{planar} \end{matrix} \right\}$ structure if the condition $\Sigma v = 2 \times p$ $\Sigma v = 3 \times p$ is satisfied. Here Σv denotes the total number of valence electrons in the group or molecule, while p is the number of valence electrons in the inert gas following atom Y in the periodic system if the number of valence electrons on the other hand has to be expressed by an equation of the form $\Sigma v = 2 \times p + \Delta$ $\Sigma v = 3 \times p + \Delta$ the group or

molecule has an angular or pyramidal structure. The deviation from co-linearity or coplanarity probably increases with increasing Δ . A few examples of the kind of structures we may expect according to this rule may be given.

Co-linear: CO_2 , ON_2 , CS_2 , $(\text{NN}_2)^-$, $(\text{HF}_2)^-$

Angular (polar): OH_2 , SO_2 , OO_2 ? (ozone), SH_2 , NO_2 , $(\text{NO}_2)^-$

Co-planar: $(\text{BO}_3)^{-3}$, $(\text{CO}_3)^{-2}$, $(\text{NO}_3)^-$, SO_3 , BH_3 , BF_3

Pyramidal (polar): $(\text{PO}_3)^{-3}$, $(\text{SO}_3)^{-2}$, $(\text{ClO}_3)^-$,

$(\text{AsO}_3)^{-3}$, $(\text{SeO}_3)^{-2}$, $(\text{BrO}_3)^-$, $(\text{OH}_3)^+$, NH_3 , PH_3 , AsH_3 , PF_3 , PCl_3 and so on.

In no case is there observed a contradiction to the rule, so it may be used with some confidence for predictions. For a more complete information about my work on the groups I can refer to my paper which is to be published shortly.

Interpretation of the Spectra of Rare Earth Crystals

From the work of J. Becquerel, Brunetti, Ephraim, Freed and Spedding, and others, it is known that the absorption spectra of rare earth crystals consist of narrow bands which become resolved into sharp lines as the temperature of the crystals is lowered. The lines tend to gather into multiplets, and arise from energy levels which resemble in their behavior the energy levels of atoms subjected to electric and magnetic fields much more than they resemble the levels of molecules. For example, the positions of the lines are but very little influenced by the negative ions present, and such influence amounts only to the expected slight shifting caused by the different electric fields set up by the various ions in the lattice. Furthermore, the lines do not fade out as the temperature is lowered, but are still strong at the temperature of liquid helium. Again, the lines are polarized, as would be the case if the levels were split apart by electric fields.

In a paper which is to be published soon in this journal, Dr. Freed and I have presented a partial energy-level diagram for Gd^{+++} self-consistent within the accuracy we were able to attain (1 cm^{-1} for position, 4 cm^{-1} for resolution), derived from eight sets of data. The data were:^{1,2,3} Absorption spectra of $\text{GdCl}_3 \cdot 6\text{H}_2\text{O}$ at ordinary temperatures, and at that of liquid nitrogen and of liquid hydrogen. Gd^{+++} even at room temperatures gives sharp spectra, but as the temperature is lowered the lines shift somewhat owing to changes in the effective electric fields caused by the in-

gathering of the crystal lattice;^{4,5} Absorption spectra of $\text{GdBr}_3 \cdot 6\text{H}_2\text{O}$ at room and liquid nitrogen temperatures;^{6,7} Transverse Zeeman effect on the a and b axis of monoclinic

$\text{GdCl}_3 \cdot 6\text{H}_2\text{O}$.⁸ Longitudinal Zeeman effect on the c axis of $\text{GdCl}_3 \cdot 6\text{H}_2\text{O}$. The diagram, shown in Fig. 1, is not consistent with other methods of reasoning. For instance, in his brilliant work on complex spectra, by making use of Russell-Saunders coupling and the Pauli exclusion principle, Hund calculates the basic levels of the rare earth ions. He then calculates the magnetic susceptibilities of the gaseous ions and his values agree remarkably well with those obtained experimentally from the solids themselves. For Gd^{+++} he obtains an 8S term, which is single, as are all S terms. Wolljer and Kamerlingh Onnes⁹ have measured the magnetic susceptibility of $\text{Gd}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$ from 1.3°K to room temperature, and Giauque³ shows that their results are in perfect accord with the assumption of an 8S basic level.

Kramers and J. Becquerel,⁴ from their work on the paramagnetic rotation of polarized light in xenotime, conclude that the rotation is due to the presence of Gd^{+++} ions in the mineral, and that the Gd^{+++} is in the 8S state, which is split into several components in the crystal field. Even in the anhydrous crystals with which they were dealing the splitting is not expected to amount to more than a few cm^{-1} . Certainly in the hydrated salts which were used by Giauque and by Freed and me the effect must be much less, less even than our resolving power.

The diagram as it is presented requires either metastable levels of high energy or wide splitting in the lower level, both forbidden by the arguments set down above. However, if the electron distributions in the rare earth elements are examined, it becomes apparent how these conflicting notions may be brought into agreement. According to the Bohr-Stoner scheme, the distribution of electrons in Gd^{+++} ion is as follows:

1s	2s	2p	3s	3p	3d	4s	4p	4d	4f	5s	5p
2	2	6	2	6	10	2	6	10	7	2	6

In previous papers Dr. Freed and I point out that the optically and magnetically active $4f$ electrons give rise in solids to atomic rather than molecular spectra since the complete $5s$ and $5p$ shells partially shield the $4f$ electrons and tend to prevent close coupling between them and neighboring ions and water molecules. There are two ways in which one of the $4f$ electrons may be excited. Firstly, it may remain under this screening influence of the $5s$ and $5p$ shells. To do this, however, n and l of

the electron can not change since the exclusion principle forbids any other values. Therefore the only possible excitation comes about through one of the spins reversing itself, thus giving rise to sextet terms. A jump of this sort rarely occurs in atomic spectra and, moreover, it is to be expected that the energy involved would be large. Secondly, the electron may jump outside the strong protection of the $5s$ and $5p$ shells and occupy the $5d$, $5f$, and $5g$ or higher shells, but most probably the $5d$ shell. In this event, Russell-Saunders coupling would presumably be effective for each part of the atom, but owing to the same screening activity on the part of the $5s$ and $5p$ levels it would be much weaker between the halves and would result in $j-j$ coupling. In this instance a 7F_0 term would be formed inside and would join with the $^2D_{3/2}$ term outside to give the combined term, $[^7F_0^2D_{3/2}]3/2$. Of course, other types of coupling are possible, especially if the splitting of the terms caused by the electric fields of the crystals is large as compared with the $j-j$ coupling. At least there would be a strongly coupled part inside joined by a relatively weak bond to the excited electron outside.

If this is true it would be expected that the intervals, $^7F_0 - ^7F_1$, $^7F_1 - ^7F_2$, and so on would occur in the spectra. Although as a first approximation they would be equal for terms of the type, $[^7F_2^2D_{3/2}]7/2$ [$^7F_2^2D_{3/2}$]9/2, there would nevertheless be some differences, greater or less depending on the difference in energy of the terms coupling with them. Also, splitting of the levels, $[^7F_2^2D_{3/2}]7/2$ [$^7F_2^2D_{3/2}$]5/2, owing to the electric fields in the crystal, should be nearly alike, but under high dispersion differences should become apparent. This is precisely what is found to be the case. I am just now repeating the work cited above, using a spectrograph with a dispersion of 2A per mm and have found small differences, amounting to about 1 cm^{-1} , between splitting arising from different groups.

Evidences of coupling of the sort suggested should also be found in the gaseous spectra of the rare earths, so that very different terms from those predicted on the basis of Russell-Saunders coupling would be obtained. The spectra would be closely analogous to x-ray spectra with the exception that the energy values of the optical levels are of such an order of magnitude that their interaction with the x-ray levels can no longer be ignored.

It may be well to mention a few of the more striking facts noted when the spectra are photographed with an instrument of high dispersion. Ordinarily, perhaps half the lines are doublets of about 1 cm^{-1} separation, but if the crystals are under strain many more lines resolve and the separation becomes greater. This splitting may be attributed to the action of the electric fields in the crystal on the basic level. Professor Kramers^{4d} has suggested that the 6S level should dissolve into four slightly separated levels. These, with the rules of selection which are applicable, should give separations of the sort observed. Just as was anticipated, the spectrum of a triclinic crystal photographed by Mr. G. C. Nutting and me shows the dissolution into pairs to be much

more pronounced, with several of the lines which apparently were single in the monoclinic $\text{GdCl}_3 \cdot 6\text{H}_2\text{O}$ resolved clearly into doublets. In a magnetic field the double lines split into several components, usually five or more, and in most instances it seems that still more components would appear under higher dispersion. As a usual thing the lines tend to separate into two groups of components which, under low dispersion, show as doublets of the sort reported by J. Becquerel, and Freed and Spedding.

High Velocity Vapor Jets at Cathodes of Vacuum Arcs

From measurements of the force of recoil on the cathode of an arc drawn in a high vacuum, and from measurements of the amount of cathode material which was lost, Tanberg¹ has calculated the mean velocity of the material leaving the cathode to be the extraordinarily high one of over 10^6 cm per sec . K. T. Compton² has proposed a theory of the development of high molecular velocities, but explains that, "... this criticism does not alter Mr. Tanberg's basic conclusion regarding a high speed neutral vapor stream. It merely suggests an electrical mechanism for the acquiring of these speeds instead of assuming a terrifically high temperature at the cathode."

Close scrutiny of Dr. Compton's suggestion that high velocity neutral molecules leave the cathode as a result of the existence of an accommodation coefficient for the positive ions neutralized at the cathode, indicates, however, that the velocity of these molecules cannot be nearly as great as the velocity obtained by Tanberg. The maximum velocity of the neutralized ions cannot be expected to be much greater than that corresponding to the cathode drop, whereas Tanberg observed velocities of an order corresponding to 70 volts. Hence, if the reaction of the neutralized positive ions is to account for the force upon the cathode observed by Tanberg, the stream of neutralized positive ions leaving the cathode with part of their original energy must be of much greater density than the high velocity stream calculated by Tanberg. In fact, Compton, by assuming that all the positive ions participate in the reaction, calculates that the average en-

ergy of the neutralized ions need be less than 0.4 volt to give the force measured by Tanberg.

The high speed stream of Tanberg must still be assumed to leave the cathode *region*, even though the mechanism proposed by Compton may possibly account for the way in which force is communicated to the cathode itself. Because of the high vacuum, the only material leaving the cathode *region* is substantially only the material lost from the cathode, which Tanberg weighed. The force on the cathode must equal the momentum of the material leaving the cathode *region*, regardless of whether this material acquires its velocity at the cathode surface or elsewhere in the region.

The argument for the necessary existence of Tanberg's high speed stream seems to be valid unless there is a high density of gas in the vessel in which the experiment is carried out. In such a case, the lower speed neutralized positive ions of Dr. Compton could communicate their momentum to many gas molecules, without any of them acquiring a high velocity. But a high gas pressure in the tube during the period of arcing does not seem likely. To obtain a high density of copper vapor throughout the vessel would require almost complete reflection of copper atoms at the walls of the vessel, a condition which does not seem very probable for heavy metal atoms. If such complete reflection did occur, one would expect to have a uniform deposit of copper on all parts

¹ Tanberg, Phys. Rev. **35**, 1080 (1930).

² K. T. Compton, Phys. Rev. **36**, 706 (1930).

of the containing vessel. Actually, however, experiment shows that the deposit is most dense directly opposite the cathode spot, with practically no deposit behind the cathode, the distribution of density following a cosine law roughly. So, little reflection must occur, condensation must take place on first impact, and vapor must flow from the cathode region at a rate just equal to the rate of vaporization measured by Tanberg. Since the momentum measured by Tanberg is carried by the mass he used, the velocity he calculated must be correct.

In the same way, the calculated high velocity of vapor striking a vane 2 cm from the cathode can be in serious error only if considerable reflection from the vane occurred,—a condition which does not seem to be true. Thus, if the force on the cathode is due to the reaction of neutralized ions, as proposed by Compton, some mechanism must exist whereby the many neutralized ions of low velocity transfer their momentum to the few atoms leaving the cathode region, with consequent high velocity.

The cathode spot itself, on the metal, need not be, and probably is not, at a high temperature. The experiment merely shows that a very high velocity vapor stream issues from the cathode region. A similarly high reaction upon the cathode of the mercury arc has been observed recently by Kobel.³

Whether or not to ascribe a high temperature to such a high velocity vapor stream is merely a matter of use of words. Perhaps, for the sake of emphasizing the unusual magnitude of the velocity, one may speak of the temperature of the vapor jet through the relation $3kT/2 = mv^2/2$.

Experiments to measure the magnitude of the vapor jet velocity by an independent means are in progress in this laboratory.

Knowledge of Past and Future in Quantum Mechanics

It is well known that the principles of quantum mechanics limit the possibilities of exact prediction as to the future path of a particle. It has sometimes been supposed, nevertheless, that the quantum mechanics would permit an exact description of the past path of a particle.

The purpose of the present note is to discuss a simple ideal experiment which shows that the possibility of describing the past path of one particle would lead to predictions as to the future behaviour of a second particle of a kind not allowed in the quantum mechanics. It will hence be concluded that the principles of quantum mechanics actually involve an uncertainty in the description of past events which is analogous to the uncertainty in the prediction of future events. And it will be shown for the case in hand, that this uncertainty in the description of the past arises from a limitation of the knowledge that can be obtained by measurement of momentum.

Consider a small box *B*, as shown in the figure, containing a number of identical particles in thermal agitation, and provided with two small openings which are closed by the shutter *S*. The shutter is arranged to open automatically for a short time and then close

again, and the number of particles in the box is so chosen that cases arise in which one par-

Fig. 1.

ticle leaves the box and travels over the direct path *SO* to an observer at *O*, and a second

particle travels over the longer path *SRO* through elastic reflection at the ellipsoidal reflector *R*.

The box is accurately weighed before and after the shutter has opened in order to determine the total energy of the particles which have left, and the observer at *O* is provided with means for observing the arrival of particles, a clock for measuring their time of arrival, and some apparatus for measuring momentum. Furthermore the distances *SO* and *SRO* are accurately measured beforehand, —the distance *SO* being sufficient so that the rate of the clock at *O* is not disturbed by the gravitational effects involved in weighing the box, and the distance *SRO* being very long in order to permit an accurate reweighing of the box before the arrival of the second particle.

Let us now suppose that the observer at *O* measures the momentum of the first particle as it approaches along the path *SO*, and then measures its time of arrival. Of course the latter observation, made for example with the help of gamma-ray illumination, will change the momentum in an unknown manner. Nevertheless, knowing the momentum of the particle in the past, and hence also its past velocity and energy, it would seem possible to calculate the time when the shutter must have been open from the known time of arrival of the first particle, and to calculate the energy and velocity of the second particle from the known loss in the energy content of the box when the shutter opened. It would then seem possible to predict beforehand both the energy and the time of arrival of the second particle, a paradoxical result since energy and time are quantities which do not commute in quantum mechanics.

The explanation of the apparent paradox must lie in the circumstance that the past motion of the first particle cannot be accurately determined as was assumed. Indeed, we are

forced to conclude that there can be no method for measuring the momentum of a particle without changing its value. For example, an analysis of the method of observing the Doppler effect in the reflected infrared light from an approaching particle shows that, although it permits a determination of the momentum of the particle both before and after collision with the light quantum used, it leaves an uncertainty as to the time at which the collision with the quantum takes place. Thus in our example, although the velocity of the first particle could be determined both before and after interaction with the infrared light, it would not be possible to determine the exact position along the path *SO* at which the change in velocity occurred as would be necessary to obtain the exact time at which the shutter was open.

It is hence to be concluded that the principles of the quantum mechanics must involve an uncertainty in the description of past events which is analogous to the uncertainty in the prediction of future events. It is also to be noted that although it is possible to measure the momentum of a particle and follow this with a measurement of position, this will not give sufficient information for a complete reconstruction of its past path, since it has been shown that there can be no method for measuring the momentum of a particle without changing its value. Finally, it is of special interest to emphasize the remarkable conclusion that the principles of quantum mechanics would actually impose limitations on the localization in time of a macroscopic phenomenon such as the opening and closing of a shutter.

Deviations from Kerr's Law at High Field Strengths in Polar Liquids

When an electric field is established in some substances they become doubly refracting with their "optic axes" in a direction parallel to the lines of force. This phenomenon was discovered by Kerr¹ and is known as the Kerr electro-optical effect. Kerr and others² have shown that if n_1 and n_2 are the refractive indices for the components of the light vibration parallel and perpendicular, respectively, to the lines of force, then their phase difference after passing through the electric field is

$$D = \frac{2\pi l(n_1 - n_2)}{\lambda} = 2\pi B l E^2$$

where λ is the wave-length of the light, l is the length of the light path through the electric field whose magnitude is E . B is Kerr's constant, but has been found to vary with different substances, wave-lengths and tempera-

¹ Kerr, Phil. Mag. (4) 50, 337, 446, (1875).

² See G. Szivessy, Handbuch der Physik, 724-808, 21, 1929.

tures. In the present work a method has been devised for testing the possible dependence of B upon the magnitude of E . The well-known theories^{3,4} show to a sufficient degree of approximation that

$$B \propto \frac{(n_0^2 - 1)(n_0^2 + 2)(K + 2)^2}{n_0 T} \left(1 + \phi \frac{\mu^2}{T} \right)$$

where n_0 is the index of refraction, K is the dielectric constant, T the absolute temperature and μ the electric moment of the molecule. It has been shown that in polar substances the dielectric constant varies with the strength of the applied electric field, and has been explained as due to an electrical saturation.⁵ Therefore in polar liquids B might be expected to decrease with increasing E .

In the present experimental arrangement light from an incandescent filament, made parallel by a lens, plane-polarized by a nicol prism, passed through a Kerr cell 5 cm in length and 3 mm spacing between the plates, then through a second Kerr cell 25 cm in length with a 3 mm spacing between the plates and finally through a second nicol prism crossed with respect to the first. The plane of polarization of the light made an angle of 45° with the lines of force in the first Kerr cell while the plane of the plates of the second cell was 90° from that of the first. A high voltage d.c. potential was applied directly across the first Kerr cell and a variable running tap-water resistance. The second Kerr cell was attached in parallel with just enough of the resistance so that the double refraction in the first Kerr cell was exactly compensated by that in the longer second Kerr cell. The electric field in the first cell was therefore more than twice that in the second. The potential

across the first cell and the resistance was then, for example, changed from 30,000 volts per cm to 60,000 volts per cm, so that any change in B with increasing E would appear as a lack of compensation of the light. In the case of CS_2 which is non-polar, practically no light was observed to pass the second nicol prism, that is, the double refraction in the first cell continued to be compensated by that in the second within the limits of precision. However, in the case of carefully distilled chloroform, which is polar, it was found necessary to lower the potential across the second Kerr cell (many times the least amount detectable) in order to make the two cells compensate each other or, again, to reduce the intensity of the light passing the second nicol to zero. This shows that for chloroform B decreases with increasing electrical field. Since the amount of light passing an arrangement of the kind here described is $I = I_0 \sin^2 D/2$ the method is very sensitive to small variations in Kerr's law and gives a simple and precise way of studying electrical saturation effects. The method is being improved and refined in order to make a study of both liquids and gases. A detailed description of the method and a discussion of the results will appear later.

BOOK REVIEWS

Gruppentheorie und Quantenmechanik. HERMANN WEYL. Second Edition. Pp. 358. S. Hirzel, Leipzig, 1931. Price, bound, RM 26.

The quantum theory has made it desirable for physicists to become acquainted with mathematical subjects of which heretofore they were allowed to remain blissfully ignorant. This mathematical apparatus is related on the one hand to partial differential equations (Schroedinger's wave-mechanics) and on the other to the theory of Hermitean quadratic forms and unitary transformations (statistical interpretation). In the third place the quantum theory makes use of the noncombining properties of term systems in the solution of special problems as well as in the familiar justification of the exclusion principle. An attempt has also been made by Dirac to introduce a symbolism having no direct relation to our number system (q numbers) which yields the numerical results necessary for physical applications only in the final stage of the symbolic operations.

For the physicist interested in the most direct experimental implications of the quantum theory the interrelations between these fields of pure mathematics are of little interest. The main parts of the subject may be presented in a small amount of printed space as has been done by Heisenberg in *The Physical Principles of the Quantum Theory*. Elementary developments of the noncombining properties of angular momenta and the related intensity relations are well known and the symmetry properties of electronic proper functions are easily handled in most practical cases by Slater's method. From a certain point of view a deeper study of the mathematical landscape seems, therefore, superfluous.

The transformation theory of classical dynamics is perhaps also superfluous in the same sense and the theory of Maxwell-Faraday stresses could be subjected to the same criticism. The engineer has little occasion to refer to either and for the same psychological reason many physicists approach the study of the more fundamental mathematical aspects of quantum theory with a certain amount of disdain. This fact does not affect however either the beauty or the usefulness of these subjects and in fact an elegant application of Weyl's presentation of the group of rotations has been made by Kramers in a recent paper on intensity formulas.

In Weyl's book the quantum mechanics is presented from the point of view of a mathematician and so far as the reviewer is able to judge in the best taste and with the most powerful machinery. The interrelations between the different aspects of the same mathematical problem are kept in mind throughout. As indicated by the title the guiding principle is that the matrices representing physical quantities define transformations which are representations of certain abstract groups. Operations with abstract groups correspond to the q number calculus. The contents of the first edition have been amplified by the addition of a discussion of the Heisenberg-Pauli wave field theory. The fifth chapter dealing with the group of permutations has been rewritten in a much more elementary form. The connection of the symmetric group with the group of homogeneous linear transformations has been kept in the foreground. Dirac's treatment of permutations as dynamical variables falls in naturally with the methods used here. This is a convenient place for reference to formulas and derivations for group characters of the symmetric group.

Throughout the book many pertinent mathematical subjects have been treated in an elegant and efficient manner. As an example section 3 of Chapter II devoted to spherical harmonics gives in three pages all the necessary material. The treatment of Dirac's relativistic equations is also very good and thorough. The reading of the book is greatly facilitated by a list of symbols used which has been added in the new edition. Contents: I. Unitary geometry II. Physical principles and simple problems of quantum theory. III. Groups and their representations. IV. Applications of groups to angular momenta, Dirac's relativistic equations, the wave field theory, V. The symmetric group.

G. BREIT

Henley's 20th Century Book of Recipes, Formulas and Processes. Edited by Hiscox. Pp. 809, Norman W. Henley Publishing Co., New York, 1930. Price \$4.00.

This book, as the title indicates, gives many recipes and formulas which may be of value to the laboratory technician or the home shop-worker. The material, taken from various lines of industry and craftsmanship, is alphabetically arranged throughout the book, with a supplementary index at the end which is a help where there is more than one popular nomenclature for the subject matter under inquiry. The printing is good and the type of a size easy to follow.

I believe the book is better suited for the amateur home worker than it is for the professional laboratory man who has at least a meager idea of what the industrial and scientific library holds in the way of literature along the various lines. Material from the trades is necessarily brief giving more of an outline than a workable procedure for the novice. For the research worker who is at a standstill for want of information on technical manipulation, the book may yield an inspiration for a new attempt. The latitude of the material might be a boon under such circumstances.

WM. B. HALIDAY

Atlas of Physical and Inorganic Chemistry. A. VON ANTROPOFF AND M. VON STACKELBERG. 29 charts and descriptive volume 64 pp. Verlag Chemie, G.m.b.H. Berlin 1929. Price RM 42.00.

The atlas consists of 29 charts (11 x 14.25 inches) printed on stiff card board, accompanied by a descriptive volume of the same size. The plates show the material in the form of histograms or columnar diagram. The following physical and chemical quantities are represented: (1) The periodic table. (2) The electron shells of the atoms. (3) Atomic diameters. (4) Ionic diameters. (5) Ionization potentials. (6) The crystal structure of the elements. (7) Melting and boiling points of the elements. (8) Mechanical properties of the elements in the solid state. (9) Atomic frequencies of the elements. (10) The atomic force constant. (11) Specific and atomic electrical conductivities. (12) Valencies of the elements. (13) Normal electrode potentials. (14) Heats of combustion. (15) Melting and boiling points of the chlorides and the electrical conductivities in the fused state. (16) Hydrides. (17) Carbides. (18) Nitrides. (19) Solubilities of hydroxides, carbonates, sulphates, chlorides, sulfides and a few other salts. (20) Isotopes. (21) The geochemical distribution of the elements. (22) The occurrence of the elements in the earth's crust and in the whole earth.

The printed volume which supplements the charts gives in every case a short discussion and the necessary definitions of the topics illustrated in the diagrams. It seems to the reviewer that the atlas is, on the one hand, too large for convenient desk use and on the other hand too small for the use with large classes. It should find its principal use with small seminar groups where a few individuals need the material as a basis for discussion.

GEORGE GLOCKLER

Les Quanta. G. DÉJARDIN. Pp. 224. Armand Colin, Paris, 1930. Price 10f.50 unbound.

Within its appointed scope as an elementary exposition of the conceptions and fundamental experiments underlying the quantum theory, this book seems for the most part quite successful. Short chapters on radiation theory and specific heats present the basic ideas of the Planck radiation formula and the Einstein-Debye theory of specific heats of solids. Chapters on the photoelectric effect and x-rays give the salient features of the Auger effect, the angular distribution of photo-electrons, the absorption of x-rays, and the Compton effect. Considerable space is devoted to a discussion of classical mechanics, Bohr's atomic theory and correspondence principle, Sommerfeld's fine structure formula and similar topics from pre-quantum mechanics atomic physics. After a short chapter on thermionics, photochemistry and Raman effect the book closes with a few pages on wave mechanics. The explanations seem uniformly clear and the material well chosen. The reviewer, however, doubts the efficacy or the need of retaining the older theoretical explanations even in elementary treatments such as this one, for in many respects the conceptions associated with the newer theory are distinctly simpler than their progenitors, and besides, once learned they will not need to be unlearned for at least some time to come.

E. L. HILL

THE PHYSICAL REVIEW

A PROBLEM IN THE QUANTUM MECHANICS OF CRYSTALS

By E. L. HILL

UNIVERSITY OF MINNESOTA

(Received February 15, 1931)

ABSTRACT

An elementary method is given for treating a one-dimensional lattice of the "tooth-valley" type containing any number of unit cells. The reflection of a beam of electrons from such a lattice is studied. For a semi-infinite lattice perfect reflection is shown to occur when the Bragg equation is satisfied, and an approximate formula for the widths of the reflection bands for high speed electrons is found. For the bound electrons the theory predicts occupied energy levels in the vicinity of the allowed levels for a single valley with infinitely high walls, in agreement with the perturbation theory. A simplified way of locating the edges of the reflection bands is discussed. The more complex case approximating real crystals is considered briefly.

INTRODUCTION

THE problem of determining the motion of the electrons in a crystal lattice has been treated by a number of authors. The usual method is to employ some type of perturbation scheme,¹ but the question has also been studied by the more direct procedure of replacing the crystal by a triply periodic field of force and then attempting the solution of the resulting equation for the characteristic function. Morse² has recently carried out this treatment in great detail, and has given many interesting results, but the mathematical technique is rather complicated and it is difficult to obtain a clear idea of the physical processes involved. Because of this it was suggested to the writer by Professor Frenkel that it would be interesting to try to carry through the calculation in detail for the case of a one-dimensional lattice of the "tooth-valley" type (Fig. 1). The work for this case is comparatively simple because the characteristic functions for the different sections of the lattice can be written down at once and then fitted together by use of the usual boundary conditions. A suitable method for handling the case of an infinite crystal is given in this paper.

METHOD AND CALCULATION

The type of one-dimensional lattice considered is illustrated in Fig. 1. The valleys³ are numbered consecutively 0, 1, 2, . . . , n as is indicated by the letters in parentheses, the region $x < 0$ corresponding to the 0th valley and the region $x > \xi$ to the n th valley. As there are just n teeth, $\xi = n\beta + (n-1)\alpha$.

Fig. 1.

The plan is first to solve the Schrödinger equation for a lattice of n teeth and then let $n \rightarrow \infty$. The equation to be solved is

$$\frac{d^2\psi}{dx^2} + (8\pi^2m/h^2)(W - V)\psi = 0. \quad (1)$$

In the p th valley the general solution of (1) can be written as

$$\psi = a_p e^{i2\pi k_1(x-x_p)} + b_p e^{-i2\pi k_1(x-x_p)} \quad (2)$$

and in the p th tooth, which lies between the $(p-1)$ th and the p th valley, as

$$\psi = a_p' e^{i2\pi k_2(x-x_p)} + b_p' e^{-i2\pi k_2(x-x_p)}. \quad (3)$$

For⁴

$$x < 0 \quad \psi = A e^{i2\pi k_1(x+\alpha)} + B e^{-i2\pi k_1(x+\alpha)} \quad (4)$$

$$x > \xi \quad \psi = a e^{i2\pi k_1(x-\xi)} + b e^{-i2\pi k_1(x-\xi)}. \quad (5)$$

where

$$hk_1 = [2mW]^{1/2}; hk_2 = [2m(W - V_1)]^{1/2}. \quad (6)$$

In these equations it is explicitly supposed that $W \geq V_1$ but it is well known that for $V_1 > W \geq 0$ the same equations can be used by giving k_2 its value as a pure imaginary number from (6).

³ By "valleys" and "teeth" are meant, of course, the regions of low ($V=0$) and high ($V=V_1$) potential energy in Fig. 1.

⁴ The extension to the case in which the wave number of the electron outside the crystal is $k_0 < k_2$ is considered later.

At the boundary between a tooth and a valley we use the ordinary boundary condition of the continuity of ψ and its first derivative.^{4a} By applying this condition to the function given by (2) and (3) one obtains a linear relation between the coefficients (a_p, b_p) and (a_{p-1}, b_{p-1}) of the form⁵

$$\begin{aligned} a_p &= c_1 a_{p-1} + c_2 b_{p-1} \\ b_p &= c_2^* a_{p-1} + c_1^* b_{p-1} \end{aligned} \quad (7)$$

where

$$\begin{aligned} c_1 &= (1/4k_1k_2) \{ (k_1 + k_2)^2 e^{i2\pi(k_1\alpha + k_2\beta)} - (k_1 - k_2)^2 e^{i2\pi(k_1\alpha - k_2\beta)} \} \\ c_2 &= - (1/4k_1k_2) \{ 2i(k_1^2 - k_2^2) \sin 2\pi k_2\beta \} e^{-i2\pi k_1\alpha}. \end{aligned} \quad (8)$$

Equations (7) permit one in principle to determine the coefficients in any part of the lattice provided they are assumed known in one valley, and in particular one can determine A and B in terms of a and b for use in Eqs. (4) and (5). In the present form this calculation is difficult because of the complicated character of c_1 and c_2 . To simplify the analysis we introduce a new set of variables y_p and z_p by a linear transformation which is to be so determined that the transformation matrix from (y_{p-1}, z_{p-1}) to (y_p, z_p) is diagonal; i.e., y_p and z_p are to be simply multiples of y_{p-1} and z_{p-1} respectively. By this artifice we can at once compute A and B in terms of a and b after calculating the associated Y and Z in terms of y and z . We assume then

$$\begin{aligned} a_p &= \gamma_{11}y_p + \gamma_{12}z_p \\ b_p &= \gamma_{21}y_p + \gamma_{22}z_p \end{aligned} \quad (9)$$

and on substituting in (7) we get as the condition that y_p and z_p shall be multiples of y_{p-1} and z_{p-1} respectively

$$\begin{aligned} \gamma_{11}/\gamma_{21} &= (c_1\gamma_{11} + c_2\gamma_{21})/(c_2^*\gamma_{11} + c_1^*\gamma_{21}) \\ \gamma_{12}/\gamma_{22} &= (c_1\gamma_{12} + c_2\gamma_{22})/(c_2^*\gamma_{12} + c_1^*\gamma_{22}) \end{aligned} \quad (10)$$

which is seen to be the condition that γ_{11}/γ_{21} and γ_{12}/γ_{22} shall be roots of the equation⁶

$$\tau = (c_1\tau + c_2)/(c_2^*\tau + c_1^*). \quad (11)$$

In general there are two different roots of (11) one of which must be taken for $(\gamma_{11}/\gamma_{21})$ and the other for $(\gamma_{12}/\gamma_{22})$ in order that the transformation (9) may be non-singular. These roots may be found directly from (11) if we set

$$c_1 = u + iv; \quad c_2 = \eta + i\xi \quad (12)$$

with

$$\begin{aligned} u &= (1/4k_1k_2) \{ (k_1 + k_2)^2 \cos 2\pi(k_1\alpha + k_2\beta) - (k_1 - k_2)^2 \cos 2\pi(k_1\alpha - k_2\beta) \} \\ v &= (1/4k_1k_2) \{ (k_1 + k_2)^2 \sin 2\pi(k_1\alpha + k_2\beta) - (k_1 - k_2)^2 \sin 2\pi(k_1\alpha - k_2\beta) \} \end{aligned} \quad (13)$$

^{4a} It is because of the character of the boundary condition that it is not necessary to give the precise value of the potential energy at the boundary between a tooth and a valley.

⁵ A similar relation can readily be found connecting the coefficients (a_{p-1}, b_{p-1}) and (a_p', b_p') .

⁶ They are the invariant points of the linear fractional transformation $z' = (c_1z + c_2)/(c_2^*z + c_1^*)$.

$$\left. \begin{aligned} \eta &= - (1/4k_1k_2) \{ 2(k_1^2 - k_2^2)(\sin 2\pi k_1\alpha)(\sin 2\pi k_2\beta) \} \\ \zeta &= - (1/4k_1k_2) \{ 2(k_1^2 - k_2^2)(\cos 2\pi k_1\alpha)(\sin 2\pi k_2\beta) \} . \end{aligned} \right] \quad (14)$$

It may be noted that

$$|c_1|^2 - |c_2|^2 = (u^2 + v^2) - (\eta^2 + \zeta^2) \equiv 1, \quad (15)$$

which is also required by the condition that the current must be constant throughout the crystal and follows from the boundary conditions and the usual expression for the current.

The solutions of (11) are most conveniently divided into three classes according to whether $u^2 > 1$, $u^2 < 1$, or $u^2 = 1$ which we shall call Case I, II, and III, respectively. Denoting the two roots by τ_1 and τ_2 we get⁷

Case I. $u^2 > 1$

$$\begin{aligned} \tau_1 &= \{ [v - i(u^2 - 1)^{1/2}] / (\eta^2 + \zeta^2) \} (-\zeta + i\eta) \\ \tau_2 &= \{ [v + i(u^2 - 1)^{1/2}] / (\eta^2 + \zeta^2) \} (-\zeta + i\eta). \end{aligned} \quad (16)$$

Case II. $u^2 < 1$

$$\begin{aligned} \tau_1 &= \{ [v + (1 - u^2)^{1/2}] / (\eta^2 + \zeta^2) \} (-\zeta + i\eta) \\ \tau_2 &= \{ [v - (1 - u^2)^{1/2}] / (\eta^2 + \zeta^2) \} (-\zeta + i\eta). \end{aligned} \quad (17)$$

Writing $\gamma_{11}/\gamma_{21} = \tau_1$ and $\gamma_{12}/\gamma_{22} = \tau_2$ the transformation from y_{p-1} to y_p and from z_{p-1} to z_p is found to be

$$\begin{aligned} y_p &= (c_2^* \tau_1 + c_1^*) y_{p-1} = \delta_1 y_{p-1} \\ z_p &= (c_2^* \tau_2 + c_1^*) z_{p-1} = \delta_2 z_{p-1}, \end{aligned} \quad (18)$$

where δ_1 and δ_2 are defined by (18) and can be found explicitly by using (16) and (17).

Case I. $u^2 > 1$

$$\delta_1 = u + (u^2 - 1)^{1/2}; \quad \delta_2 = u - (u^2 - 1)^{1/2} \quad (19)$$

Case II. $u^2 < 1$

$$\delta_1 = u + i(1 - u^2)^{1/2}; \quad \delta_2 = u - i(1 - u^2)^{1/2}. \quad (20)$$

By repeated application of (18) one can write at once for the relation between (Y, Z) and (y, z) which are associated respectively with (A, B) and (a, b) ,

$$y = \delta_1^n Y; \quad z = \delta_2^n Z. \quad (21)$$

Inverting (9) we find (A, B) from (Y, Z) and (a, b) from (y, z) and then from (21) find A and B in terms of a and b . The result is

$$\begin{aligned} A &= \left\{ \frac{-\delta_1^n + (\tau_1/\tau_2)\delta_2^n}{(\tau_1/\tau_2) - 1} \right\} a + \left\{ \frac{\tau_1(\delta_1^n - \delta_2^n)}{(\tau_1/\tau_2) - 1} \right\} b \\ B &= \left\{ \frac{(1/\tau_2)(\delta_2^n - \delta_1^n)}{(\tau_1/\tau_2) - 1} \right\} a + \left\{ \frac{(\tau_1/\tau_2)\delta_1^n - \delta_2^n}{(\tau_1/\tau_2) - 1} \right\} b. \end{aligned} \quad (22)$$

⁷ Case III is treated in a later paragraph.

With the aid of these formulae we can now study the behavior of ψ as $n \rightarrow \infty$. We obtain the essential results, however, in a somewhat clearer fashion by studying the reflection and transmission properties of the grating.

REFLECTION AND TRANSMISSION

To study the reflection of a beam of electrons from the grating assume that $b=0$ so that to the right ($x > \xi$) there is only a progressive wave to the right while for $x < 0$ there is an incident and also a reflected beam. The reflection coefficient is then

$$R_n = |B/A|^2 = |(1/\tau_2)(\delta_1^{2n} - 1)|^2 / |\delta_1^{2n} - (\tau_1/\tau_2)|^2 \quad (23)$$

as from (19) and (20) $\delta_2 = 1/\delta_1$.

Case I. $u^2 > +1$.

From (19) δ_1^2 is real and > 1 , and from (16) and (17) $|\tau_1| = |\tau_2| = 1$. Hence from (23)

$$\lim_{n \rightarrow \infty} R_n = 1. \quad (24)$$

Thus whenever $u^2 > 1$ there is perfect reflection from the semi-infinite lattice, although not from a finite crystal. From (22) we find the limiting relation^{7a} between A and B

$$A = \tau_2 B. \quad (25)$$

It is quite easy to find the characteristic function in any part of the crystal by inverting the transformation (22) and replacing a and b by a_p and b_p and δ_1^n and δ_2^n by δ_1^p and δ_2^p respectively. The determinant of the transformation is readily shown to be $+1$ (for any p) and on inserting (25) one finds

$$a_p = \tau_2 \delta_2^p B = \tau_2 b_p, \quad (26)$$

the characteristic function in the p th valley being

$$\psi = \{ \tau_2 e^{i2\pi k_1(x-x_p)} + e^{-i2\pi k_1(x-x_p)} \} (\delta_2^p / \tau_2) A. \quad (27)$$

A similar expression can be found for the p th tooth.

This result brings out very clearly the difference between a lattice bounded on one side only, and a lattice which is unbounded in both directions.^{7b} In the former case⁴ there exist solutions of (1) which are finite at $x = \pm \infty$ for all values of W , whereas in the latter case there are no non-vanishing solutions finite at both $+\infty$ and $-\infty$ when the electron energy is such that $u^2 > 1$. This is to be compared with Morse's method in which the function is written in all cases as

$$f(x) e^{i2\pi kx} \quad (28)$$

where $f(x)$ is periodic with period $(\alpha + \beta)$, the "forbidden" energies being associated with complex values of k . This function does not represent the gen-

^{7a} Note that from (22) this relation must be satisfied in order that $|a|$ and $|b|$ may remain finite as n becomes infinite.

^{7b} We shall distinguish these as "semi-infinite" and "infinite" lattices respectively.

eral solution of (1) as we must assume a relation between a_p and b_p in order that our solution (2) and (3) may be put in this form. It has not been possible as yet to show that the regions of complex k in (28) are identical with energies for which $u^2 > 1$. As $|\delta_2| < 1$ we see that ψ is damped out within the lattice, $|\psi|^2$ being diminished approximately by a factor $|\delta_2|^2$ in a distance $(\alpha + \beta)$.

Case II. $u^2 < 1$.

From (20) δ_1 is complex and $|\delta_1| = 1$. Let

$$\theta = \tan^{-1} [(1 - u^2)^{1/2}/u]; \quad \delta_1 = e^{-i\theta}$$

$$-\pi < \theta < \pi, \quad \theta \neq 0.$$

Substituting for τ_1 and τ_2 from (17) in (23)

$$R_n = \frac{(\eta^2 + \zeta^2) \left[\frac{\sin n\theta}{\sin \theta} \right]^2}{1 + (\eta^2 + \zeta^2) \left[\frac{\sin n\theta}{\sin \theta} \right]^2} < 1. \quad (29)$$

This expression is always less than unity and as $n \rightarrow \infty$ it does not approach any limit but merely oscillates. In particular if θ is commensurable with π there are always values of n for which it is zero. There is no obvious reason for this type of "resonance" in terms of a fitting up of the electron wavelength with the lattice distances.⁸

Case III. $u^2 = 1$.

This case must be considered separately for as $\tau_1 = \tau_2$ (9) is a singular transformation, the preceding analysis does not apply. Its treatment is not entirely unambiguous as there are two limiting processes to be considered; i. e. the simultaneous passage of n to infinity and the behavior of R_n in the neighborhood of $u^2 = 1$. For a semi-infinite crystal as we approach a point for which $u^2 = 1$ passing through values of W for which $u^2 > 1$, the limiting value of the reflection coefficient is unity. To find the limiting value by traversing points for which $u^2 < 1$ we may use (29) which yields

$$n^2(\eta^2 + \zeta^2) / [1 + n^2(\eta^2 + \zeta^2)] \quad (29')$$

where it is supposed that n has some finite, although large value. On allowing n to become indefinitely large we again get unity unless $\eta^2 + \zeta^2 = 0$, which can occur only as a very special case since it implies $u^2 = 1$ and at the same time $\sin 2\pi k_2 \beta = 0$ from (8).

It is worthwhile to notice another method which offers a natural way of arriving directly at the formula for the positions of these reflection band edges. From (16), (13), (14) and (15) we see that when $u^2 = 1$

$$\tau_2 = \pm e^{i2\pi k_1 \alpha}$$

⁸ Cf. R. d'E. Atkinson, *Zeits. f. Physik* **64**, 507 (1930).

the sign depending on whether $v > 0$ or < 0 . (27) then becomes

$$\psi = (\pm)^p \{ e^{i2\pi k_1(x-x_p-\alpha/2)} \pm e^{-i2\pi k_1(x-x_p-\alpha/2)} \} e^{i\pi k_1\alpha} A,$$

where the upper or lower sign in $(\pm)^p$ is taken according to whether $u = +1$ or $u = -1$. As a similar equation can be shown to hold for the teeth we see that the energies for which $u^2 = 1$ are characterized by the fact that the wave function can be written in the form of a standing wave in each valley and tooth. Moreover, the amplitudes in two consecutive valleys (or teeth) are the same or of opposite sign depending on the sign of u , there being no damping out of the function within the crystal. In the next section it is shown that the even ordered Bragg reflections occur when $u > +1$ and the odd ordered when $u < -1$, so that for the former the characteristic function is approximately the same in consecutive valleys (or teeth) while for odd orders it is approximately the same except for reversal of sign.

This standing wave method was used by Professor Frenkel in his lectures, under the impression that it would pick out electron energies at the centers of the reflection bands, whereas it actually locates the edges. Knowing this, the method can be used to give the results of this paper for widths of the bands, etc.

STUDY OF THE FUNCTION $u(W)$

"Free" electrons. k_1 and k_2 real and positive.

By use of (13), u can be written in either of the forms

$$\begin{aligned} u &= +1 - (1/2k_1k_2) [(k_1 + k_2)^2 \sin^2 \pi(k_1\alpha + k_2\beta) - (k_1 - k_2)^2 \sin^2 \pi(k_1\alpha - k_2\beta)] \\ &= -1 + (1/2k_1k_2) [(k_1 + k_2)^2 \cos^2 \pi(k_1\alpha + k_2\beta) - (k_1 - k_2)^2 \cos^2 \pi(k_1\alpha - k_2\beta)] \end{aligned} \quad (30)$$

from which we see that $u > +1$ if

$$(k_1 - k_2)^2 \sin^2 \pi(k_1\alpha - k_2\beta) > (k_1 + k_2)^2 \sin^2 \pi(k_1\alpha + k_2\beta), \quad (31)$$

and $u < -1$ if

$$(k_1 - k_2)^2 \cos^2 \pi(k_1\alpha - k_2\beta) > (k_1 + k_2)^2 \cos^2 \pi(k_1\alpha + k_2\beta). \quad (32)$$

While it is not easy to specify precisely the values of W for which (31) or (32) is satisfied, it is clear that they are respectively satisfied in the immediate neighborhood of energies such that

$$k_1\alpha + k_2\beta = s \text{ or } s + \frac{1}{2} \quad (33)$$

where s is a positive integer.⁹ If we define the wave-length of the electron inside the lattice as

$$\lambda = (\alpha + \beta)/(k_1\alpha + k_2\beta) \quad (34)$$

then (33) is just the Bragg reflection condition for normal incidence. This analysis is incomplete as we have not taken account of the fact that the aver-

⁹ The order of the reflection is $2(k_1\alpha + k_2\beta)$ and is just the number of "wave-lengths" contained in $2(\alpha + \beta)$.

age potential in a crystal is negative with respect to the surrounding region, but the expression for the reflection coefficient can be readily set up when the wave number of the electron outside the crystal ($x < 0$ and $x > \xi$) is k_0 , where $k_1 > k_2 > k_0 \geq 0$, and on passing to the limit $n = \infty$ it is easily seen that perfect reflection still occurs when $u^2 > 1$. The wave-length of the electron outside the lattice is then λ_0 with

$$k_0 = [2m(W - V_0)]^{1/2}/\hbar = 1/\lambda_0$$

the "index of refraction" being

$$\mu = \lambda_0/\lambda$$

the Bragg condition reduces to

$$s\lambda_0 = 2\mu(\alpha + \beta)$$

in agreement with the simple theory for the case of normal incidence.

Within the regions of validity of (31) and (32) reflection is perfect, so that for given values of α and β one can determine graphically the breadths of the reflection maxima. We can get a rough estimate of the breadths for large energies where k_1 and k_2 are large and approximately equal. For simplicity suppose $\alpha = \beta$, and consider especially (31). Noticing that k_1 , k_2 and $\sin \pi (k_1 - k_2)\alpha$ are slowly varying quantities compared with $\sin \pi (k_1 + k_2)\alpha$ and assuming that the reflection band is approximately symmetrical about the point for which $(k_1' + k_2')\alpha = s$ we can let $k_1 = k_1' + \Delta$ and $k_2 = k_2' + \Delta$ where Δ is small and is to be chosen such that (31) becomes an equality. To quantities of first order in Δ we get

$$2\pi\Delta s = \pm (k_1' - k_2') \sin \pi(k_1' - k_2')\alpha$$

but as

$$(k_1' - k_2') = (2mV_1/\hbar^2)/(k_1' + k_2') = 2mV_1\alpha/s\hbar^2$$

this yields

$$\Delta \approx (mV_1\alpha/\pi s^2\hbar^2) \sin [2\pi m\alpha^2 V_1/s\hbar^2]$$

or for the width on the energy scale

$$(\Delta W) \approx 2k_1'\Delta\hbar^2/m \approx (k_1' + k_2')\hbar^2\Delta/m \approx (V_1/\pi s) \sin [2\pi m\alpha^2 V_1/s\hbar^2]$$

which, apart from the trigonometric term varies inversely as the order of the reflection. A similar result is obtained from (32). This result seems to be in general agreement with other calculations.^{2,10}

"Bound" electrons. k_1 real and positive, k_2 pure imaginary.

Let

$$k_2 = ik = i(2m(V_1 - W))^{1/2}/\hbar.$$

Although not of importance in electron scattering experiments this region is of

¹⁰ L. Brillouin, Journ. de Physique (7) 1, 377 (1930).

interest in the theory of metallic conduction. From (30) u is expressed in terms of hyperbolic functions¹¹

$$\begin{aligned} u &= +1 - (2/k_1 k) [k_1 (\cosh \pi k \beta) (\sin \pi k_1 \alpha) + k (\sinh \pi k \beta) (\cos \pi k_1 \alpha)] \\ &\quad \times [k (\cosh \pi k \beta) (\sin \pi k_1 \alpha) + k_1 (\sinh \pi k \beta) (\cos \pi k_1 \alpha)] \\ &= -1 + (2/k_1 k) [k (\cosh \pi k \beta) (\cos \pi k_1 \alpha) - k_1 (\sinh \pi k \beta) (\sin \pi k_1 \alpha)] \\ &\quad \times [k_1 (\cosh \pi k \beta) (\cos \pi k_1 \alpha) - k (\sinh \pi k \beta) (\sin \pi k_1 \alpha)]. \end{aligned} \quad (35)$$

This shows that $u < +1$ if

$$\left\{ \begin{array}{l} \tan \pi k_1 \alpha > - (k/k_1) \tanh \pi k \beta \\ \tan \pi k_1 \alpha > - (k_1/k) \tanh \pi k \beta \end{array} \right\}$$

or if

$$\left\{ \begin{array}{l} \tan \pi k_1 \alpha < - (k/k_1) \tanh \pi k \beta \\ \tan \pi k_1 \alpha < - (k_1/k) \tanh \pi k \beta \end{array} \right\}$$

and $u > -1$, if

$$\left\{ \begin{array}{l} \tan \pi k_1 \alpha > (k/k_1) \coth \pi k \beta \\ \tan \pi k_1 \alpha > (k_1/k) \coth \pi k \beta \end{array} \right\}$$

or if

$$\left\{ \begin{array}{l} \tan \pi k_1 \alpha < (k/k_1) \coth \pi k \beta \\ \tan \pi k_1 \alpha < (k_1/k) \coth \pi k \beta \end{array} \right\}$$

From rough graphs of these functions it is apparent that $u^2 < 1$ in the immediate vicinity of energies for which $k_1 \alpha = 1/2, 1, 3/2, \dots$ which are just the positions of the energy levels allowed by the perturbation method, as they are the levels for a single valley with width α and infinitely high walls. It is difficult to give an estimate of the widths of these bands, but it is clear from the graph that they are very narrow when V_1 is large and k_1 small, approximately coinciding with the discrete levels for a single valley.

REAL CRYSTALS

In order to apply this method to real crystals, it is necessary to improve the starting point by considering a potential function similar to that shown in Fig. 2.

When $W > V_0$ the results are quite unchanged, the reflection regions being determined by the Bragg condition as previously discussed. All energy values are allowed even in the case of a semi-infinite lattice.

When $W < V_0$ some additions must be made to the previous results. The concepts of reflection and transmission being no longer applicable, one must make a study of the characteristic function itself, or what is the same thing, of the coefficients (a_p, b_p) . There is now the possibility that as $n \rightarrow \infty$, the modulus of the wave function will not remain bounded, so that certain ener-

¹¹ It can be verified from (8) that the real and imaginary parts of c_1 are still given by (13) when k_2 is pure imaginary.

gies may need to be excluded. Even for a finite lattice certain energy ranges will be excluded due to the circumstance that for any value of n , the boundary conditions at the edges of the lattice and (22) must be simultaneously satisfied; while for the semi-infinite lattice one must insure in addition the finiteness of the wave function. Probably the standing wave method described

Fig. 2.

previously will still be applicable, although it seems possible that there may be additional excluded energies not appearing in such an analysis. This question would need to be studied in greater detail before the method of the present paper could be applied to metallic conduction problems.

Note added in proof: Kronig and Penney, Proc. Roy. Soc. A130, 499 (1931) have just published a treatment of the *infinite* lattice of the type shown in our Fig. 1 using functions of the type (28). The results are similar to these found here. The author intends to study in greater detail the connection of our general solution with this more special method since it seems possible that the use of a single function of the type (28) is associated with assumptions of periodic properties of ψ which are not altogether required by the nature of the problem.

HYPERFINE STRUCTURE AS A TEST OF A LINEAR
WAVE EQUATION IN THE TWO-BODY PROBLEM

BY DAVID R. INGLIS
UNIVERSITY OF MICHIGAN
(Received February 21, 1931)

ABSTRACT

The proper treatment of the two-body problem is not known. Dirac's relativistic considerations, so successful in the problem of one electron, have been applied by Breit to the two-electron problem. Energy terms appear of which the physical reality is very doubtful. Here a very similar application is made to the problem of a nucleus and an electron, because of the failure of previous treatments of this problem to agree with measurements of hyperfine structure. The doubtful terms do not bring about agreement, so their reality remains improbable. The present state of the theory suggests that the proper interactions have not yet been introduced in the problem of hyperfine structure.

INTRODUCTION

DIRAC has satisfied the demands of relativity for the problem of one charged particle in a force field, obtaining spin as a consequence. Breit¹ has treated the problem of two bodies in a similar manner. He has improved the calculations of Gaunt² on the same subject by including the classical effects of retardation of potentials, as given by Darwin. A straightforward reduction of the linear equation, involving good approximations, leads to an equation for the largest components of the wave function. This may be compared directly with the wave equation resulting from a treatment of the atomic model with spins by the usual wave mechanical perturbation theory.³ Breit's equation contains terms representing spin-orbit interactions (with factors in agreement with the relativistically correct results of Dirac and of Thomas and Frenkel for single electrons), terms expressing the magnetic spin-spin and orbit-orbit interactions, terms due to relativistic change of mass, terms appearing in Dirac's results and having a meaning only for *s*-states, and in addition unexpected terms containing e^4 and no \hbar as factors, which contradict the correspondence principle. One of these terms in e^4 Breit has tested⁴ by calculating its probable effect on the He triplet. The results do not agree with experiment, whereas without this one term the agreement is quite as good as could be expected, considering the approximate nature of the wave functions involved. This contradiction means that the term making the disagreement, and perhaps all the terms in e^4 , have no physical meaning. It is still barely possible that that invalidation may not be final, and even that the doubtful terms have a different meaning for a nucleus and an electron than for two

electrons. The importance of the problem nurtures the hope that the following test of two of the terms in e^4 may be helpful, after the appearance of more copious data.

1. Consider an electron and a nucleus moving under one another's influence. No assumption is made regarding the spin of either. This differs from the helium problem in the absence of the field of the fixed nucleus and in the metamorphosis of one of the electrons into a nucleus. The Darwin-Hamiltonian will be,

$$H = p_I^2/2m_I + p_{II}^2/2m_{II} - p_I^4/8c^2m_I^3 - p_{II}^4/8c^2m_{II}^3 + e_I e_{II}/r - (e_I e_{II}/2c^2 m_I m_{II}) [(p_I \cdot p_{II})r + (p_I \cdot r)(p_{II} \cdot r)/r^3]. \quad (1)$$

Here the numeral I refers to the nucleus, II to the electron; $e_I = Ze$, $e_{II} = -e$; and r is a vector from the nucleus to the electron. This leads one to the equivalent of Breit's Eq. (6),

$$\left(p_0 + \sum_{k=1,2,3} (\alpha_k^I p_k^I + \alpha_k^{II} p_k^{II}) + \alpha_4^I m_I c + \alpha_4^{II} m_{II} c + (e_I e_{II}/2c) \left\{ \sum_{k=1,2,3} \alpha_k^I \alpha_k^{II} r^{-1} + (\alpha^I \cdot r)(\alpha^{II} \cdot r) r^{-3} \right\} \right) \psi = 0 \quad (2)$$

with

$$p_0 = -\frac{h}{2\pi i} \frac{\partial}{\partial t} - \frac{e_I e_{II}}{cr}; \quad p_k^I = \frac{h}{2\pi i} \frac{\partial}{\partial x_k^I}.$$

Here we have omitted entirely the four-potential A . The reduction of this equation will be identical with the calculation of Breit, and will lead to the following modification of his Eq. (48'):

$$\{ E - (m_I + m_{II})c^2 - e_I e_{II}/r - p_I^2/2m_I - p_{II}^2/2m_{II} \} \psi = 0 \quad (3.0)$$

$$+ p_I^4/8m_I^3 c^2 + p_{II}^4/8m_{II}^3 c^2 \quad (3.1)$$

$$+ (e_I e_{II}/2m_I m_{II} c^2) [(p_I \cdot p_{II})r^{-1} + \sum_{i,j} r^{-3} (x_i^{II} - x_i^I)(x_j^{II} - x_j^I) p_i^I p_j^{II}] \quad (3.2)$$

$$- (e_I e_{II} h/8\pi c^2) r^{-3} (r \cdot [p^I m_I^{-2} - p^{II} m_{II}^{-2}]) \quad (3.3)$$

$$+ (e_I e_{II} h/8\pi c^2) r^{-3} (-m_I^{-2} [r \times p^I] \cdot \sigma^I + m_{II}^{-2} [r \times p^{II}] \cdot \sigma^{II}) \quad (3.4)$$

$$+ (2/m_I m_{II}) \{ -[r \times p^{II}] \cdot \sigma^I + [r \times p^I] \cdot \sigma^{II} \} \quad (3.5)$$

$$- (e_I e_{II}/m_I m_{II}) (h/4\pi c)^2 \langle (\nabla^{II} \cdot \sigma^I) (\nabla^I \cdot \sigma^{II}) r^{-1} \rangle \quad (3.6)$$

$$- (e_I^2 e_{II}^2/4(m_I + m_{II})c^2) [3r^{-2} - 2(\sigma^I \cdot \sigma^{II})r^{-2} + (\sigma^I \cdot r)(\sigma^{II} \cdot r)r^{-4}] \} \psi_{a,b} = 0 \quad (3.7)$$

For the sake of easy comparison, the energy equation which will be derived in §2 from this wave equation is entered here.

$$E = E_1 + E_2$$

E_1 is the same for all the states in which we are interested and consists of the unperturbed energy augmented by the contributions of (3.1), (3.2), and (3.3). E_2 splits up the doublet and is given by

$$-E_2 = (h^2 e_I e_{II} / 8\pi^2 c^2) \overline{r^{-3}} [m_I^{-2} (\overline{I \cdot S^I}) + m_{II}^{-2} (\overline{I \cdot S^{II}})] \quad (4.4)$$

$$- (2/m_I m_{II}) \{ (\overline{I \cdot S^I}) + (\overline{I \cdot S^{II}}) \} \quad (4.5)$$

$$- (e_I e_{II} / m_I m_{II}) (h/2\pi c)^2 \overline{r^{-3}} [(\overline{S^I \cdot S^{II}}) - 3(\overline{S^I \cdot r})(\overline{S^{II} \cdot r}) \overline{r^{-2}}] \quad (4.6)$$

$$+ (e_I^2 e_{II}^2 / (m_I + m_{II}) c^2) \overline{r^{-2}} [(\overline{S^I \cdot S^{II}}) - (\overline{S^I \cdot r})(\overline{S^{II} \cdot r}) \overline{r^{-2}}] \quad (4.7)$$

(3.4) (and also (4.4)) represent the interaction of each spin with the field due to its own orbital motion, while (3.5) gives the interaction of the spin of each particle with the orbit of the other. (3.6) corresponds to the classical interaction energy of two dipoles. (3.7) contains the doubtful terms in e^4 . If physically extant, only the last of the three terms would effect the helium triplet separation, so it alone was tested by Breit. Each of the last two terms would effect hyperfine structure, so we can test them both. The first gives only a displacement common to all the levels.

2. In the perturbation problem, (3) is the perturbed wave equation. To determine the unperturbed wave functions, we consider all the terms beyond (3.0) as perturbation terms, so that (3.0) becomes the unperturbed equation. The coordinates are taken to be those in which the center of gravity is at rest, since a transformation can always be made from more general coordinates of two particles to the coordinates of the center of gravity and the relative coordinates of the particles. The translation of the center of gravity being separated from the problem, $\mathbf{p}^I = -\mathbf{p}^{II}$. Thus we have the hydrogen wave equation, and hence use hydrogenic wave functions. The wave function in the unperturbed equation, as in (3), has two indices, each of which may have two values. The first index refers to the nuclear spin orientation, and is operated upon by σ^I ; the second to the spin of the electron, and is acted upon by σ^{II} . As a function of space and spin coordinates, the unperturbed function is separable,

$$\psi_{a,b}(r, \theta, \phi) = S_a^I S_b^{II} u(r, \theta, \phi)$$

where a and b may each be either α or β of Pauli's theory, and σ^I and σ^{II} operate on S^I and S^{II} , respectively, in the usual manner. $S^{II}u$ might be replaced by the one-electron wave function stabilized for spin-orbit interaction, such as given by Bartlett,⁵ e.g., and the resulting ψ would give the diagonal terms of an energy matrix from which hyperfine splitting could be had by sum rules. Since the wave function is separable in radial and angular parts, we may obtain the result of the angular integrations by considering the operators as vectors in the vector model, and averaging over the precessions. $[\mathbf{r} \times \mathbf{p}^I] = -[\mathbf{r} \times \mathbf{p}^{II}]$ is the orbital angular momentum operator. Since Breit has used in effect the negative of the Pauli matrices, σ becomes $-2\mathbf{s}$, where $|\mathbf{s}| = \frac{1}{2}$. These substitutions in (3) give (4). In reducing it to an expression in the quantum numbers, Landé cosines are used. Goudsmit⁶ has explained in detail a method for obtaining $(\overline{S^I \cdot r})(\overline{S^{II} \cdot r}) \overline{r^{-2}}$. It consists essentially in making angular integrations in the case of a strong field, when the quantum vectors

⁵ J. H. Bartlett, Jr., Phys. Rev. 35, 230 (1930).

⁶ S. Goudsmit, Phys. Rev. 37, 663 (1931).

are decoupled, and using the results to find the value of the interaction without field by means of energy sum rules.

From the latter term of (4.4) (the other term in $(I \cdot s^{II})$ is negligible) we get the energy that gives rise to the doublet separation:

$$E' = - (h^2 e_I e_{II} / 8\pi^2 c^2 m_{II}^2) \bar{r}^{-3} (I \cdot s^{II}) \\ = A' (I \cdot s^{II}) = A' \frac{1}{2} \{j(j+1) - l(l+1) - \frac{3}{4}\} \quad (5)$$

It is apparent in (4) that the hyperfine structure contains the same constant A' which is determined empirically by the doublet separation. The following expressions, which give the splitting up of the two doublet levels, are derived from (4.4), (4.5), and (4.6). The order of the terms has been preserved.

$$E''_j = A'_j (s^I \cdot j) = A'_j \frac{1}{2} \{f(f+1) - j(j+1) - s^I(s^I+1)\} \quad (6)$$

$$A''_{l+\frac{1}{2}} = \frac{m_{II}}{m_I} A' \left[\frac{2l}{l+\frac{1}{2}} - \frac{1}{l+\frac{1}{2}} + \frac{3}{(2l+3)(l+\frac{1}{2})} \right. \\ \left. + \delta \frac{8\pi^2 e_I e_{II} m_{II}}{h^2} \frac{\bar{r}^{-2}}{\bar{r}^{-3}} \left\{ \frac{1}{l+\frac{1}{2}} - \frac{2}{(2l+3)(l+\frac{1}{2})} \right\} \right] \quad (7)$$

$$A''_{l-\frac{1}{2}} = \frac{m_{II}}{m_I} A' \left[2 \frac{l+1}{l+\frac{1}{2}} + \frac{1}{l+\frac{1}{2}} + \frac{3}{2(l-\frac{1}{2})(l+\frac{1}{2})} \right. \\ \left. - \delta \frac{8\pi^2 e_I e_{II} m_{II}}{h^2} \frac{\bar{r}^{-2}}{\bar{r}^{-3}} \left\{ \frac{1}{l+\frac{1}{2}} + \frac{1}{(l-\frac{1}{2})(l+\frac{1}{2})} \right\} \right]. \quad (8)$$

The symbol δ has the value unity of the terms in e^4 are physical, otherwise it is zero.

3. To compare the terms we must have an idea of the ratio of the radial integrals. For a Coulomb field,

$$\bar{r}^{-2} = \frac{Z^2}{n^3(l+\frac{1}{2})} \frac{1}{a_0^2}, \quad \bar{r}^{-3} = \frac{Z^3}{n^3 l(l+\frac{1}{2})(l+1)} \frac{1}{a_0^3}, \quad a_0 = \frac{h^2}{4\pi^2 m_{II} e^2}. \quad (9)$$

For the heavy elements some sort of approximation must be used. The electron cloud alters the radial part of the wave function by producing a non-coulomb interaction. We will content ourselves with the classical application of the charged shell model of the atom, as used by Landé for doublet separations.⁷ Using (9) for outer and inner orbital segments, we get

$$\bar{r}^{-2} = \frac{2Z_0^2}{n_0^3(l+\frac{1}{2})} \frac{1}{a_0^2}, \quad \bar{r}^{-3} = \frac{Z_i Z_0^2}{n_0^3 l(l+\frac{1}{2})(l+1)} \frac{1}{a_0^3}$$

of which the ratio is

$$\bar{r}^{-2} / \bar{r}^{-3} \approx 2l(l+1)a_0/Z.$$

This in (7) and (8) gives

$$A''_{l+\frac{1}{2}} = \frac{m_{II}}{m_I} A' \left\{ \frac{2l(l+1)}{(l+\frac{1}{2})(l+\frac{3}{2})} - \delta \frac{8l(l+1)}{2l+3} \right\} = \frac{m_{II}}{m_I} A' \left\{ \frac{16}{15} - \delta \frac{16}{5} \right\}$$

⁷ A. Landé, Zeits. f. Physik 25, 46 (1924).

$$A''_{l-\frac{1}{2}} = \frac{m_{II}}{m_I} A' \left\{ \frac{2l(l+1)}{(l-\frac{1}{2})(l+\frac{1}{2})} + \delta \frac{4l(l+1)}{l-\frac{1}{2}} \right\} = \frac{m_{II}}{m_I} A' \left\{ \frac{16}{3} + \delta 8 \right\}.$$

The last members are for the case $l=1$. The presence of other electrons also replaces Zr^{-3} by $Z_{eff}r^{-3}$ in the expression for A' , but the numerical change is small enough that it need not interest us here.⁸

The present treatment leads naturally to a nuclear spin with but two orientations possible and a Landé g -factor 2 in units $e\hbar/4\pi m_I c$. For the terms that classically have a meaning it is easy to believe that we may extend the result to other cases with the vector model by assuming a larger nuclear spin vector s^I in (6), selecting its value and a different value of g to accord with observed intervals or intensity ratios. We postulate tentatively that a similar treatment of the terms in e^4 will give an estimate of their contribution to the energies.

A comparison is made with the few experimental data available,⁹ which are for 2P . In Tl the nuclear moment is $\frac{1}{2}$ but in Bi it is $4\frac{1}{2}$.

The classical values, with $\delta=0$, do not agree with experiment even when multiplied by the arbitrary factor $g(I)$ which the usual theory allows. When such an arbitrary factor is introduced, the agreement in the case $\delta=1$ is even worse. However, the present treatment of the problem, when not extended hypothetically, does not permit of such a factor. For the large separations, of which the measurements are most certain, the agreement is better with $\delta=1$ than with $\delta=0$.

In the classical terms the value of the nuclear magnetic moment is definitely determined as Zm_{II}/m_I Bohr magnetons for the nuclear spin $\frac{1}{2}$. This is as assumed and discussed by Jackson⁹ and by Fermi⁸.

This paper stresses once more the fact that we have at present no satisfactory theory of spin-spin interaction.

I thank Professor Uhlenbeck and Professor Goudsmit for very helpful suggestions.

⁸ E. Fermi, Zeits. f. Physik 60, 332 (1930).

⁹ The results for In I by Jackson (Proc. Roy. Soc. A128, 508, 1930) and by McLennan and Allin (Proc. Roy. Soc. A129, 208, 1930) disagree too radically to be of use at present. In Bi III and Tl III the second member of the P series is known, but second order effects make the values of A'' for our purpose uncertain. (Vide H. Casmir, Phys. Rev., in print.)

ABSORPTION BANDS OF HYDROGEN CYANIDE GAS
IN THE NEAR INFRARED

BY RICHARD M. BADGER AND JOHN L. BINDER

GATES CHEMICAL LABORATORY, CALIFORNIA INSTITUTE OF TECHNOLOGY

(Received February 20, 1931)

ABSTRACT

The absorption spectrum of gaseous hydrogen cyanide has been investigated by photographic methods in the region $\lambda 7000$ – 9200 . Two weak bands of very simple structure were found, having *P* and *R* branches but no *Q* branches. The band at $\lambda 7912$ is apparently a harmonic of a fundamental band at 3.04μ , and the very weak band at $\lambda 8563$ is a combination band. The hydrogen cyanide molecule is linear in the normal state, and has a moment of inertia $I = 18.79 \times 10^{-40}$ g·cm². The distance of separation of the carbon and nitrogen atoms is estimated to be 1.15×10^{-8} cm. Hydrogen cyanide is discussed in regard to its three fundamental oscillations which have frequencies 3290, 2090, and 710, respectively, and in regard to its dissociation energy and dissociation products. The evidence requires a molecular structure represented by the formula HCN, and shows that the normal molecule is built from a normal hydrogen atom and a normal CN radical. The absorption of cyanogen gas has also been investigated in the photographic infrared, but no absorption bands could be detected.

INTRODUCTION

HYDROGEN cyanide has been the subject of two previous infrared investigations. W. Burmeister¹ observed two double bands with maxima at 14.33μ and 13.60μ , and at 7.22μ and 6.95μ , respectively, a single strong maximum at 3.04μ , and doubtful bands at 4.8μ and 3.6μ . E. F. Barker,² working with greater dispersion, confirmed the doubtful bands and found for the one three maxima at 4.79 , 4.756 , and 4.723μ , and in the case of the other apparently a strong *Q* branch with maximum at 3.564μ and two weak maxima on either side. Slight evidence of a rotational structure was found in the band at 7μ .

A calculation of the moment of inertia of the hydrogen cyanide molecule from the separation of the maxima of the double band at 14μ , with the use of a classical formula, yielded the improbably large value $I = 33 \times 10^{-40}$.³ The separation of the maxima in the band at 7μ is much greater and has been interpreted as due to rotation about an axis with moment of inertia $I = 0.907 \times 10^{-40}$.⁴

EXPERIMENTAL PROCEDURE

The hydrogen cyanide gas used in the investigation was prepared by dropping a concentrated solution of sodium cyanide into sulphuric acid. The gas

⁴ Schaefer and Matossi, Das Ultrarote Spectrum, Berlin, 1930.

evolved was dried with calcium chloride and then condensed in a tube immersed in a freezing mixture. This tube was then connected to the evacuated absorption cell until equilibrium between liquid and vapor was established at room temperature. The gas pressure in the cell was consequently usually slightly less than one atmosphere. It seemed undesirable to attempt to increase the pressure by warming the apparatus, since even at atmospheric pressure the absorption lines were rather broad.

The absorption cell was a steel tube 280 cm in length, with a mirror at one end so that the light from the tungsten lamp source traversed it twice. The exposures were taken with the first order of a ten-foot grating in an Eagle mounting, using Eastman Infrared Sensitive Plates hypersensitized in ammonia. As calibration spectrum the iron lines in the second order were used.

Since both absorption bands were very weak it was not possible to make direct measurements on the plates with the use of a comparator. Microphotometer records were consequently made of absorption and comparison spectra, side by side on the same plates, using a linear enlargement of ten times. The tabulated wave-lengths, except for a few weak lines, were calculated from the mean of measurements made on four photometer curves obtained from different parts of two spectral plates.

EXPERIMENTAL RESULTS

A careful examination of spectrograms covering the region $\lambda 7000$ – 9200 resulted in the discovery of two similar absorption bands at $\lambda 7912$ and $\lambda 8563$, respectively. Both are weak, the latter extremely so, and the lines are broad as is to be expected in a saturated vapor. Each band has a *P* and an *R* branch, a missing zero line, and no apparent *Q* branch. The convergence in the *R* branches is so large that at first sight the bands appear to have a head. Due to the weakness of the absorption no attempt has been made to estimate relative intensities. The two branches have in each case about equal intensity, and as should be expected there is no indication of alternating intensities.

The wave-lengths and corresponding frequencies on the lines measured are recorded in the accompanying tables. A single question mark indicates low probable accuracy of measurement, and a double question mark, possible doubt as to the reality of the line. The measurements of the lines in the *R* branches are probably the less reliable due to incomplete resolution of the rather broad lines.

It should be mentioned that cyanogen gas was also studied in the course of this investigation, with pressures up to three atmospheres, but no absorption could be detected.

DISCUSSION OF THE RESULTS

The rotational energy levels of the upper and lower vibrational states of the molecule were isolated by means of the usual combination relations:

$$\Delta_2 F'(J) = R(J) - P(J) = F'(J+1) - F'(J-1) \sim 4B'(J + \frac{1}{2})$$

$$\Delta_2 F''(J) = R(J-1) - P(J+1) = F''(J+1) - F''(J-1) \sim 4B''(J + \frac{1}{2}).$$

These differences are presented in the right side of Tables I and II. No effect of the stretching of the molecule as a result of rotation could be detected, and within the accuracy of measurement the rotational energies in all three vibrational states may be represented by simple formulas of the form:

$$E_{\text{rot}} = J(J + 1)B.$$

The best values for the constants for the two bands are given in Table III. The differences in vibrational energies of upper and lower states, and the

TABLE III. Constants of the HCN bands at $\lambda 7912$ and $\lambda 8563$.

λ	ν_0	B''	$B' - B''$	I''
7911.9	12635.8	1.472	-0.044	18.79×10^{-40}
8563.3	11674.5	1.480	-0.042	18.69×10^{-40}

difference in the rotational energy constants, $B' - B''$, were obtained from a graphical treatment of the combinations:

$$\frac{1}{2}[R(J) + P(J + 1)] = \nu_0 + (J + 1)^2(B' - B'').$$

The slight difference in the value of B'' , the rotational constant for the ground state, as determined from the two bands, is probably not greater than experimental error as the two bands seem to have a common lower level. The value determined from the data on the band at $\lambda 7912$ is probably the more accurate.

STRUCTURE OF THE HYDROGEN CYANIDE MOLECULE

The simplicity of the two bands here investigated leaves no doubt as to the linearity of the hydrogen cyanide molecule in its normal state, and also in the two other vibrational states concerned. It still remains to be discussed which of the three possible arrangements of the three atoms in a straight line is the correct one. The arrangement with the hydrogen in the center is at once ruled out by the relatively small moment of inertia, ($I = 18.79 \times 10^{-40}$) and need not be discussed on the grounds of chemical improbability. Whether the gas known to chemists should be designated as hydrogen cyanide, HCN, or iso-cyanide, HNC, or whether it may be a mixture of two molecular species has been the subject of numerous discussions, and it seems to be worth while to consider what the spectroscopic evidence has to say in this regard.

We will simply mention at this point that the relation of all the observed infrared bands is such that they are apparently due to only one type of molecule. Further, their intensity is so great that this molecular species must constitute by far the greater part of hydrogen cyanide gas. This particular molecule will be the one with which we shall be concerned, and from now on we shall speak of it as the hydrogen cyanide molecule, and shall examine the data with the purpose of determining its structure. We shall now proceed to discuss three pieces of information which are derived from spectral data, namely the moment of inertia of the molecule, the frequencies of vibration, and the heat of dissociation.

The moment of inertia of the hydrogen cyanide molecule in the normal state, as determined from the data on the band at $\lambda 7912$ is, $I = 18.79 \times 10^{-40} \text{ g} \cdot \text{cm}^2$. The fact that this constant is about half as large as that previously estimated from the doublet separation of the band at 14μ may possibly be accounted for by the low resolution used in studying this latter band. It is of course not possible to determine uniquely both interatomic distances in the molecule from the moment of inertia alone. However, the moment of inertia is not very sensitive to the position of the light hydrogen atom, and an estimate of the carbon-nitrogen separation may be made. In Fig. 1 is plotted

Fig. 1. The C-N separation plotted as a function of the C-H, or N-H separation for HCN and HNC molecular models with $I = 18.79 \times 10^{-40}$.

this distance as a function of the H-C separation, assuming the structure HCN, and of the H-N separation for the HNC structure, with the given moment of inertia. In either case the distance is small and strongly suggests a triple bond linkage between carbon and nitrogen. We may compare with the internuclear separation in the normal state of the CN radical, $1.17 \times 10^{-8} \text{ cm}$.

MODES OF OSCILLATION OF THE HYDROGEN CYANIDE MOLECULE

The observed hydrogen cyanide bands may all be fitted into one simple scheme as given in Table IV, requiring three fundamental frequencies.

TABLE IV. Designation of the HCN bands.
 $\nu_1 = 3333.7 \text{ v} - 43.7 \text{ v}^2$; $\nu_2 = 2090$; $\delta = 710$

Band	$\nu(\text{cm}^{-1})$	Designation
14μ	710	δ
7μ	1411	2δ
4.7μ	$\begin{cases} 2090 \text{ (approx)} \\ 2112 \end{cases}$	ν_2
3.6μ	2805	3δ
3.04μ	3290	$\nu_2 + \delta$ (and possibly 4δ)
0.8563μ	11675	ν_1
0.7912μ	12636	$3\nu_1 + \nu_2$
		$4\nu_1$

The designation of the strong band at 3.04μ as a fundamental, and the band at $\lambda 7912$ as one of its harmonics seems without objection. These two bands are represented within experimental error by the formula $\nu = 3333.7\nu - 43.7\nu^2$. That the bands at 14μ and 7μ are fundamental and first harmonic of a "deformation" oscillation is also reasonable, as such an oscillation should be expected to have a low frequency. A deformation oscillation does not necessarily lead to the presence of a strong Q branch as has been shown in the case of acetylene.⁵ The choice of the other fundamental frequency, which seems to be comparatively inactive, is more difficult. The form of the unresolved band at 4.7μ suggests the overlapping of two bands, one of which is probably the fundamental in question and the other a harmonic of the 14μ band. The choice of a frequency around 2100 is confirmed by the combination band at $\lambda 8563$, and seems settled by recent work on the Raman spectrum of liquid hydrogen cyanide.⁶

Fig. 2. The fundamental modes of oscillation of the HCN molecular model.

If we represent the hydrogen cyanide molecule by a mechanical model with three masses in the ratio 1.008:12:14, bound by Hooke's law forces, and arranged in a straight line, we find that this model does in fact have three fundamental modes of vibration, all of which will be "active," so to speak. Two of these may be designated as "valence" oscillations, the third as a "deformation" oscillation, as seen in Fig. 2. (Cf. the discussion of molecular oscillation by Mecke.⁵) By the application of normal coordinate methods it is possible to evaluate the ratio of the "valence" force constants which is required to fit the observed frequencies ν_1 and ν_2 . That is we may estimate the ratio k_1/k_2 of the constants of the restoring forces which tend to maintain the equilibrium separation between carbon and nitrogen, and between hydrogen and the atom to which it is linked. Since the carbon and nitrogen atoms are of nearly equal mass it does not matter very much which of the two possible

⁵ R. Mecke, *Zeits. f. Physik*, **64**, 173 (1930).

⁶ Dadiou and Kohlrausch, *Berichte* **63**, 1657 (1930).

molecular models is considered. For the HCN arrangement we find $k_1/k_2 = 3.2$ and for HNC nearly the same value, 3.1. The former is nearly exactly the ratio of the force constants for CN in the normal state, and for HCl (or CH), and whichever model we choose is strong evidence for a triple bond between carbon and nitrogen. The ratio would be approximately 2 for a double bonded structure, as can for example be seen from a comparison of the binding constants in acetylene and ethylene.⁵

DISSOCIATION PRODUCTS AND DISSOCIATION ENERGY OF HYDROGEN CYANIDE MOLECULE

We shall now consider the products of a dissociation process in which the hydrogen atom is removed from a hydrogen cyanide molecule. Three energy states of the CN radical are known. The normal state is a $^2\Sigma$ state formed from a 4S nitrogen atom and a 5S carbon atom.⁷ A small internuclear separation and high oscillational frequency are evidence of a triple bond. The two excited states are formed from 4S nitrogen and 3P carbon. The lower of these, a $^2\Pi$ level with 1.8 volts excitation energy, has a relatively loose binding indicative of a double bond, but the higher, a $^2\Sigma$ state, has surprising rigidity considering its dissociation products and small dissociation energy.

The consideration of the oscillational frequencies rendered it improbable that the normal hydrogen cyanide molecule is formed from the CN radical in the $^2\Pi$ state, and this improbability is confirmed by the following energy considerations. The dissociation energy of normal hydrogen cyanide gas molecules into normal hydrogen atom and CN radical may be calculated from the data embodied in the following equations. These data are partly spectroscopic values, and partly thermal values corrected to the absolute zero by the use of specific heat data.

$$\frac{1}{2}H_2 + C(\text{graphite}) + \frac{1}{2}N_2 = \text{hydrogen cyanide} - 30,200 \text{ cal} (-1.31 \text{ volts}) \quad (1)$$

$$N_2 = 2N - 212,000 \text{ cal} (-9.2 \text{ volts}) \quad (2)$$

$$H_2 = 2H - 100,000 \text{ cal} (-4.34 \text{ volts}) \quad (3)$$

$$C(\text{graphite}) = C(\text{gas}) - 158,000 \text{ cal} (-6.86 \text{ volts})^8 \quad (4)$$

$$CN(\text{normal}) = C(\text{normal}) + N(\text{normal}) - 187,000 \text{ cal} (-8.1 \text{ volts})^7 \quad (5)$$

$$CN(\text{normal}) = CN(^2\Pi) - 41,500 \text{ cal} (-1.8 \text{ volts})^7 \quad (6)$$

From a combination of these data we find:

$$\text{hydrogen cyanide}(\text{normal}) = H(\text{normal}) + CN(^2\Pi) - 138,000 \text{ cal} (-6.0 \text{ volts}) \quad (7)$$

This is again strong evidence that normal hydrogen cyanide molecule is not directly formed from $^2\Pi$ CN radical, since an abnormally strong binding for the hydrogen would be required by Eq. (7). We should expect a molecule so built to be of the form HNC, and there seems to be no reason to suppose that the binding energy of hydrogen to nitrogen in this case should be much greater than the energy of the H-C linkage. We find for example that the

⁷ W. Heitler and G. Herzberg, *Zeits. f. Physik* **53**, 52 (1929).

⁸ Brody and Millner, *Chem. Zent. I*, 237 (1928).

dissociation energy of NH_3 into its atoms is about 4.0 volts per hydrogen atom. A similar argument renders it even less likely that hydrogen cyanide is formed from CN in a state of excitation higher than the $^2\Pi$ state.

We are then left with the one possibility that the dissociation products of normal hydrogen cyanide are a normal hydrogen atom and a normal CN radical. This seems to require the molecular structure HCN, and we may write:

$$\text{HCN}(\text{normal}) = \text{H}(\text{normal}) + \text{CN}(\text{normal}) - 97,000 \text{ cal} (-4.2 \text{ volts}) \quad (8)$$

This result is thoroughly reasonable and may be compared with the value $-100,000 \text{ cal}.$ (-4.34 volts) which is the dissociation energy of HCl molecule.

It is interesting to consider the possibility of the existence of a hydrogen iso-cyanide molecule formed from hydrogen atom and $^2\Pi$ CN radical. This molecule, as stated above, would probably have the form HNC but would be non-linear. If we may estimate the H-N binding energy at about 4.2 volts, HNC should have about 41,500 cal (1.8 volts) more energy than HCN. We may make a rough estimate of the relative amounts of the two forms in an equilibrium mixture if we assume that the two forms have about the same specific heat and the same entropy. We find

$$K_{298^\circ} = \frac{\text{HCN}}{\text{HNC}} = 10^{30} \text{ (approx).}$$

We must then conclude that hydrogen cyanide gas consists almost entirely of linear molecules of the form HCN.

One may be tempted to calculate a dissociation energy for HCN by the use of the vibrational constants in the formula representing the bands with fundamental at 3.04μ . The value so obtained is 6.4 volts, but can not be very significant since only one band of the series has been accurately measured and the constants are consequently inexact. In any case linear extrapolations are found to give uncertain results even in the case of diatomic molecules, and with polyatomic molecules seem to give consistently too high values. This might in some cases be explained by saying that the dissociation leaves a radical in an excited electronic state, but in other cases this is improbable. There seems to the authors to be a certain difficulty in principle in calculating dissociation energies of polyatomic molecules from spectral data. When one of the fundamental oscillations of such a molecule is increased in amplitude until an atom splits off, at the moment of separation the radical remaining may very likely be in a distorted condition, and after the separation will continue to vibrate with considerable energy. This remaining vibrational energy must be subtracted from the value obtained from the band series extrapolation in order to obtain the true dissociation energy. We hope to discuss this question more in detail in a later paper, and have some experiments in progress which may clarify the situation.

THE IONIZATION OF MERCURY VAPOR BY ELECTRON IMPACT

By P. T. SMITH

DEPARTMENT OF PHYSICS, UNIVERSITY OF MINNESOTA

(Received February 16, 1931)

ABSTRACT

Quantitative measurements have been made of the total number of positive charges per electron per centimeter path at a definite pressure and temperature in mercury vapor as a function of the energy of the impacting electrons out to 750 volts. The maximum efficiency 19.40 occurs at about 85 volts.

"Ultra-ionization potentials" were found at 10.60, 10.76, 10.88, 11.06, 11.27, 11.40, 11.55, 11.70, 11.78, 11.92, 12.00, 12.06, 12.17, 12.28, 12.40, 12.77, 13.55, 18.20, 19.36, 20.40, and 29.50 volts. Most of these agree with those previously observed.

A METHOD has recently been described¹ for measuring the total number of positive charges formed by electron impact in gases at low pressure. The results in helium, neon, and argon have been reported. The present paper gives a description of the results of a study of mercury vapor.

Compton and Van Voorhis,² T. J. Jones,³ and Bleakney⁴ measured the efficiency of ionization of mercury vapor by electron impact and obtained values which agree qualitatively. Lawrence,⁵ and Hughes and Van Atta⁶ have observed by indirect methods sharp increases, near the ionization potential, in the number of ions formed by electrons as their energy was increased. Haupt,⁷ and Nielsen and Potter,⁸ by more direct methods, also observed several of these critical potentials which Lawrence has called "ultra-ionization potentials."

The writer has redetermined the efficiency of ionization of mercury vapor and has observed a number of abrupt changes in the slope of the efficiency curves. The potentials at which these new modes of ionization set in agree quite well with those previously observed and several of the new ones found account for some of the apparent discrepancies between those found by Lawrence and by Hughes and Van Atta.

APPARATUS AND PROCEDURE

The apparatus, Fig. 1, was constructed entirely of tantalum. The more essential parts were insulated with quartz. The metal parts were baked out at a yellow heat before they were sealed into the Pyrex tube.

⁸ W. M. Nielsen, Phys. Rev. **37**, 87 (1931).

The filament, F , was a thin tungsten ribbon about 0.075 cm wide and placed within 1 mm of the hole, S_1 , which was about 0.034 cm in diameter.

Fig. 1. Diagrammatic sketch of the apparatus.

The IR drop across this 0.034 cm length of the filament was less than 0.02 volt so that the velocity distribution of the electrons was determined almost entirely by the temperature of the filament.

The positive end of the filament was connected to S_1 , which in turn was maintained about 7 volts negative with respect to S_2 . The velocity of the electrons was determined by a variable potential between S_2 and S_3 .

Fig. 2. The efficiency of ionization by electron impact of Hg vapor near the ionization potential. The ordinates represent the efficiency in arbitrary units.

This arrangement gave an electron beam whose magnitude was quite independent of the field between S_2 and S_3 and insured a voltage correction which was independent of the speed of the electrons.

Figs. 3 and 4. The ionization of Hg vapor by electron impact from 10.4 to 11.7 volts.
 I^+ is proportional to the efficiency of ionization.

Figs. 5 and 6. The ionization of Hg vapor by electron impact from 11.7 to 12.3 volts.
 I^+ is proportional to the efficiency of ionization.

Figs. 7 and 8. The ionization of Hg vapor by electron impact from 12.3 to 13.8 volts.
 I^+ is proportional to the efficiency of ionization.

The holes S_2 and S_3 were about 0.18 cm in diameter, whereas S_4 and S_5 were 0.6 cm and 0.5 cm in diameter, respectively. The plates P_3 and P_4 were about 6 cm long and 3 cm wide. Plate P_4 was 0.5 cm below P_3 and was maintained 300 volts positive with respect to P_3 . With the magnetic field, H , equal to 300 gauss, it is quite improbable that an electron will leave the trap, T , once it has entered, as both experiment and theory show.

RESULTS

Fig. 2 shows the efficiency curve for the first 2 volts above the ionization potential. The ordinates are proportional to the efficiency of ionization. The curve indicates that the ionization does not rise sharply at the ionization potential, the rapid rise occurring almost a volt above this potential. Curves obtained with a poor velocity distribution did, however, show a more rapid rise at 10.40 volts.

Figs. 3-8 show the efficiency curve plotted on a large scale. (They are not all plotted to the same scale.) The accuracy with which the breaks could be reproduced is shown in Fig. 3 where two independent sets of data have been plotted.

Fig. 9. The ionization of Hg vapor by electron impact from 17 to 21 volts. I^+ is proportional to the efficiency of ionization.

From 13.8 to 18 volts the curves were smooth and showed no obvious discontinuous changes in the slope. Fig. 9 shows the curve from 17 to 21 volts. The four breaks in this interval could be reproduced very accurately. Beyond 21 volts evidences of breaks were observed but the experimental errors in the measurements were greater than the deviations from a smooth curve, so that no satisfactory results were obtained although it is believed that several critical potentials do exist beyond 21 volts. However, at 29.5 volts a definite in-

crease was always observed, which may be attributed to the formation of Hg^{++} . Fig. 10 shows a typical set of data in this region.

A list of the critical potentials reported by the various investigators, together with those found by the writer, is given in Table I. The values given in the same row were assumed to correspond to the same critical potential. The agreement is in general very good.

An "ultra-ionization potential" at 11.06 volts has not been previously reported, but as Fig. 3 shows, it apparently represents the minimum energy necessary for some quite efficient mode of ionization. It is of interest to note that in a study of the electron energy losses in mercury vapor, Castle W. Foard⁹ found a pronounced peak which corresponded to a loss of 11.07 volts of energy. He was unable to account for this loss on spectroscopic grounds. This loss of energy can probably be associated with the ultra-ionization potential at 11.06 volts if we assume that ionization can result as a consequence of the simultaneous excitation of the two valence electrons. This would require a quantized energy loss.

The measurements of the positive ion current were made with a Compton electrometer having a sensitivity of about 3700 mm per volt. The electron current used in obtaining the data for the curves shown in Figs. 3-10 was about 5×10^{-8} amperes and for some of the work was measured with a galvanometer having a sensitivity of 2.70×10^{-11} amperes per mm deflection by employing a suitable balancing-out arrangement. With this sensitive measuring device, very small variations in the electron current could be detected. A very careful study showed that there was no correlation between any observed deviations in the electron current and the observed critical potentials.

The pressure used ranged between 3×10^{-5} and 1.85×10^{-4} mm mercury. The data shown in Fig. 11 and in Table II were taken with a pressure of 8×10^{-5} mm of mercury and agrees very closely with data taken at different pressures. The ordinates represent the total number of positive charges per electron per cm path reduced to a pressure of 1 mm of Hg at 0°C . The posi-

tive ion current for these data was measured with a galvanometer having a sensitivity of 2.70×10^{-11} amperes per mm deflection. The electron current used was about 6×10^{-7} and was measured with a galvanometer having a sensitivity of 8.00×10^{-10} amperes per mm deflection.

Fig. 11. The total number of positive charges per electron per cm path at 1 mm pressure and 0°C plotted as a function of the velocity of the impacting electrons in volts.

DISCUSSION

It is very difficult to reconcile the values for the efficiency of ionization of mercury vapor given here with those obtained by Bleakney and by Jones, both of whom employed the same method. The present work was carried out with a better vacuum and a very careful study of all of the characteristics of the apparatus failed to reveal any objectionable features in the apparatus, method, or procedure. It is interesting to note that the copper apparatus, used in the study of helium, neon and argon, gave essentially the same values for Hg vapor as those given here.

The author takes this opportunity to acknowledge the constant interest and many suggestions of Professor John T. Tate.

OSCILLATIONS IN THE GLOW DISCHARGE IN ARGON

BY GERALD W. FOX

DEPARTMENT OF PHYSICS, IOWA STATE COLLEGE

(Received February 16, 1931)

ABSTRACT

Report is made of radio frequency oscillations observed in argon glow discharges. The frequencies lie in the range of 10^4 cycles/sec to 10^5 cycles/sec in approximate harmonic relations. They are very sensitive to pressure changes but appear to bear no relation to the tube current. The peculiar action of a magnetic field on the oscillations is described. Some frequency calculations are made on the assumption that the potential distribution throughout the Faraday dark space can be represented by a parabola.

SOME time ago the writer¹ described experiments with oscillations observed in hot cathode glow discharges in neon. The present paper deals with a continuation of the same type of work in argon. The same discharge tube was used except that direct current was employed on the heater coil, since it was found that the a.c. introduced an extraneous sixty-cycle modulation. The argon was purified by a lengthy exposure to the action of a misch-metal arc. The experimental procedure was in all respects like that previously described.

CHARACTERISTICS OF THE DISCHARGE

The discharge in argon was steadier than in neon. The color appeared very nearly white to the eye but the brightness of the discharge for a given power input was not nearly so pronounced as in neon, while the heating was much greater. In neon, a current of 20 amperes could be run for a short interval and 10 amperes was possible continuously, with ordinary fan and water cooling. With argon, however, a current of two amperes caused the heavy copper anode to glow red in less than a minute and for this reason no observations were possible with currents larger than four amperes.

The pressure range over which oscillations were observed was quite narrow, the limits being approximately 0.2 mm Hg to 1.0 mm Hg. It was impossible to obtain oscillations for random current values in this pressure range. Oscillations were present only for particular values of current and pressure and when observed their frequency appeared to be independent of the tube current. As in the case of neon the discharge must be steady to exhibit oscillations. The slightest flickerings on anode or cathode produce enormous irregularities which are detected as "static" noises in the pick-up circuit. If one starts in at low pressure values a discharge may be maintained in argon at as low as 0.001 mm Hg but as listened to it is very noisy and the glow is feeble. With increasing pressure no noticeable change occurs in tube current,

¹ Fox, Phys. Rev. 35, 1066 (1930).

tube voltage, or glow until a pressure of about 0.1 mm Hg is reached, when the light from the tube suddenly increases many times and the discharge becomes noiseless except for a slight hiss. Tuning through the frequency range then shows the presence of oscillations which seem to start simultaneously with the increase of light from the tube.

The maintaining voltage for the argon discharge averaged about 255 volts which is approximately 75 volts higher than the maintaining voltage for neon.

As in the case of neon the interesting flashes described by Whiddington² and Aston and Kikuchi³ were generally present.

RESULTS

1. Frequencies present at a given pressure.

Tables I and II show typical data on frequencies present in the discharge. As in the case of neon these frequencies seem to be harmonics of one particu-

2. Variation of oscillation frequency with pressure.

In the argon discharge, the frequency range covered was not as wide for a given pressure difference as in neon. A noticeable peculiarity was that the discharge frequency changed almost linearly with the pressure down to a certain critical value when no further change could be produced, the frequency remaining constant but becoming weaker until, on further pressure reduction, it broke completely. (Fig. 1.)

Fig. 1. Variation of oscillation frequency with pressure.

3. Relation of frequency to tube current.

It was not possible to show any frequency dependence on tube current such as appeared in neon. Having set on a particular frequency, this frequency persisted within a few cycles of the same value while the current was changed as much as an ampere when the oscillation would stop suddenly, to start again when the current was returned to its former original value.

4. Effect of a magnetic field on oscillations.

Some peculiar effects were noticed when a magnetic field was placed at right angles to the discharge. When a horseshoe magnet was moved from the anode end of the discharge toward the cathode, the frequency of the beat note in the telephone receiver fluctuated periodically from zero to a maximum, while moving the length of the positive column as shown in Fig. 2. On coming to the Faraday dark space, the regular oscillations disappeared altogether and the discharge became very noisy. Upon the removal of the magnet, however,

the discharge became quiet again and the oscillations reappeared after a time of the order of thirty seconds. This observation was made repeatedly.

DISCUSSION

From the work of Compton, Turner, and McCurdy⁴ we have a fairly good picture of the potential distribution throughout the glow discharge. They have shown the existence of a potential minimum in the Faraday dark space, especially in cases of large ionization. In the discharges in both argon and neon, the tube currents were of the order of several amperes so that we may expect a large concentration of positive ions in the negative glow, for the ionization processes going on are more effective than the needs of the circuit as a whole demand. Positive ions from the cathode end of the positive column and from the negative glow, will both be accelerated into this region of minimum potential. This accelerating field is really necessary to prevent the ac-

Fig. 2. As the magnet is moved along the positive column the sound in the telephone receiver fluctuates regularly in intensity.

cumulation of a negative space charge here by diffusion of electrons from the negative glow. The positive ions from the positive column and probably also those from the negative glow approach the potential minimum with terminal velocities attained in the fields through which they have travelled and, since these fields are rather weak, their velocities will be small. Thus some ions will be trapped for a time and we may imagine them oscillating about the potential minimum until they acquire sufficient energy to get over the hump on the cathode side. An ion's escape probably comes suddenly after a collision with a molecule or another ion which provides a suitable energy transfer.

The action of the magnetic field in the Faraday dark space lends some support to this idea of the origin of the oscillations. When the field is applied here, the additional magnetic force to which the ions are subjected, upsets the regularity in their motion and brings about the noise that is heard in the pick-up circuit. The high-frequency oscillatory component of the tube current is really very small. It is merely superimposed upon the main steady current through the tube. The fact that the frequency increases with decreasing pressure seems reasonable for we can imagine fewer collisions taking place to slow the ion down while it remains in motion about the potential minimum.

⁴ Compton, Turner, and McCurdy, *Phys. Rev.* **24**, 597 (1924).

The action of the magnetic field throughout the positive column makes one think of the presence of standing waves. It seems possible that electric sound waves of the type mentioned by Tonks and Langmuir⁵ may be present, since the observed frequencies fall within the range of their calculations. The flashes, observed by Whiddington,² which travel from anode toward cathode, and which are of low frequency and can be observed with a rotating mirror, can be explained by assuming the presence periodically of a large anode drop which produces excess ionization in the anode sheath. This excess of positive ions would travel toward the cathode, modifying the potential distribution as they go and causing local ionization and excitation. This would appear as a travelling striation.

SIMPLE THEORY OF OSCILLATION IN THE GLOW DISCHARGE

If one assumes as a first approximation that the curve representing the potential distribution throughout the Faraday dark space is a parabola, it is not difficult to arrive at an expression for the frequency of the oscillation which gives a value which is of the observed order of magnitude.

Fig. 3.

Let P represent the potential according to the equation $P = 4ax^2$. Then since

$$\frac{m}{2} \left(\frac{dx}{dt} \right)^2 + 4aex^2 = W, \quad \frac{d^2x}{dt^2} + \frac{8ae}{m} x = 0.$$

The solution to this equation gives

$$x = C \cos (8ae/m)^{1/2}t + D \sin (8ae/m)^{1/2}t$$

in which it is seen that x repeats itself at intervals of 2π in the time $(8ae/m)^{1/2}t$. The period of a complete vibration is $2\pi(m/8ae)^{1/2}$ and the frequency is the

⁵ Tonks and Langmuir, *Phys. Rev.* **33**, 195 (1929).

reciprocal. The quantity a can be determined from estimates of dimensions of the Faraday dark space in the discharge. Thus assuming the dark space to be 4 cm wide and 20 volts deep, which is not unreasonable, we can write $P_0 = 4ax^2$, $a = P_0/4x^2$, or $a = 10^{-3}$ esu/cm² approximately. Taking e/m for hydrogen as 3×10^{14} esu/gram and 40 as the atomic weight of argon, the calculated frequency is 4×10^4 cycles per second. This is of the observed order of magnitude. The frequency appears to be quite dependent on the ratio of the width of the pit to its depth in volts. On the other hand, the frequency, is not very dependent on the type of ion in the discharge. The e/m for argon is of the same order of magnitude as e/m for neon. As mentioned before, the observed oscillations for both gases occurred in the same range.

The presence of a series of harmonic frequencies indicates that the potential distribution is not so simple a function as has been assumed. We do not know the actual potential distribution throughout the Faraday dark space, but since a slight distortion of our assumed distribution would allow the presence of harmonics, their presence can thus be accounted for.

In conclusion, the writer wishes to thank Professor H. M. Randall, director of the Physics Laboratory of the University of Michigan, for extending the privileges of the laboratory, where the experimental work was done.

THE RELATIVE INTENSITIES OF MERCURY LINES UNDER DIFFERENT CONDITIONS OF EXCITATION

BY MARCEL J. E. GOLAY

UNIVERSITY OF CHICAGO

(Received December 15, 1930)

ABSTRACT

The relative intensities of the lines of the $2s-2p_i$ triplet have been measured by a photographic method with a calibrated tungsten lamp as a standard of comparison. The intensity ratios have been found to vary with conditions of excitation due to the absorption of the 5461 and 4047 lines by atoms in the metastable states $2p_1$ and $2p_3$. About three-quarters of the 5461 radiation and about one-third of the 4047 radiation were absorbed in a commercial mercury-filled tube with three electrodes when a high plate current was passed through the tube. A lesser absorption was found when an ordinary arc was used and when small plate currents were passed in the three-electrode tube. A tube specially built to excite mercury by electronic bombardment and provided with means for controlling the mercury pressure gave uniform results under various conditions of mercury pressure and plate current, and the double ratio of 8.5:3.3:1 was found for the intensities divided by the fourth powers of the corresponding frequencies. The ratio of 4078:4047 was found to vary with plate voltage in a manner similar to the variation of efficiency of ionization with electron velocity. It was attributed to the presence of two mechanisms of emission giving widely different intensity ratios, namely, excitation of the neutral atom to a higher energy level, and recombination of the ionized atom. A roughly quantitative survey of the intensities of the excitation and of the recombination spectra indicated that in comparison with atoms excited to a higher level by electronic impact as occurs in the arc, recombined atoms will prefer the singlet to the triplet system, while within each system their order of preference is P, S, D , and p, s, d , respectively. Also, within each state, a level at about the height of the $4S$ level is preferred to the others.

GENERAL

THE purpose of the research reported here was primarily the study of the $2s-2p_i$ triplet. The intercombination line $2S-2p_2$ of wave-length 4078 was also included in this study because of the work of Houston,² who treats the lines $2S-2P$, $2S-2p_2$, $2s-2P$ and $2s-2p_i$ ($i=1, 2, 3$) as a whole. According to this author the ratio 5:3:1 must be found for

$$\frac{A(5461)}{N_3} : \frac{A(4358)}{N_3} + \frac{A(4078)}{N_1} : \frac{A(4047)}{N_3},$$

where A designates the intensity divided by the fourth power of the frequency and N the number of atoms in the respective initial states. The quantities written above are proportional to the squared amplitudes of the corresponding lines, and it is for these squared amplitudes that the "sum-rule" must hold.

¹ Notation of Paschen.

² W. V. Houston, Phys. Rev. 33, p. 297. (1929).

The squared amplitudes of the individual lines can also be determined from the formulas given by Houston. They give approximately the ratio 5:2.9:1 for the relative intensities of the triplet lines, divided by the fourth powers of the corresponding frequencies. They also give the ratio of 0.1:1 for the lines 4078 and 4047. This signifies that for an equal population of their respective initial levels, line 4078 will have approximately one-tenth the intensity of line 4047, the relative intensities of these two lines giving thus a basis for a computation of the relative population of their respective initial levels.

METHOD OF INTENSITY MEASUREMENTS

When two lines are but a few angstroms apart in wave-length, their relative intensities may in principle be measured by weakening one line by a known amount until it has the same intensity as the other, that is, until the blackening of the photographic plate is the same for the two lines. Usually both lines are weakened by a series of absorbing screens, and their relative intensities are obtained through some process of interpolation which affords at the same time a number of results, which must verify each other, when the image of the weaker line through the clearer weakeners is comparable in intensity to the image of the stronger one through the more opaque portions.

When the lines to be compared are sufficiently separated to warrant a determination of the sensitivity of the emulsion for the corresponding wave-lengths, a source of known spectral distribution such as a black body or an incandescent filament of known temperature and emissivity is used for this purpose. Each line is then compared with the continuous radiation of the same wave-length. This can of course be done as before, by means of weakeners, calibrated for each of the different wave-lengths of the group under study.

Their use, however, can be avoided very simply by using the standard of comparison to put on the plate a series of intensity marks of known relative intensities. As the standard of comparison emits a continuous spectrum, the gradation of intensities can be obtained by varying the width of the slit, and if a lens is used to focus on the slit an image of the tungsten ribbon of the lamp used as a standard, one can also place diaphragms of known geometrical transmission in front of the lens.

A lower limit for the slit-width is set by the accuracy with which this width can be measured, and by the size of the diffraction pattern formed on the prism. It is desirable that the main fringe and at least one or two lateral fringes appear on the prism when sighting it from the camera side of the spectrograph, in order to avoid losing more than a few percent of the light. Conversely, the largest slit-width must not allow the integrated spectrum thus obtained to misrepresent the intensity of the source, and the sensitivity of the emulsion. According to Ornstein no errors due to the integration of the spectrum will be appreciable if the width of the slit corresponds to less than 60A on the plate for any of the wave-lengths studied.

The diaphragms placed in front of the lens must cover enough of the latter so that a full image of the uncovered portion can be seen on the prism from

the camera side, while if but little light is desired, these diaphragms must have holes not small enough to create on the slit a main fringe equal in width to the difference between the image of the filament and the opening of the slit.

When a set of intensity marks has been put on a plate it is necessary to take only one spectrogram of the source of light, taking care to use a rather wide slit, and to compare the lines with the comparison spectrum at the same wave-length. One can thus take many exposures on one plate, which is advantageous when studying the variations of relative intensity with certain conditions of experimentation. One obtains indeed but one figure for every exposure, while several are obtained when the source is photographed through a series of weakeners. If it is desired to obtain a few figures for every condition of light emission studied, one has to take as many exposures, preferably using various diaphragms in front of the lens projecting an image of the source on the slit.

In the work reported here, care was taken that light from all sources photographed followed the same optical path. As an added precaution it was

Fig. 1. Diagram of mercury-filled tube.

also verified that the transmission of the whole optical system was sensibly the same along the optical axis and away from this axis.

As sources of known radiation incandescent lamps with a flat tungsten ribbon were used and their temperatures determined photographically by comparison with a standard of known temperature and emissivity, supplied to Ryerson Laboratory by Dr. Forsythe of Nela Park. The secondary standards were generally operated at 2780 to 2800°K, and the time of exposure was the same for the standard and for the spectrum studied, to avoid errors due to a difference in Schwarzschild's constant for different wave-lengths. The radiation emitted by the standard lamp was calculated from the black body radiation formula. Corrections for the emissivity of tungsten at 2800°K at various wave-lengths were introduced. Corrections were also introduced for the dispersion of the spectrograph and for a difference in broadness of the lines due to different distances of the plate from the camera lens.

SOURCES OF LIGHT AND RESULTS, $2s-2p$, TRIPLET

Some preliminary measurements were carried out, with a home-made arc, a Cooper-Hewitt arc, and a mercury-filled tube, obligingly furnished by the Bell Telephone Laboratories. Fig. 1 shows a schematic drawing of this tube.

The spectrum of the ordinary arc was photographed at various time intervals, beginning at the moment the arc was started, and continuing until the steady state was attained. It was then observed that the ratio of 5461:4047 increased from about 4 to about 7, while the ratio of 4358:4047 decreased from about 5 to about 3. Similar results were obtained for the Cooper-Hewitt arc. Table I shows a set of results obtained similarly for the tube furnished by the Bell Telephone Laboratories, by observing the white streaks emerging from the grid at a potential just sufficient to maintain an arc.

TABLE I I/ν^4 values for lines from tube shown in Fig 1.

Condition of tube	5461:4047 ³	4358:4047
First exposure, tube cold	5.1	3.7
	5.6	3.7
	5.8	3.8
	6.8	3.6
	7.4	3.5
	7.3	3.4
Last exposure, tube hot	7.4	3.4

The results to be discussed later suggest the following explanation of these figures. It will be shown that the true intensity ratio is about 8.5:3.3:1. The lines 5461 and 4047 are, however, absorbed by the atoms in the metastable states $2p_1$ and $2p_3$. As the line 4358 terminates on the level $2p_2$ where the strong resonance line 2537 originates, it seems plausible to assume that the population of the $2p_2$ level is not large enough to cause any appreciable absorption of the line 4358. The population of the metastable states is roughly proportional to the ratio of the rate at which these states are reached by the excited atoms, to the rate at which they leave them owing to collisions of the second kind. The rate at which atoms are sent into metastable states is roughly proportional to the current, while the rate at which they leave them increases with the number of collisions per unit time; this number increases about linearly with the temperature, and the density, this latter quantity rising rapidly with the temperature. It can therefore be expected that at a low pressure, the ratio of 5461:4047 will be considerably reduced, line 5461 being much more absorbed than line 4047 on account of the greater population of the state $2p_1$, while the ratio of 4358:4047 will be found somewhat too high on account of the absorption of line 4047. As the temperature and the pressure increase these ratios will approach their true values, due to the diminished population of the metastable states, as can be verified in the above table.

The following tables show a typical set of results susceptible of similar interpretation. The temperature of the tube was kept approximately constant during the observation. The time of exposure for the spectrum and for the standard light was the same for each plate. Diaphragms were placed in front of the condensing lens to reduce the very different intensities photographed to approximately the same level of blackness on the plate.

³ All ratios given in this article refer to the intensities divided by the fourth powers of the frequencies.

TABLE II. I/ν^4 ratios for constant tube temperature but varying plate current.
(Observation of light emitted between grid and plate)

Plate current	5461:4047	4358:4047
1.0 amp.	3.2	
1.0	3.6	4.9
0.27	5.9	4.4
0.27	5.0	4.3
0.0075	8.1	4.0
0.0065	7.9	3.9
0.0055	8.3	3.9
0.004	9.0	3.7

The explanation of these results is obvious. A higher plate current increases the rate at which atoms are thrown into metastable states, and higher absorption of line 4047, and especially of line 5461, results therefrom.

From the foregoing it appears that the Hg density affects the results in a two-fold manner. A direct effect of higher density would be a more rapid elimination of the metastable states, thus reducing the effect of absorption in the intensity ratios. This first effect would be masked, however, by the more complicated and more intense phenomena accompanying high pressures.

Determination of the true intensity ratios of the triplet. The facts mentioned above were not apparent at the time these experiments were carried out, for it was expected that the ratio 5:3:1 would be found for the relative intensities of the triplet divided by the fourth powers of the frequencies, and ratios higher than 5 for lines 5461 and 4047 could not be explained by an absorption of line 5461. At the same time it was obvious that the absorption of line 4047 was much less than the absorption of line 5461, for the population of the $2p_1$ state is much larger than the population of the $2p_3$ state, and this theoretical prediction was confirmed by the comparatively smaller variations of the ratio of 4358:4047. Also, the glass of the three-electrode tube used was not very clear, and had a larger transmission for the 5461 line than for the other lines of the triplet.

A tube was then built, with means for controlling the Hg pressure, and with a quartz window for the eventual study of the ultraviolet lines.

This tube is shown in Fig. 2. Electronic emission was provided by a tungsten filament. The leads into the tube were tungsten rods, while the other metallic portions were of nickel. A plate, *P*, with a rectangular hole cut to correspond to the opening, *A*, of the cage was inserted as shown in the figure, to prevent the white light of the filament from reaching the slit of the spectrograph. A number of spectra were taken with the end, *B*, of the cage open, so that a considerable amount of light due to the blue glow filling the tube contributed to the radiations photographed. Any amount of shielding in the far end of the tube failed to eliminate this glow. As it was thought that this glow was due to a somewhat different mode of excitation from that which produced the light in the cage by electrons of a definite velocity, the far end of the cage was subsequently closed, as shown in the figure. This was done by means of a little strip of platinum, blackened in the flame of a match. A

small strip of nickel, *C*, was welded over the far end of the grid to prevent a direct illumination of this end wall by the filament. At the time this change was effected, the nickel grid of rather coarse mesh, hitherto used, was replaced by a nickel grid of the finest mesh obtainable. This was done for the purpose of obtaining a more uniform flow of electrons in the cage, and surprisingly enough this new grid stood higher currents than the coarse one formerly used, without showing any trace of deterioration. In spite of the electrical screening provided by the shield, *S*, and the front plate, *P*, the space, *F*, in the front end of the tube was filled with a weak glow, the part of this glow in the prolongation of the cage contributing, therefore, to the light photographed.

The Hg pressure in the tube was indirectly controlled by placing the Hg trap in a beaker of water of a certain temperature.

Fig. 2. Diagram of apparatus.

A thorough baking out of the tube was found necessary to avoid nitrogen and carbon monoxide bands. This was done by wrapping asbestos around the tube and letting a plate current of 0.8 to 1 amp. flow under a potential of about 200 volts for a few hours. Even though the CO bands were observable at the end of this period, they would quickly disappear after the asbestos had been removed and the tube brought to its normal running temperature.

A few refinements were introduced in the method of intensity measurements. They are outlined below.

A little strip of gray glass was placed in the camera on the path of line 4358, in order to bring this line to the same blackness level as lines 4047 and 5461. As this line and the standard radiation for its measurement were both modified in the same manner, no change was called for in the method of measurement. While more accurate, the results thus obtained for the 4358:4047 ratios agreed well with a number of results obtained before this precaution was taken. About 40 exposures were taken on each plate, a little less than half this number being assigned to the intensity marks. Two was chosen for the ratio of the geometric progression of intensities, and two or three exposures were taken for each intensity, the slit width and the number of holes used in the diaphragm being both varied so as to check the method used, and to reduce chance errors due to setting and variations in the emulsion. (The different measurements of blackness for marks of the same theoretical intensity proved to be closely grouped in the great majority of cases.) Also, each condition of plate current and plate voltage studied was photographed two

or three times, as the light intensity permitted, using the diaphragm with maximum openings, and others of one-half and one-quarter the area of the first. As a last precaution, all plates were wiped continuously while in the developer, to insure uniformity of development.

Two current values, 0.3 and 0.6 amp. were used under various voltages to bring out any systematic dependence of the intensity ratios observed upon the plate current, as well as to bring out any voltage dependence for any one fixed current, especially with reference to the 4078:4047 ratio.

The narrow range of Hg temperature explored (limited for the high temperature by the coolest point of the tube to avoid condensation in this point, and for the low temperature by the light intensity fit for convenient exposures) was considered wide enough to detect any dependency upon pressure on account of the comparatively large range of pressures corresponding to these temperatures.

No dependence upon plate current, plate voltage and Hg pressure was found for the relative intensities of the triplet, while the ratio of 4078:4047 showed a marked dependency upon plate voltage.

The averages obtained for the triplet are given in Table III.

TABLE III. I/ν^4 values for triplet lines obtained with tube shown in Fig. 2.

Plate No.	Temp. of Hg	4358:4047	5461:4047
14	100°C	3.3	8.3
22	0	3.0	8.5
23	22	3.3	8.5
"	60	3.4	
25	20	3.2	7.8
29	20	3.2	8.8
"	40	3.3	7.9
30	40	3.4	7.9
31	22		9.2
34	23		8.8
35	41.5	3.3	8.6
36	25		9.5
37	24		8.5
Average		3.3	8.5

The experimental error attached to the average given for the ratio of 5461:4047 is probably larger than for the other one, but should not exceed 10 percent, assuming, however, that the temperature of the lamp used as standard is correct.

RATIO OF 4078:4047 AND GENERAL STUDY OF THE ELECTRONIC BOMBARDMENT EMISSION

As mentioned above, the ratio of 4078:4047 varies with plate voltage. This is shown in Fig. 3, where this ratio has been plotted as a function of the plate voltage from the data obtained from five plates. These curves point to a rapid rise to a maximum, reached at about 100 volts, and then a slow downward trend.

The existence of a variation in relative intensity of two lines makes it necessary to assume the operation of at least two different mechanisms—if there were only one, the absolute intensity might vary, but not the relative. Each of these mechanisms will presumably be operative in producing both lines, but with a different ratio of intensities. The ratio measured will be some weighted average of the ratios which are characteristic of each of these mechanisms.

This variation with voltage is strikingly similar to the variation of the efficiency of ionization as found by a number of authors. For the purpose of comparison, the probability of ionization of mercury atoms by electrons has been plotted as the dotted curve. It was obtained from Bleakney's⁴ data by adding the ordinates of his curves for the probability of single, double, and triple ionization. It also represents the variation in the intensity of the light due to atoms which have been ionized and recombined with electrons if it be

Fig. 3. Ratio 4078:4047 plotted as a function of the plate voltage from data obtained from five plates.

assumed that doubly and triply ionized atoms recapture successively, two and three free electrons respectively from the negative space charge inside the cage.

The parallelism of this curve with the ratio of 4078:4047 seems to suggest the following explanation. Atoms which have been previously ionized will emit a recombination spectrum with a comparatively larger ratio of 4078:4047 than excited atoms, while the observed ratio will vary somewhat parallel to the amount of light emitted which is due to recombined atoms, if the number of excited atoms is assumed to have no variations, as marked as the one shown by Fig. 3, beyond the ionization potential. This explanation would be supported by the fact that many ionized Hg lines were quite conspicuous at the higher voltages used (40 volts and above), while the presence in the cage of slow secondary electrons made conditions favorable for the recombination of Hg ions.

If the large differences found between the intensity distributions in an

⁴ Bleakney, *Phys. Rev.* **33**, 139 (1930).

ordinary arc and in an electronic bombardment spectrum were attributed to the presence in the latter of a recombination spectrum certain consequence would follow which are brought out by Table IV. This table has been prepared from a table giving the intensities of the lines in an electronic bombardment spectrum at 70 volts using the intensities of the lines of an arc spectrum as units. All the values obtained for lines originating at a certain level have been averaged, and these averages have been given in Table IV. This table therefore gives an estimate of the population of the various levels in an electronic bombardment spectrum in comparison with an arc spectrum. According to what has been said above Table IV would indicate that by comparison

TABLE IV. *Relative population of levels—electronic bombardment—spectrum vs. arc spectrum.*

Level	Relative Population	Level	Relative Population
2S	1.5	2s	0.15
3S	3.	3s	0.15
4S	11.	4s	0.8
5S	4.	5s	0.4
		6s	0.15
4P	55.		
5P	25.	4p ₁	0.6
6P	2.	5p ₁	1.4
7P	1.5	6p ₁	0.6
3D	0.4	3d ₁	0.14
4D	2.2	4d ₁	0.15
5D	1.7		
6D	0.4	3d ₂	0.16
7D	0.2	4d ₂	0.3
8D		5d ₂	0.8
		3d ₃	0.2
		4d ₃	0.1

with excited atoms, recombined atoms will occupy a much larger proportion of singlet terms, while within each system of terms the *P*-state (or the *p*-state), and within each state a level at about the height of the 4S level would be most favored in this new population distribution.

This explanation for the variation of the ratio of 4078:4047, and the consequences of this explanation, are given with much reserve, however, as it has been the conclusion reached by F. L. Mohler⁵ and other authors that in a recombination spectrum the triplet terms are comparatively more populated than in an excitation spectrum.

The writer wishes to express his appreciation to Professors Monk and Eckart for the suggestion of the problem and assistance throughout the duration of the work.

THE SPECIFIC HEAT OF METHANE

By P. C. LUDOLPH

DEPARTMENT OF PHYSICS, UNIVERSITY OF ILLINOIS

(Received February 16, 1931)

ABSTRACT

Two different forms have been suggested for the methane molecule by various authors. They are the symmetrical tetrahedron and the symmetrical pyramid. Calculations have been made for the values of the specific heat at constant volume for the two types of structure. It is found that neither type gives values in agreement with experiment. The curve obtained on the basis of a tetrahedral structure however gives much better agreement than the resulting curve for the pyramidal structure.

THE infrared absorption spectra of methane was investigated quite carefully by J. P. Cooley¹ several years ago. Dennison,² on the basis of Cooley's results and with certain other fundamental assumptions, was able to ascribe a symmetrical tetrahedral structure to the molecule.

J. Kunz³ called attention to the fact that there was quite a difference between the specific heat of methane as calculated from this model and the experimental values.

V. Guillemin⁴ has shown, however, that on the basis of certain definite assumptions as to the forces between the ions in the molecule, the potential energy for the symmetrical pyramidal configuration is smaller than the value obtained for the tetrahedral structure. Hence the pyramidal structure is more stable than the tetrahedral.

Numerous facts have been advanced by Glockler,⁵ Henri,⁶ and others supporting one or the other of the two alternative forms.

Each model yields fifteen degrees of freedom, three of translation, three of rotation, and nine of vibration. Moreover, each model gives four fundamental vibrational frequencies. Hence, giving to the translations and rotations their equipartition values, we obtain for the specific heat at constant volume

$$c_v = R \left(3 + \sum_{i=1}^4 n_i \left(\frac{h\nu_i}{kT} \right)^2 \frac{e^{h\nu_i/kT}}{(e^{h\nu_i/kT} - 1)^2} \right)$$

where the n_i gives the number of degrees of freedom of the corresponding vibration frequency ν_i .

The values of ν_i and n_i are given below in Table I.

TABLE I. Values of ν_i and n_i .

ν_i	n_i	ν_i cm ⁻¹ Tetrahedral	ν_i cm ⁻¹ Pyramidal
ν_1	1	4217	7760
ν_2	2	1520	3150
ν_3	3	3014	6730
ν_4	3	1304	1990

² D. M. Dennison, *Astrophys. Journal* **62**, 84 (1925).

³ J. Kunz, *Phys. Rev.* **29**, 220 (1927).

⁴ V. Guillemin, *Ann. d. Physik* **386**, 81, 173 (1926).

⁵ G. Glockler, *Jour. Amer. Chem. Soc.* **48**, 2021 (1926).

⁶ V. Henri, *Chem. Reviews* **4**, 189 (1927).

Values of c_v have been calculated for temperatures ranging from 273°K to 873°K. The results together with the experimental⁷ values are given below in Table II.

TABLE II. *Specific heats, experimental and calculated.*

Temp.	c_v Experimental	c_v Tetrahedral	c_v Pyramidal
273°K	6.656	6.311	5.982
373	8.738	7.188	
473	10.577	8.342	
573	12.419	9.620	7.081
673	14.288	10.855	
773	16.015	12.039	
873	17.883	13.151	9.011

The curves, Fig. 1, show the variation of c_v with temperature. The one marked *A* corresponds to the experimental values while *B* and *C* give the relation for the tetrahedral and pyramidal structures respectively. *A* and *B* are essentially linear while *C* is decidedly convex to the axis. The calculated values of c_v for the tetrahedral model agree much better with the experimental values than the values calculated from the pyramidal model.

Fig. 1. Variation of c_v with temperature.

If the degrees of freedom of the vibrators with frequencies ν_3 and ν_1 are interchanged, then one obtains the curve *D* in place of *B*. These values of c_v are the maximum possible values using the frequencies given in Table I.

Undoubtedly some of the discrepancy (especially at the higher temperatures) is due to the centrifugal stretching of the molecule. This effect is not sufficient, however, to account for all the difference between the experimental and the calculated values.

It is a pleasure to thank Professor Kunz for his suggestions in regard to this work.

THE EQUATION OF STATE OF HELIUM*

BY JOHN G. KIRKWOOD AND FREDERICK G. KEYES
RESEARCH LABORATORY OF PHYSICAL CHEMISTRY,
MASSACHUSETTS INSTITUTE OF TECHNOLOGY

(Received February 24, 1931)

ABSTRACT

A brief review of the statistical theory of the equation of state is presented. Upon the basis of a recent quantum mechanical calculation of the interatomic energy, the second virial coefficient of helium has been calculated. With the use of the theoretically determined virial coefficient some properties of helium have been computed. A detailed comparison with experimental data is given.

INTRODUCTION

THE past several years have seen a great advance in our understanding of intermolecular forces. The work of Heitler and London on the resonance interaction of two hydrogen atoms suggested the nature of the repulsive force operating at small intermolecular distances to determine the effective molecular cross-section. More recently the work of Eisenschitz and London followed by that of other investigators has permitted a calculation of the polarization force, operating at larger intermolecular distances to produce the van der Waals' attraction. However the theory has so far been subjected to no critical comparison with experiment. It is the object of the present paper to make such a comparison in the case of helium, the only gas for which a fairly accurate calculation of the intermolecular energy has been carried out.

THEORY OF THE EQUATION OF STATE

Many empirical equations of state have been suggested for gases. All of them, however, may be expanded in the familiar virial form

$$\frac{pV}{RT} = 1 + \frac{B}{V} + \frac{C}{V^2} + \dots \quad (1)$$

where p is the pressure, V the volume of a gram-mol of gas, R the ideal gas constant, and T the absolute temperature. The coefficients, B , C , \dots are in general functions of the temperature.

Although a complete statistical theory of the equation of state has not been worked out in detail, it is possible under certain conditions to obtain a correlation between the second virial coefficient, B , and the intermolecular forces.

Above the critical temperature, it seems legitimate to assume that the fraction of the molecules in quantized collision states will be insignificant. Moreover, the Boltzmann distribution function may probably be regarded as

* Contribution No. 262.

valid for all gases until temperatures in the neighborhood of absolute zero are reached. Thus even in the case of hydrogen at a pressure of one atmosphere and a temperature of 2°K, both the Fermi-Dirac and the Bose-Einstein distribution functions give the same result as that of Boltzmann within a few percent insofar as the translational energy is concerned.¹ Subject to these limitations, it is possible to identify the sum of state with Gibbs' phase integral²

$$z = \int \cdots \int e^{-\bar{E}/kT} dq_1, \cdots dp_{3N} \quad (2)$$

where \bar{E} is the total energy of a gas consisting of N molecules averaged over all internal coordinates and k is Boltzmann's constant. The integration is to be taken over all of the $6N$ dimensional momentum-configuration space available to the system. If the thermodynamic potential, ψ , (Helmholtz free energy function) is defined by the relation

$$\psi = E - TS$$

where S is the entropy, Gibbs has shown that

$$\psi = -kT \ln z \quad (3)$$

Moreover,

$$\left(\frac{\partial \psi}{\partial V} \right)_T = -p. \quad (4)$$

The integral (2) may be evaluated in simple form under certain conditions.³ It is to be assumed that the density of the gas is low enough so that molecular configurations in which the fields of more than two molecules overlap, are sufficiently rare that they may be ignored. In the case of neutral gas molecules where the molecular forces are effective only at very short range, this condition is often fulfilled even at relatively high densities. Under these circumstances it is possible to write

$$z = f(T) \prod_{n=1}^N (V - 2nB) \quad (5)$$

where

$$B = \frac{1}{2} \int \int \int (1 - e^{-\bar{\epsilon}/kT}) dx dy dz.$$

Here $\bar{\epsilon}$ is the mutual potential energy of two molecules and the integration is to be taken over all values of their relative coordinates. From Eqs. (3), (4), and (5), after expansion of the logarithm in powers of B/V , it is found that

$$\frac{pV}{RT} = 1 + \frac{B}{V} + \frac{4B^2}{3V^2} + \cdots$$

³ F. G. Keyes, *Chem. Rev.* **4**, 175 (1929). K. F. Herzfeld, *Müller-Pouillet's Lehrbuch der Physik*, Vol. 3, *Kinetische Theorie der Wärme*, p. 167.

where the second term may be identified with that of the virial Eq. (1). If, as in the case of helium the molecules are spherically symmetrical

$$B = 2\pi N \int_0^\infty (1 - e^{-\epsilon(r)/kT}) r^2 dr \quad (6)$$

where r is the distance between the two molecules.

Perhaps the most well known of empirical equations of state is that of van der Waals:

$$p = \frac{RT}{V - b} - \frac{A}{V^2}$$

It is of interest to see what form the intramolecular potential, ϵ , must assume to be consistent with it. The virial Eq. (1) may be transformed into van der Waals' equation if B/V is assumed to be very small relative to unity and

$$B = b - A/RT.$$

If the molecules are treated as rigid spheres of diameter, σ , it is obvious that when $r \leq \sigma$, $\epsilon = \infty$, and formula (6) yields, after expansion of $e^{-\epsilon/kT}$;

$$B = b - A/RT$$

where

$$b = \frac{2\pi N \sigma^3}{3} = 4 \text{ (total volume of the molecules)}$$

and

$$A = A_0 + \sum_{n=1}^{\infty} A_n / (RT)^n; A_0 = -2\pi N^2 \int_{\sigma}^{\infty} \epsilon r^2 dr$$

$$A_n = -2\pi N^{n+2} \int_{\sigma}^{\infty} \epsilon^{n+1} r^2 dr.$$

It must be concluded, therefore, that the coefficient A appearing in van der Waals' equation is not a constant, but a slowly varying function of the temperature. This conclusion is born out by experiment in the region of low temperatures where the sum $\sum_{n=1}^{\infty} A_n / (RT)^n$ may no longer be neglected.

Moreover, experiment at high temperatures, invalidates the assumption of rigid molecules. Thus, it is found that b is a slowly decreasing function of the temperature, a fact which can only be explained as due to an interpenetration of the molecules. Van der Waals' equation is therefore to be regarded as merely a first approximation even at small densities.⁴

THE MOLECULAR FIELD

Empirical information furnished by the equation of state suggests that the general character of the force between two molecules may be conveniently represented by means of two potentials, ϵ_r and ϵ_a . The potential ϵ_r , which predominates at small molecular separations, must ascend steeply with in-

⁴ F. G. Keyes and R. S. Taylor, J. Am. Chem. Soc. 49, 896 (1927).

creasing slope as two molecules approach and diminish rapidly as they recede, thus giving rise to a strong repulsive force at small intermolecular distances. The potential, ϵ_a , nullified at small separations by ϵ_r , must fall off less rapidly with the distance, giving rise to an attractive force at larger intermolecular separations. Thus the total intermolecular potential, ϵ , might be written

$$\epsilon = \epsilon_r + \epsilon_a.$$

This representation is to be regarded as more or less schematic, since no sharply defined physical significance can be independently assigned to ϵ_r or ϵ_a . Still, it has the advantage of suggesting two different types of molecular interaction which we believe to be effective in determining the intermolecular energy.

According to present quantum mechanical ideas, the "repulsive" potential, ϵ_r , is to be regarded as arising from a resonance interaction between the molecules. A calculation of the resonance energy has so far been accomplished only for atomic hydrogen⁵ and helium.⁶ In the case of atomic hydrogen, the situation is complicated by the existence of two alternative modes of interaction, one of them giving rise to the repulsion of which we have spoken, and the other to valence union. Helium is, therefore, the only simple gas for which we have a knowledge of the repulsive field. Although a somewhat complicated function of the interatomic distance, the resonance energy in the range of importance in the thermal interaction of gas molecules may be adequately represented by the formula

$$\epsilon_r = \lambda e^{-cr}.$$

The "attractive" potential is to be regarded as arising from a mutual polarization of the molecules,⁷ chiefly due to a rapidly pulsating field associated with the internal motion of the electrons in the molecule. The dominant term in this energy comes from the oscillating dipole. If terms from multipoles of higher order are ignored, the attractive potential has the form

$$\epsilon_a = -\frac{\beta}{r^6}.$$

A general scheme for the calculation of ϵ_a has been developed by London and Eisenschitz.⁸ They have made an exact calculation of the mutual energy of two hydrogen atoms as well as rough estimates in the case of some other gases.

⁵ Heitler and London, *Zeits. f. Physik* **44**, 455 (1927); Sugiura, *Zeits. f. Physik* **45**, 484 (1927).

⁶ Slater, *Phys. Rev.* **32**, 349 (1928).

⁷ In 1920 Debye (*Phys. Zeits.* **21**, 178, 1920) suggested that the van der Waals attraction in gases had its origin in a mutual electrical polarization. Upon the basis of an electrostatic molecular model, he attempted to calculate the van der Waals A constant for several gases in terms of their electrostatic multipole moments. That his theory was not very successful from a quantitative standpoint, is readily understandable in view of the inadequacy of the molecular model employed.

⁸ Eisenschitz and London, *Zeits. f. Physik* **60**, 491 (1930); London, *Zeits. f. Physik* **63**, 245 (1930).

⁹ Slater and Kirkwood, *Phys. Rev.* **37**, 682 (1931).

A calculation of the mutual energy of two helium atoms by another method has been carried out by Slater and Kirkwood.⁹ They obtain for the total intermolecular potential of helium:

$$\epsilon = \left\{ 7.7e^{-2.43r/a_0} - \frac{0.68}{(r/a_0)^6} \right\} 10^{-10} \text{ ergs} \quad (7)$$

where a_0 is the Bohr radius of the hydrogen atom. In this expression, terms arising from variable multipole moments of higher order than the dipole have been neglected. Moreover, an error of a few percent in the coefficient of the exponential term is not unlikely since an approximate wave function was employed in its calculation.

THE EQUATION OF STATE OF HELIUM

With the expression for the intermolecular potential given by Eq. (7), we have computed the second virial coefficient of helium at several temperatures, by graphical integration of Eq. (6). The results are listed in Table I together

TABLE I. *Second virial coefficient of helium.*

T (°K)	B (theory) cc/mol	B (H and O) cc/mol
350	10.80	11.60
300	11.14	11.80
250	11.34	11.95
200	11.58	11.95
100	10.75	10.95
20	-6.94	-4.00

with experimental values of Holborn and Otto.¹⁰ The theoretical values of the virial coefficient B have been plotted as a function of the reciprocal temperature in Fig. 1, and as a function of the temperature in Fig. 2. For comparison, the experimental results of a number of investigators have been included.^{11,12} From Table I it may be seen that the computed values of the virial coefficient, while consistently lower than the experimental ones of Holborn and Otto, do not differ from them by more than five or six percent between 100°K and 400°K. Below 50°K, the agreement between the two is not quite as close. This fact may probably be attributed as much to error in the experimental measurements as to error in the theoretical values of the virial coefficient. However, a real discrepancy at low temperatures might be expected if the proportion of molecules in quantized collision states became appreciable, for in that event, Gibbs' phase integral would cease to be an adequate representation of the sum of state and Eq. (6) would lose its validity. At present it is impossible to decide whether or not this effect is of im-

Fig. 1. The second virial coefficient of helium plotted as a function of the reciprocal temperature.

Fig. 2. The second virial coefficient of helium plotted as a function of the temperature.

portance because of inconsistency in the experimental values themselves in the low temperature region.

On the whole the agreement between the theoretical and experimental values of the virial coefficient is extraordinarily good. The slight discrepancy between them is not surprising in view of the approximations which were made in the calculation of the intermolecular energy, Eq. (7).

An examination of Fig. 1 shows that both the theoretical and experimental curves pass through a maximum at about 173°K. This phenomenon has been observed only in the case of helium, but presumably it should occur at sufficiently high temperatures for all gases. Thus, for hydrogen, neon, nitrogen and a number of other gases, the curve obtained by plotting B against $1/T$ shows a decided concave bending in the region of high temperatures. The limitations of van der Waals' equation are clearly brought out in Fig. 1. Below 100°K, it would be possible to apply van der Waals' equation to helium, since in a narrow temperature range the relation between B and $1/T$ may be approximated by a linear function. However, above 150°K, the van der Waals form of equation is entirely inadequate. Not only does the coefficient, A , cease to be constant, but it becomes very sensitive to temperature variation.

SOME PROPERTIES OF HELIUM

In order to obtain a more detailed comparison with experiment, some properties of helium have been computed with the aid of the theoretically determined virial coefficients. By means of Eq. (1) the pressure has been calculated at several temperatures and volumes. The computed and experimental pressures are given in Table II.

TABLE II. Helium pressures calculated from the first three terms of the theoretical virial.
Expansion: $p = (RT/V)(1 + B/V + 4B^2/3V^2)$

V (liters/mol)	p (calc.)	p (obs.)	Δ
$t = 200^\circ\text{C}$			
2.000	19.51 atm.	19.52 atm.	-0.01 atm.
0.400	99.60	99.82	-0.22
$t = 100^\circ\text{C}$

2.000	11.27	11.27	0.00
0.250	93.97	94.12	-0.15
$t = -100^\circ\text{C}$			
2.000	7.15	7.15	0.00
0.200	75.45	75.66	-0.21

The Joule-Thomson coefficient, μ , may be expressed in terms of the virial coefficient B , and the heat capacity C_p in the following manner:

$$\mu = -\frac{1}{C_p} \left[B + \frac{1}{T} \frac{dB}{d\left(\frac{1}{T}\right)} \right] = + \left(\frac{\partial T}{\partial p} \right)_H \quad (8)$$

At 25°C, μ is calculated to be $-0.061^\circ \text{ atm.}^{-1}$. Moreover, between $+100^\circ$ and -100°C , the value of $dB/d(1/T)$ is extremely small and therefore the temperature coefficient of μ is very small. Roebuck¹³ has recently obtained the value $-0.06^\circ \text{ atm.}^{-1}$ from measurements of the Joule-Thomson effect between $+100^\circ \text{C}$ and -100°C . The temperature variation in μ lay within his experimental error. A rough calculation of the Joule-Thomson inversion point leads to the temperature, 54°K . Although there is no reliable experimental determination with which to compare it the temperature 54°K is in accord with the fact that helium cannot be liquefied at the lowest temperature attainable by evaporating liquid nitrogen, about 70°K .

The thermodynamic temperature scale may be identified with the scale of the ideal gas thermometer. In order to reduce the scale of an actual gas thermometer to the thermodynamic temperature scale, corrections which are functions of the virial coefficients of the gas must be applied. We have used the theoretically determined values of B in conjunction with recent measurements of the coefficient of expansion and the coefficient of pressure of helium¹⁴ to determine the position of the freezing point of water under a pressure of one atmosphere on the absolute temperature scale. The coefficient of pressure of a gas at constant volume is defined as,

$$\alpha_p = \frac{p_{100} - p_0}{100p_0}$$

where p_0 is the pressure at 0°C and p_{100} the pressure at 100°C . It is easily shown that

$$T_0 = 1/\alpha_0$$

where T_0 represents the position of 0°C on the absolute temperature scale and α_0 is the coefficient of pressure of an ideal gas, for which $pV = RT$. Moreover, it is possible to calculate α_0 in terms of the α_p of an actual gas if its second virial coefficient is known.

$$\alpha_0 = \alpha_p + p_0(6.098B_0 - 4.464B_{100}) \cdot 10^{-7}$$

where p_0 is again the pressure at 0°C , B_{100} the virial coefficient at 100°C expressed in cc/mol , and B_0 its value at 0°C . α_0 may also be obtained from the coefficient of expansion in a similar manner. From the measurements of Heuse and Otto on helium, we compute for the average value of α_0 .

$$0.0036609 \text{ atm./}^\circ$$

which corresponds to

$$T_0 = 273.16.$$

By linear extrapolation Heuse and Otto find that

$$T_0 = 273.16.$$

The International helium thermometer is defined as a constant volume gas thermometer in which the pressure of helium at 0°C is equal to that of a

¹³ J. R. Roebuck and H. Osterberg, *Phys. Rev.* **37**, 110 (A) (1931).

¹⁴ W. Heuse and J. Otto, *Ann. d. Physik* [5] **2**, 1012 (1929).

one meter column of mercury at 0°C and standard gravity. The gas temperature is defined as

$$t_g = \frac{p_{t_g} - p_0}{p_{100} - p_0}.$$

The corresponding temperature on the absolute scale is of course

$$t = T - T_0.$$

The correction Δt which must be added to the gas temperature t_g to bring it into agreement with the absolute temperature scale may be computed from the second virial coefficient by means of the formula

$$\Delta t = 5.870 \{ 3.731 t_g (B_{100} - B_0) - (373.1 + t_g)(B_{t_g} - B_0) \} \cdot 10^{-5}$$

where the virial coefficients B_{100} , B_0 , and B_{t_g} are expressed in cc/mol. The corrections have been calculated for several temperatures. They are listed with those given by the Reichsanstalt in Table III.

L. Holborn and J. Otto, *Zeits. f. Physik* **38**, 359 (1926); **30**, 1 (1925).

Baxter and Starkweather¹⁵ have measured the density of helium. Their value at 0°C and a pressure of one international atmosphere (pressure of a column of mercury 76 cm in height at 0°C and at standard gravity; $g = 980.665$ dynes sec⁻²) is

$$0.17847 \text{ g/liter.}$$

Using this density together with our value of B at 0°C and taking the gas constant, R , as 0.08206 liter atm. the mean for a large number of gases, we calculate the atomic weight of helium as 4.0022. This is to be compared with the atomic weight 4.0020 obtained by Baxter and Starkweather from the density given above and their own compressibility measurements at low pressures.

In all of the cases which have been considered, the theoretically determined virial coefficient gives results which are in substantial agreement with experiment. When it is remembered that the calculation of the virial coefficient is based upon purely *a priori* considerations and depends upon experiment only through the values of certain universal atomic constants, it seems to furnish a striking confirmation of the present theory of intermolecular forces.

LETTERS TO THE EDITOR

Prompt publication of brief reports of important discoveries in physics may be secured by addressing them to this department. Closing dates for this department are, for the first issue of the month, the twenty-eighth of the preceding month; for the second issue, the thirteenth of the month. The Board of Editors does not hold itself responsible for the opinions expressed by the correspondents.

Mass Defects of C^{13} , O^{18} , N^{15} , from Band Spectra, and the Relativity Relation of Mass and Energy

Chadwick, Constable and Pollard,¹ in a recent article, give on page 482 a plot of the "mass defect" of a number of atomic species, as a function of the number of α -particles in the nucleus. It is of considerable interest to add to this plot certain atomic species recently discovered by means of band spectra. In the case of C^{13} , O^{18} and N^{15} , the mass of the new isotope, relative to the mass of the more abundant species, has been calculated from the band spectra data. Thus King and Birge² find that the mass of C^{13} relative to C^{12} is 13:12 exact, to about one part in 10,000. The mass defect plot just mentioned is based on the atomic masses obtained by Aston.³ Accepting his results, one obtains 10.7×10^{-3} as the mass defect of C^{13} . (Henceforth all mass defects will be given in 10^{-3} mass units). This result is given (as 11×10^{-3}) in a footnote, page 481 by C.C.P.

For O^{18} Babcock and Birge⁴ have obtained a mass of 18.0065, based on $O^{16}=16$ exactly, which is also Aston's basis. The probable error is only about one part in 10^5 . The resulting mass defect of O^{18} is 17.7.

Herzberg⁵ has obtained the mass ratio N^{15}/N^{14} , from his measured isotope shift for the heads of the 1-0 and 2-0 bands of the second positive group of nitrogen, the molecules concerned being $N^{15} \cdot N^{14}$ and $N^{14} \cdot N^{14}$. The

measured shifts are appreciably less than his calculated values, but unfortunately he made a theoretical error in his calculations which definitely affects his conclusion. All isotope shifts are expressed as a function of $(\rho^n - 1)$ where n is some positive integer. $\rho = (\mu_1/\mu_2)^{1/2}$ and μ , is the reduced mass of the more abundant molecule. Thus for the band systems containing O^{18} , C^{13} and N^{15} , the value of ρ is less than unity, and the vibrational shift is to the red, for bands located on the violet side of the origin of the system.

Herzberg, however, calculated ρ as $(\mu_2/\mu_1)^{1/2}$ and so obtained a value greater than unity. This leads not only to a shift in the direction opposite to that observed, but also to an incorrect absolute magnitude. In order to obtain the calculated shift Herzberg made new measurements of certain band heads of this system. He thus derived a new vibrational energy function $f(v')$ for the upper state, and combined this with the writer's $f(v'')$ of the lower state, to get an energy equation of the system. Birge and Sponer⁶ had already given a $f(v')$ for this system, based on all available data, reduced where necessary to the I. A. system. The two $f(v')$ appear somewhat different, but fortunately lead to practically the same calculated vibrational shifts for the 1-0 and 2-0 bands. The correct value of ρ , assuming even 14 and 15 masses, is 0.98319, and the vibrational shifts are, from the Birge and Sponer equation, -35.16 and -65.79 cm^{-1} , and from Herzberg's equation, -35.19 and -65.72 cm^{-1} . It seems best to adopt the average values -35.17 and -65.76 cm^{-1} .

Since a fine structure analysis of these two bands has not been carried out, one must use for the rotational isotope shift the sufficiently

⁴ H. D. Babcock and R. T. Birge, (abstract) Phys. Rev. 37, 233 (1931).

⁵ G. Herzberg, Zeits. f. phys. Chemie B9, 43 (1930).

⁶ R. T. Birge and H. Sponer, Phys. Rev. 28, 259 (1926).

accurate approximation $(\rho^2 - 1)\nu_m$, where ν_m is the distance from the origin to the head, for the *middle* component of the triplet series found in these bands. Fortunately the desired origin can be located, by mere inspection, on spectrograms of an "effective low temperature" source. The resulting rotational shifts, as given by Herzberg, are $+0.6 \text{ cm}^{-1}$ and $+0.8 \text{ cm}^{-1}$ respectively, corresponding to *origin-head* distances of 18 and 24 cm^{-1} . (This distance in the 0-0 band is 13.3 cm^{-1} , according to the writer's fine structure analysis.)

Now the $f(v')$ to which reference has been made are based on measurements of the heads, and are slightly in error, due to the varying distance of origin to head. The resulting correction to the vibrational shift I find to be -0.08 and -0.18 cm^{-1} , for the 1-0 and 2-0 bands, respectively. The final calculated shifts for the *heads* are then -34.65 and -65.14 cm^{-1} , as compared with Herzberg's *observed* shifts -34.6 and -64.6 cm^{-1} . One thus obtains the result that the mass ratio N^{16}/N^{14} is *less* than $15/14$ by one part in 10,000, and one part in 1700, from the 1-0 and 2-0 bands, respectively. Then, using Aston's value $N^{14} = 14.008$, one obtains $N^{16} = 15.0065$ and 14.999 respectively. From these figures there results a mass defect for N^{16} of 23.3 and 30.6, or an average value of 27.0

We may now place these mass defects on the plot previously mentioned. The C^{13} defect (10.7) lies just above the value obtained from α -ray disintegration experiments (given as 9.9 by C.C.P. but calculated as 9.8 by the writer). This mass defect, 9.8, is obtained from Aston's mass defect 6.38 for B^{10} combined with an energy loss equivalent to 3.42 (in 10^{-3} mass units), as observed by C.C.P. in

the transformation $B^{10} \rightarrow C^{13}$. The close agreement of the two mass defect values for C^{13} (10.7 and 9.8) is of more than passing interest, for it constitutes a *very* rough, but direct experimental check of the accepted relation between mass and energy $\Delta E = c^2 \Delta m$. So far as I am aware, it is the first experimental check by this very direct method.

The mass defect for O^{18} (17.7) may be compared with that for O^{17} (12.6), as evaluated by C.C.P. from their disintegration experiments,⁷ for O^{16} (8.64). The fact that these three points (corresponding to masses of 18.0065, 17.0029 and 16.0000) are nearly equally spaced is probably significant. The spectral data for O^{17} are very meager, as compared to O^{18} , but the mass of O^{17} is now being calculated from such data and the result, if of sufficient accuracy, will constitute a second check on the mass-energy relation.

Finally, the mass defect of N^{16} should lie on the curve passing through B^{11} , F^{19} etc. The predicted value, from the published curve, is 24.5, agreeing well within limits of error with the average observed value of 27.0. Other interesting relations may be deduced from the mass defect graphs published by C.C.P. but it is the primary purpose of this letter merely to locate on these graphs the new data for C^{13} , O^{18} and N^{16} .

University of California,
March 4, 1931.

⁷ The first calculation of the mass of O^{17} by such a process, with the result 17.0033 ± 0.0009 , was made by W. F. Giaque, *Nature* 124, 265 (1929).

Momentum Transfer to Cathode Surfaces by Impacting Positive Ions in a Helium Arc

The present problem was suggested by K. T. Compton and may best be introduced by the following quotation from one of his papers (*Phys. Rev.* 36, 706, 1930). "Although, as we have seen, the impact of a charged ion against the cathode contributes nothing to the pressure against it (on account of the counterbalancing pull during its attraction to the cathode), nevertheless if the neutralized ion leaves the cathode with any momentum there is imparted to the cathode an equal opposite momentum." In the experiment here reported this hypothesis is tested by studying the mo-

mentum imparted to an auxiliary cathode in a helium arc.

The auxiliary cathode (or plane collector) was suspended from a vertical side tube in the negative glow of a hot cathode helium arc. The collector was a flat molybdenum plate one centimeter in diameter, insulated on one side by a glass plate. This collector was non-volatilizing so that there was no possibility of a pressure as a result of a stream of metal vapor leaving the collector. The suspension consisted of a long period glass pendulum supported on two steel points and carrying a small

mirror. Thus by means of the deflection of a light beam, small forces on the collector could be measured. The forces were determined as a function of the negative potential applied to the collector using several different values of the total current through the arc.

From the data obtained the calculation of an accommodation coefficient for helium positive ions is quite simple if corrections for the current that reaches the collector at its edges are neglected. Let β be the fraction of the incident energy of the ion which is retained after neutralization. β is approximately equal to $1-\alpha$ where α is the accommodation coefficient. Assuming that the neutralized ions escape in random directions, the pressure on the collector is given by

$$P = \frac{i}{2e} (2meV\beta)^{1/2}$$

where P is the pressure exerted on the collector, i the positive ion current density, e the

charge, m the mass of a helium ion and V the negative potential of the collector with respect to the surrounding space. Putting in the constants,

$$\beta = \frac{4.63(10^3)P^2}{i^2V}$$

where P is in milligrams per square centimeter, i in milliamperes per square centimeter and V in volts. α follows immediately from the relation $\beta = 1 - \alpha$.

When a small correction for edge effects is included preliminary results indicate a value of about 0.5 for α . In further work the elimination of edge effects will be attempted and the experiments continued using a number of other gases.

Raman Spectra of Silico-Chloroform

We have been investigating the Raman spectra of silico-chloroform and have succeeded in observing a number of its Raman frequencies and particularly that characteristic of the Si-H-bond. The spectra were observed by illuminating with a mercury arc a tube filled with the liquid immersed in liquid ammonia contained in an unsilvered Dewar flask. The light was reflected from the top of the tube into a Hilger D78 glass spectrograph.

The frequencies which we have observed together with those of chloroform (Proc. Roy. Soc. A127, 360 (1930)) are shown in the following table:

CHCl ₃	SiHCl ₃
261 (5)	179 (strong)
367 (6)	250 (strong)
669 (6)	489 (very strong)
762 (3d)	587 (strong diffuse)
1218 (2d)	799 (strong diffuse)
1441 (1)	—
3019 (3d)	2258 (strong diffuse)

It is to be noted that we observe six frequencies which can be correlated with those of chloroform, the frequencies of silico-chloroform being always smaller than those of the other compound. We have been unable to de-

tect the seventh frequency which should be the weakest of the frequency displacements. The highest frequency which we observe, namely, 2258, is that which corresponds to the frequency usually assigned to the vibration of the proton along its valency bond with respect to the carbon atom in chloroform; so that it is to be interpreted as a similar vibration of the hydrogen atom with respect to the silicon atom along the Si-H-bond.

The differences in these two frequencies can be due only to the difference in the restoring force constants for the two cases, for the effective mass in both cases should be approximately the mass of the hydrogen atom. We have also been able to observe both positive and negative displacements for the lower frequencies from the yellow lines of mercury in addition to those more easily observed from the blue and violet lines. Complete details of this investigation and that of other compounds of this type will be reported at a later date.

New Lines in the Near-Infrared Spectrum of the Neutral Hg Atom

Thirty-nine new lines have been observed in the region 0.9μ to 2.25μ with an automatic recording spectrograph¹ of the Littrow type using the equivalent of five 60° prisms. The lines are extremely weak so that an effective slit-width of approximately 15 A° was necessary for detection with a single junction ther-

Research Tokyo, Sci. Papers No. 232, March 20, 1930). All the lines in the region 0.9 to 1.0μ , observed photographically by Takamine and Suga were discernible, and the line at 0.940μ resolves into two, 0.9432 and 0.9447μ . The line at $2.108\mu \pm 10^{-3}$ is of the same intensity as the one 2.2489μ observed by F. Pas-

Spark Spectrum of Caesium (Cs II)

In pursuance of the systematic investigation of the alkali spark spectra by means of the hollow cathode excitation (Phys. Rev. **36**, 219, 1931) we have now carried the analysis to the first spark spectrum of caesium. Contrary to Rb II, the excitation of the caesium hollow

cathode discharge in helium is about two volts more than sufficient to produce excitation of all the levels of the caesium ion so that higher members of the resonance series were excited and a total of eight lines appeared in the vacuum region (see table below).

(12)	639.42	156392	$5p^6 - 5p^5(^2P_{1/2})7s$ and $6d$
(7)	612.82	163180	
			$5p^6 - 5p^5(^2P_{3/2})7s$ and $6d$

With the separation of these lines as a guide, it has been possible to interpret the classification of the Cs II lines in the visible region as given by Sommer (Ann. d. Physik **75**, 163, 1924). The energy level scheme given by this author is correct but incomplete. For, due to the large separation of the $5p^5(^2P)$ term of Cs III, the energy levels of each configuration are split up into two distinct groups according to whether they are built upon $^2P_{1/2}$ or upon $^2P_{3/2}$. Sommer's classified lines are to be interpreted (α) as transitions from five of the six levels of the configuration $5p^5(^2P_{1/2})6p$, to five of the ten levels of the configurations $5p^5(^2P_{1/2})6s$ and $5p^5(^2P_{1/2})5d$, (β) as transitions from eight of the ten levels of the configurations $5p^5(^2P_{1/2})7s$ and $5p^5(^2P_{1/2})6d$ to the

aforesaid five levels of $5p^5(^2P_{1/2})6p$. No levels built upon $^2P_{3/2}$ were found by Sommer, but the present data give clear indications concerning their position. In the above table, the intensities, wave-lengths, and frequencies of the resonance lines are given as well as their spectroscopic origin.

The resonance potential corresponding to the two strongest lines 926.75 and 901.34 is equal to 13.32 and 13.70 volts, respectively.

Hyperfine Structure and Incomplete Polarization of Mercury Resonance Radiation

The author has made studies of the Zeeman effect of the mercury resonance line in absorption and has shown, that for certain intensities of the magnetic field mercury vapor transmits, from the five hyperfine-structure components of the 2537A-line: (1) only the outer short wave-length component, -25.4 mA, or (2) one inner and one outer component, -10.4 and $+21.5$ mA, or (3) two inner components, 0 and $+11.5$ mA. Further the author has determined the absorption coefficients and the life-times of the mercury atoms excited with the above mentioned filtered radiations. A full account appeared in Bull. Acad. Pol. Nov.-Dec. p. 464, 1930; preliminary communications in Nature, Nov. 1, 1930, and Phys. Rev. Nov. 15, 1930.

Recently the author has extended the investigations on the hyperfine structure of the resonance radiation excited with these filtered radiations. These investigations now in progress show, that by excitation with the outer component -25.4 mA alone, there appears in emission only the same component, that is, we have to deal with a pure monochromatic resonance effect. It is to be seen on the accompanying photographs obtained with a Lummer-Gehrcke parallel plate, from which the first shows the five-fold structure of the resonance radiation excited with the unfiltered radiation of the mercury vapor arc, the second, the single structure of the same radiation obtained by the excitation with the -25.4 mA component alone.

The experiments made up to the present on other components seem to show, that in general each of the five components gives a pure resonance effect, consequently there are no hyperfine levels of the 2^3P_1 -energy level from which more than one component can be emitted.

The results communicated above and those from investigations of the Zeeman effect show that the five-fold structure of the 2537A line is due rather to the isotope effect than to a magnetic moment of the nucleus. At the same

Fig. 1.

Fig. 2.

time they give interesting views concerning the cause of the incomplete polarization of the mercury resonance radiation in absence of magnetic field.

In the first place, according to the supposition of Olson (Phys. Rev. **32**, p. 443, 1928), the degree of polarization must depend on the relative intensity of the components in the exciting light. Further, in the case of the excitation with the outer -25.4 mA component, previously investigated by the author, one should expect that the degree of polarization should be about 32 percent (in comparison

with 50 percent by excitation with all five components). This difference is so small that I could overlook it in the approximate estimations of the visibility of the interference fringes (I did not take into account the dependence of the plate density upon the time of exposure). It must be remarked that experiments made recently by A. Ellett and described by him in a letter in the January 15th issue of this Review do not contradict the results of my investigations. From Fig. 2 of my paper (Bull. Acad. Pol. I.c.) it is to be seen, that under the conditions chosen by Ellett (2000 gauss) the filtering absorption cell does not transmit the outer -25.4 mA component; the resonance radiation is excited probably not with cores, but by the transmitted wings of the hyperfine-structure components.

As regards the other experiment, on the basis of which Ellett supposes that the parallel Zeeman component of the outer long wavelength component ($+21.5$ mA) is shifted by the magnetic field, it must be remembered, that such a shift is not detected either in emission (McNair) or in absorption (the author, I.c.). On this account I think that another explanation should be sought for this experiment of Ellett. It is possible, for instance, that the whole effect could be explained by the relatively large difference of the absorption coefficients for the inner and the outer components.

THE PHYSICAL REVIEW

DIFFRACTION OF HYDROGEN ATOMS

BY THOMAS H. JOHNSON

BARTOL RESEARCH FOUNDATION OF THE FRANKLIN INSTITUTE

(Received March 11, 1931)

ABSTRACT

Diffraction patterns of a beam of hydrogen atoms reflected from LiF.—Improved technique in the photography of the diffraction patterns produced by the reflection of a beam of hydrogen atoms from a crystal of lithium fluoride has resulted in more complete patterns than those previously described by the author. The observed patterns are those expected on the assumptions (1) that the incident beam contains the distribution of wave-lengths derived from the Maxwellian velocity distribution by the use of the de Broglie relation between wave-length and velocity, and (2) that the surface of the crystal constitutes an impenetrable square array of scattering points with the arrangement and spacing of the ions of a single type as known from x-ray measurements.

Wave-length distribution.—The intensity distributions in the diffraction patterns were measured, and were found to have maxima at positions in good agreement with those expected on the basis of the above assumptions.

Interpretation of relative intensities in the different orders.—The relative intensities in the observed orders are discussed in relation to the scattering coefficients of the two types of ions, and in relation to the dependence of the scattering coefficient on azimuth.

Diffraction by the secondary structure of the crystal.—A secondary spectrum is described, arising from a lattice of wide spacing the lines of which are parallel to the 100 cleaved edges of the crystal face.

IT HAS been well established for some time that the quantum mechanics correctly describes the motion of a free or a bound electron. Its success in the interpretation of band spectra has also shown that the motions of atomic nuclei within the molecule could be included in the theory, and because of this, it appeared almost certain that the new mechanics would be found correct in its description of the free motion of atoms and molecules. The comparatively recent experiments of Estermann and Stern¹ and of the author² were not disappointing in this regard for they have demonstrated that atoms and molecules of low atomic weight behave as predicted, in that they exhibit the properties of a wave radiation of wave-length $\lambda = h/mv$ in the plane-grating diffraction phenomena which appear when these are reflected from the surface of a crystal. These experiments are of interest not only because of their confirmation of the predictions of quantum mechanics, but also because

² T. H. Johnson, *Phys. Rev.* **35**, 1299 (1930).

they introduce the possibility of applying atom diffraction to investigations of the atomic constitution of surfaces. A beam of atomic hydrogen, for example, with ordinary thermal velocities, has a range of wave-lengths of the right magnitude for this purpose, centering around 1A, and the complete absence of penetration of these waves will insure that the effects observed arise entirely from the outermost atomic layer.

The first experiments demonstrating the diffraction of hydrogen atoms when reflected from a crystal of lithium fluoride were described in some detail in the *Journal of the Franklin Institute*.³ The diffraction patterns which were photographed in that earlier work were of low intensity and they showed only a part of the complete structure which should have been produced by the array of ions on the surface of the crystal. Because of the low intensity in these earlier patterns, satisfactory intensity measurements were impossible, and only a rough comparison could be made between the observed distribution of wave-lengths and that predicted from the Maxwellian velocity distribution and the de Broglie relation between velocity and wave-length.

Fig. 1. Collimating system for normal incidence.

Recent improvements in the technique of obtaining photographic records of the diffraction patterns have overcome in large measure the deficiencies of the earlier work, and patterns of far greater intensity have been photographed which show all of the expected first-order branches. The intensity is now sufficient for the purposes of making photometric measurements of the wave-length distribution, and it has been possible to make some rough estimates of the relative intensities in the principle branches. In addition, some new features have been recorded which throw light upon the secondary structure of the crystal.

With the exception of a few modifications, the apparatus and the experimental procedure were the same as in the earlier work. A sharply defined beam of hydrogen atoms had its origin in a chamber *T*, Fig. 1, in which molecular hydrogen was dissociated by an electric discharge, and it was collimated by a series of tubes with suitable pumping systems for eliminating the excess gas. This beam was reflected from a freshly cleaved surface of a crystal (*C*) of lithium fluoride, and the reflected atoms were recorded on a plate (*P*)

³ T. H. Johnson, *Jour. Frank. Inst.* 210, 135 (1930).

coated with molybdenum oxide. After an exposure the patterns recorded on the molybdenum oxide plate were made permanent by photographing in the usual way.

Since it is believed that atom diffraction may prove useful in studying the structure of surfaces a discussion of some of the technical features will be included for its interest to other investigators in this field.

FORMATION OF THE BEAM

In designing a collimating system for the production of a molecular beam for use in diffraction experiments there are two requirements; the beam should be intense and it should be sufficiently sharp to resolve the effects sought. In the limit these demands are conflicting in that an increase in the sharpness of the beam results in a decrease in its intensity, and *vice versa*. Over the range of source chamber pressures which is of interest, the intensity of the beam, as regards its dependence on the configuration of the collimating system, is proportional to the area of the source aperture and inversely proportional to the square of the distance from the source to the point of detec-

Fig. 2.

tion, and it is independent of the position and size of the collimating aperture as long as the point of detection is not occluded from any part of the source aperture. The sharpest beam, for a given intensity, may be obtained by making the collimating aperture a section of the cone of which the source aperture is the base, and the point of detection is the vertex. The linear dimensions (S_2 , S_2') of the collimating aperture are therefore related to the corresponding dimensions (S_1 , S_1') of the source aperture by

$$S_2 = S_1 b / (a + b), \quad (1)$$

where a and b are the distances indicated in Fig. 2. The corresponding dimensions of the cross-section of the beam at the point of detection are given by

$$S_3 = 2S_1 b / a. \quad (2)$$

Similar expressions also hold for the S' dimensions.

If a perfect reflector is placed a negligible distance behind the collimating aperture two reflected beams separated by an angle $\Delta\theta$ will be just resolved if their linear separation is equal to the beam width, i.e.

$$b\Delta\theta = 2S_1 b / a. \quad (3)$$

The resolving power of the collimating system, in the plane determined by S and the beam, defined as

$$R = 1/\Delta\theta = a/2S_1, \quad (4)$$

is independent of b and would remain unaffected by shortening this distance as much as permitted by convenience of construction.

The intensity I of the beam depends upon these dimensions of the collimating system in the manner

$$I \sim \frac{S_1 S_1'}{(a+b)^2} = \frac{aS_1'}{2R(a+b)^2} = \frac{a^2}{4RR'(a+b)^2}. \quad (5a, b)$$

From (5a) it is seen that, with fixed resolving power in one direction and fixed dimension S_1' normal to this direction, I has its greatest value, as regards its dependence on b when $b=0$, and, as regards its dependence on a , when $a=b$. If the resolving power is to be fixed in two dimensions, as, for example, would be the case with circular beams, (5b) shows that the intensity undergoes no variation with changes of the size of the collimating system, but it is inversely proportional to RR' .

Under the first of these conditions the greatest intensity is obtained with the collimating system as short as possible and the sizes of the apertures determined by (4) and (1) to yield the required resolving power.

The variation of beam-intensity with source-tube pressure is the next point to consider. The principles involved are not as clear in the case of atomic hydrogen beams as with other gases, for the degree of dissociation in the discharge tube depends, among other things, upon the pressure. With an incomplete understanding of discharge tube phenomena, considerations of this kind will be omitted and only the usual elements of the kinetic theory of gases will be taken into account.

On this basis the number of atoms leaving the source aperture in the direction of the beam is proportional to the pressure in the source chamber over the range of pressures for which "molecular flow" subsists. This number is diminished by collisions over the path a' , between the source and the entrance to the collimating aperture, by the factor $e^{-a'/L}$ where L is the mean free path in this region. Since the speed of the diffusion pump which is used to eliminate the excess gas from the region between the first two apertures is approximately independent of the pressure, a constant ratio exists between the pressure within the source chamber (p) and that in the intermediate region, and L is inversely proportional to p . The intensity of the beam then varies with the pressure in the source chamber in the manner

$$I = A p e^{-p/p_0} \quad (6)$$

in which the constant p_0 is the pressure in the source chamber for which the intensity of the beam is a maximum. An expression of this form is in agreement with the observations on beam intensities in these experiments as well as with other published data, and with the apparatus used in these experi-

ments p_0 was found to be 0.3 mm. Corresponding to p_0 , the intensity of the beam, from (6), is

$$I_0 = A p_0 / e. \quad (7)$$

From the above considerations it may be seen that p_0 is proportional to the resistance of the source aperture, to the speed of the pumping system operating between the source and first collimating aperture, and inversely proportional to the path a' of the beam in this region, while the constant A is proportional to the ratio of the number of atoms which have the direction of the beam to the total emission from the source, and inversely proportional to the resistance of the source aperture. To realize a large value of I_0 , a high speed pump and large connecting tubes were used at the first stage, the path a' was made as short as possible by the use of an auxiliary collimating tube (Fig. 1), and the source aperture was tubular in shape to produce a favorable directional distribution of the emitted atoms.

Fig. 3. Collimating system for 45° incidence.

Insofar as the directional distribution of the atoms emerging from the source aperture is unaffected by changes in its dimensions, the resolving power can be increased without affecting the intensity by diminishing the dimensions of the source aperture and simultaneously increasing the pressure in the source chamber so that the total number of atoms which emerge from the source aperture remains unchanged. A change of this character should leave the number of collisions in the intermediate chamber unaffected, for there the free path depends only on the rate at which gas is flowing in from the source chamber. This consideration therefore leads to the conclusion that the intensity can be increased, with fixed resolving power in *two* dimensions, by diminishing the size of the collimating system and simultaneously increasing the pressure in the source tube.

The collimating systems (Figs. 1 and 3) used in these experiments were constructed along the lines of these principles except that, in the arrangement for normal incidence, it was inconvenient to place the crystal directly in front of the last collimating aperture. The important dimensions are included in the following table.

Diameter of source tube	0.65 mm
Length of source tube	1.3 mm
Diameter of first collimating tube	0.67 mm
Diameter of second collimating tube	0.18 mm
Distance (a') from source tube to first collimating tube	1.0 mm
Distance (a) from source tube to far end of second collimating tube	24 mm
Distance (b) from end of second collimating tube to plate by way of specular reflection from the crystal at normal incidence	9 mm
Distance (b) for 45° incidence	10.5 mm

ELIMINATION OF HIGH ENERGY IONS FROM THE ATOM BEAM

One of the principal obstacles which stood in the way of the recording of intense patterns in the earlier work was the disintegration of the crystal surface by ion bombardment. Ions diffusing from the discharge chamber were

Fig. 4. Electrical connections.

subjected to a potential fall of the order of 5,000 volts between the center of the discharge and the observation chamber and some of these entered the beam and bombarded the crystal. The importance of their effect may be realized from the fact that, if unimpeded, the ion bombardment was sufficient to disintegrate the surface of the crystal in less than one minute to the extent of putting a stop to the regular reflection of atoms. The introduction of an electrode E (Figs. 4 & 1) to sweep the ions from the beam, materially improved the situation and exposures of three hours were feasible. There remained, however, a smaller number of neutral atoms of high energy in the beam which were formed in the first collimating tube by the neutralization of ions and these were not eliminated in this way. In the latest work, therefore, two additional precautions were taken. (1) The potential of the observation chamber was adjusted to be approximately the same as that of the center of

the discharge tube, so that ions diffusing from the source tube were accelerated as little as possible. (2) The remaining field between the center of the discharge and the entrance to the first collimating tube was made asymmetrical so that the ions were accelerated out of the line of the beam. The result of these precautions has been an almost complete elimination of the effects of bombardment with a resulting increase in the possible time of exposures to 24 hours or longer and a corresponding increase in the intensity of the patterns.

Fig. 4 is a diagram of the electrical circuit which was used to operate the discharge. A d.c. source of potential was supplied by a transformer and two kenetrons connected for half-wave rectification. This method of connecting the kenetrons had the advantage that the potential of the observation box, when adjusted to equal that of the center of the discharge, was close to the ground potential, and no trouble was experienced with leakage currents although the design of the apparatus made it inconvenient to insulate the box to withstand high voltages. To reduce the fluctuation of potential which took place during the cycle of alterations of the primary e.m.f., a condenser (*C*) having a capacity of 0.08 mf was used. A water resistance (*R*) served as a convenient potential divider and ballast resistance for the discharge. This was constructed of a series of four interconnected glass U-tubes, each 1.5 meters in length and 5 mm in diameter through which tap water was continuously circulated. This resistance could be varied in any of its parts by the insertion of wires into the arms of the U's, and it was adjusted so that no current was registered through the galvanometer (*G*).

GENERAL DARKENING OF THE DETECTING PLATE

In the recording of faint patterns requiring long exposures it was necessary to exercise care to avoid a general over-all darkening of the molybdenum oxide detecting plate. A darkening of this character might have been produced by any one of three causes. (A) Atomic hydrogen, dissociated in the source chamber, might have been diffusely emitted from the collimating tube after scattering from its walls, and these might have reached the detecting plate either directly or after other reflections in the observation chamber. (B) Atomic hydrogen might have been formed in the observation chamber itself by electrons which were emitted either photoelectrically from the walls of the observation chamber or thermionically from the crystal holder and its heating unit, and which attained high velocities in the fields which surrounded the electrode *E* and its lead wire. (C) The most important cause of over-all darkening was the reduction of the molybdenum oxide by molecular hydrogen. This reaction can take place only if the molybdenum oxide is heated, but unless precautions were taken, the radiant heat from the crystal holder at the temperature used for degassing the surface of the crystal was sufficient to cause trouble.

Unquestionably some trouble had been experienced from cause (A) but this was rendered negligible by plating the inside walls of the collimating tubes with platinum black so that scattered atomic hydrogen was adsorbed until recombination to molecular hydrogen took place. The effects of (B) and

(C) were almost eliminated by protecting the detecting plate with a metal shield which completely surrounded it except for a small opening close to the crystal through which the reflected atoms entered. (See Figs. 1 and 3.) The inside and outside walls of this shield as well as the interior walls of the observation chamber were cleaned and freshly plated with platinum black before each exposure. To facilitate the cleaning of the interior of the observation chamber a copper lining was constructed which was easily removed, cleaned and plated.

PHOTOGRAPHIC TECHNIQUE

The detecting plate consisted of either a "black-nickel" plated brass plate or a blackened photographic plate upon which was deposited a thin coating of molybdenum oxide formed by the oxidation of metallic molybdenum in an oxygen-gas flame. Since the blue reduced molybdenum oxide faded slowly when exposed to the air, the detecting plate was photographed as soon as possible after it was removed from the apparatus. The camera was of special construction and gave a 2.86 to 1 enlarged image. The plate was illuminated from the front by two 100 watt lamps placed beside the camera lens. To prevent fading of the pattern by reoxidation when exposed to the heat from these lamps, water filters were introduced between the lamps and the plate. A Wratten Aero No. 1 color filter was used in front of the camera lens to increase the photographic contrast between the white background and the blue pattern. The best reproductions of the patterns were obtained on Eastman Process plates with their D-9 developer.

PREPARATION OF THE CRYSTAL

The crystals of lithium fluoride were grown from a melt by the method of Kyropoulos,⁴ which proved to be extremely simple and satisfactory. These crystals are of the simple cubic lattice, and they are cleavable along the 100 planes. From the lens shaped crystals which were grown in this way rectangular blocks 2 mm \times 2 mm \times 4 mm were cut, the faces of which were parallel to the cleavage planes. During an exposure one of these crystal blocks rested in a groove in a copper holder of which two types were used to realize the desired orientations. These holders contained heating coils of tungsten wire wound on mica and imbedded in alundum cement. After all other adjustments had been made the crystal was cleaved and mounted, and as quickly as possible the apparatus was evacuated. Without further treatment the freshly cleaved surface at the start was generally found to give a weak specularly reflected beam of the order of 1 percent of the incident beam. An initial heating at 500°C for about 3 min. with a subsequent cooling to room temperature increased the reflecting power to something of the order of 10 percent of the incident beam, but this again fell off in the course of an hour to very nearly nothing. If the temperature of the crystal was maintained steadily at about 300°C its reflecting power was higher and it persisted for a much longer period of time, but it was still helpful to heat the crystal at 500°C for a few minutes

⁴ Kyropoulos, *Zeits. f. anorg. allgemein. Chem.* **154**, 308 (1926).

at four or five hour intervals. With this procedure it has been possible to maintain a high reflecting power during 24 hour exposures with no apparent diminution. During the major part of the exposure it has been found best to maintain the crystal at as low a temperature as is possible without seriously interfering with its reflecting power, for at the higher temperatures, in addition to difficulties introduced by the heating of the detecting plate, there was some troublesome diffuse reflection which might have arisen from either or both of two causes. (1) The roughening of the surface by thermal agitation may have produced a diffuse blurring of the regularly reflected and the diffraction beams. (2) Adsorbed hydrogen atoms may have been re-emitted from the hot crystal in the monatomic state, although at low temperatures these remained on the crystal surface until recombination to molecular hydrogen had taken place.

The best explanation which can now be given of the continually diminishing reflecting power at low temperatures is that vapors from the picein wax, which sealed the many joints leading into the reflection chamber, gradually condensed on the crystal surface. To minimize this difficulty the concentration of this wax vapor was made as low as possible by the use of independently evacuated guard rings between the wax seals and the inside chamber. As further precautions against this vapor, a liquid-air-filled glass tube protruded into the observation chamber, and the inside walls were covered with an adsorbing layer of platinum black.

THE DIFFRACTION PATTERNS

For the purpose of demonstrating the principal features of the phenomenon of the diffraction of atoms, patterns were obtained by exposures with three different arrangements of the crystal and detecting plate. These will be referred to as (a) normal incidence (b) 45° incidence in the 110 azimuth and (c) 45° incidence in the 100 azimuth. In each case the patterns were those expected from the following two assumptions: (1) The distribution of wavelengths in the beam was that calculated from the Maxwellian velocity distribution by the use of the de Broglie relation, and (2) The diffraction grating was made up of scattering points arranged on the surface in a plane square array with a spacing d equal to the value 2.835Å obtained by x-ray measurements for the distance between two adjacent ions of the same type. The principal axes of this array lie in the 110 azimuths and the angular positions (ϕ , θ) of the diffraction beams with respect to these axes can be correctly calculated from the plane cross-grating equations

$$\cos \theta_0 - \cos \theta = m\lambda/d \quad (8a)$$

$$\cos \phi_0 - \cos \phi = n\lambda/d \quad (8b)$$

in which m and n have the values 0, ± 1 , etc.

Of the patterns which have been recorded, the most complete is that reproduced in Fig. 5 which was obtained with the crystal and the detecting plate arranged for normal incidence as is shown in Fig. 1. The specularly reflected

beam appears in the photograph at the center of the pattern superposed upon the hole drilled for the incident beam. The more intense dispersed branches of the pattern, which are reproduced in the vertical and horizontal directions, lie in the 110 azimuths of the crystal. These correspond to the four ways of assigning 0 and ± 1 to m and n in equations (8), and may be appropriately designated as (1, 0) beams. In addition to these, four other fainter beams are visible in the 100 azimuths corresponding to $n = \pm 1, m = \pm 1$. These will be designated as (1, 1) beams. The dispersion in these beams seems to be greater than that in the (1, 0) beams as would be expected since these may be considered as arising from a grating of the spacing $d/2^{1/2}$. The angular dimensions of the pattern may be judged from the fact that the distance from the crystal to the detecting plate, when increased in the ratio of the enlargement of the photograph, was 12.9 mm.

Fig. 5. Diffraction of hydrogen atoms reflected at normal incidence from an LiF crystal.

Fig. 6. Diffraction of hydrogen atoms reflected at 45° incidence in the 110 azimuth.

Fig. 7. Diffraction of hydrogen atoms reflected at 45° in the 100 azimuth.

A pattern produced by reflecting the beam at 45° incidence in the 110 azimuth is reproduced in Fig. 6. In this instance the arrangement of the crystal and detecting plate was that represented in Fig. 3. The (0, 0) specularly reflected beam again appears at the center of the pattern and the (1, 0) beams are now a straight line in the plane of incidence and a parabola symmetrically placed with respect to this line and intersecting it in the specularly reflected beam. If θ designates the angles measured from the rows of ions which are parallel to the plane of incidence, and ϕ those measured from the perpendicular rows, then the beam which is dispersed in the plane of incidence is represented by $m = +1, n = 0$ in equations (8). The two branches of the parabola, on the other hand correspond to $m = 0, n = \pm 1$. The straight branch in the plane of incidence on the lower side of the specular beam corresponding to $m = -1, n = 0$ might have been expected to appear but the dispersion was such that the most probable wave-length fell below the plane of the crystal, and, on account of the greater dispersion in this branch and the paucity of the wave distribution in the region of short wave-lengths, this branch was too faint to appear in the photograph.

The (1, 1) beams in this case take the form of two hyperbolae intersecting in the specular beam but these were perhaps too faint to be distinctly visible

in the reproduction. Unquestionably they could be brought out more intensely if a special effort were made.

The pattern at 45° incidence in the 100 azimuth (Fig. 7) was obtained with the same arrangement of Fig. 3, except that the crystal was rotated in its own plane 45° from its former position. The plane of incidence was in this case parallel and perpendicular to the cleaved edges of the crystal so that the principal axes of the surface lattice intersected the plane of incidence at angles of 45°. The (1, 0) branches of the pattern now appear as the two hyperbolic intercepts with the plane of the detecting plate of the two cones, $\theta = 60^\circ$, and $\phi = 60^\circ$. The branches which lie above the specular beam are intense but those lying between the specular beam and the plane of the crystal, although visible, are weak for the same reasons as were given in regard to the $n = 0$, $m = -1$ beam of Fig. 6. The (1, 1) beams in Fig. 7 should have the form of the (1, 0) beams of Fig. 6 except for greater dispersion but these were too faint to appear.

THE DISTRIBUTION OF WAVE-LENGTHS

Assuming the Maxwellian law for the distribution of velocities of the atoms per unit volume in the beam, the distribution in wave-lengths of the intensity of the atom waves falling on the crystal as predicted by the de Broglie relation is given by

$$dI/d\lambda = Ae^{-\lambda_0^2/\lambda^2}/\lambda^5 \quad (9)$$

in which λ_0 has the value $h/(2mkT)^{1/2}$. The expected distribution of intensity along the path s of a branch of the diffraction pattern is calculable from (9) by the relation

$$\frac{dI}{ds} = \frac{dI}{d\lambda} \frac{d\lambda}{d\theta} \frac{d\theta}{ds} \quad (10)$$

$d\lambda/d\theta$ may be obtained by differentiation of the grating equations (8) and $d\theta/ds$ is calculable from the geometry of the arrangement.

Since the intensity measurements were to be made with a densitometer the straight line patterns at normal incidence seemed at first sight to be the easiest to manipulate. A comparison of these patterns with those obtained at 45° incidence however showed that the latter were less obscured by diffuse radiation and for this reason were less subject to errors. To combine this advantage with ease of measurement it was decided to use a pattern obtained with the crystal oriented for 45° incidence in the 110 azimuth and a slightly different arrangement of the detecting plate as shown in Fig. 8. With this arrangement branches dispersed along the periphery of the 45° cone appeared on the detecting plate as a circle (Fig. 9) and this form of pattern was easily measured with a Koch and Goos densitometer by the use of a simple attachment constructed to give rotary motion. Besides its adaptation to measurement this pattern had two other great advantages. (1) All points of the circle were equally distant from the surface of the crystal and for this reason the general

darkening of the plate was distributed somewhat evenly. (2) The calculations were extremely simple and involved only the measurements of the angular positions ψ on the plate.

Fig. 8. Arrangement of plate holder for circular patterns.

The grating equation (8b) in this instance reduces to

$$\cos \phi = n\lambda/d \quad (11)$$

and the measured angle ψ of the circular pattern is related to ϕ by

$$\cos \phi = \sin \psi \sin 45^\circ, \quad (12)$$

from which

$$dI/d\psi = A'e^{-2\lambda_0^2/d^2 \sin^2 \psi} \cos \psi / \sin^5 \psi. \quad (13)$$

Fig. 9.

The angle ψ_0 of maximum intensity is found by equating to zero the derivative of the right hand member of (13) and it is given by

$$\cos^2 \psi = - (2\lambda_0^2/d^2 - 3)/8 + [(2\lambda_0^2/d^2 - 3)^2/64 + \frac{1}{4}]^{1/2} \quad (14)$$

If it is assumed that the temperature of the source of the atom beam was

that of the water which circulated in a jacket surrounding the discharge tube⁵ then

$$\begin{aligned} T &= 300^\circ K & d &= 2.835\text{\AA} \\ \lambda_0^2 &= 3.13 \times (10)^{-16} \text{ cm}^2 & \psi_0 &= 32.7^\circ. \end{aligned}$$

Intensity measurements were made from the photographic negatives. As regards the position of maximum intensity this method of measurement would have been independent of the plate calibration were it not for the fact that the pattern was superposed upon a background of variable intensity in spite of the advantages of the arrangement for overcoming this trouble. In order to correct the measurements for this background intensity the plate was also measured along the circumference of a circle of slightly different diameter from that of the diffraction pattern itself, and this set of measurements was applied to the first set as corrections. A calibration of the densitometer deflection in terms of the intensity of an atom beam was obtained by exposing a separate plate in various places to the primary beam for successively increasing times so that a series of dark spots was formed which covered the intensity range of the patterns. This plate was photographed and developed under exactly the same conditions as pertained in the case of the plates which contained the patterns. Densitometer measurements then showed that the difference of the deflection produced by the center of one of the spots and that produced by the unexposed portions of the plate was very nearly proportional to the time of exposure of the spot. This fortunate coincidence led to the simple rule that the deflections of the densitometer could represent atom beam intensities if corrected by subtracting the deflection at an adjacent point of the background. Although this method of making intensity measurements cannot be regarded as possessing a high degree of reliability, as will be recognized by those familiar with the precautions necessary in ordinary photographic photometry, yet it led to surprisingly consistent results in good agreement with what was expected for the angle of maximum intensity. Eight corrected sets of measurements from plates made from three different molybdenum oxide originals gave a weighted mean value of $\psi_0 = 31.6^\circ$ with a probable error of 2.2° as compared with the calculated value of 32.7° . This accuracy probably speaks more for the uniformity of the background than for the method of calibration and correction, and it is felt that a more reliable calibration must be devised before the photographic method can be used satisfactorily for precise intensity measurements.

RELATIVE INTENSITIES OF THE (1, 0) AND (1, 1) BEAMS

Measurements of the relative intensities in different orders of x-ray spectra have been applied⁶ to a determination of the relative scattering powers of the different atom species in the crystal. It is of interest to attempt the same thing using the different orders in the atomic diffraction patterns.

⁵ From the work of J. B. Taylor, *Phys. Rev.* **29**, 309 (1927) this seems to be a reasonable assumption.

⁶ W. H. Bragg and W. L. Bragg, *X-rays and crystal structure*, page 187, et seq.

Because of the overlapping of the 1, 0 and 2, 0 orders these beams are not well adapted to this purpose until more homogeneous velocities can be used, but it is interesting to compare the intensities in the 1, 0 and 1, 1 branches. In terms of the scattering powers U of the two ion types in the two directions, the ratio of the intensity of a (1, 1) beam of a particular wave-length to that of a (1, 0) beam of the same wave-length may be expressed, by the use of the principle of the superposition of amplitudes, as

$$I_{11}/I_{10} = (U_{11F} + U_{11Li})^2 / (U_{10F} - U_{10Li})^2. \quad (15)$$

If the U 's are assumed to be spherically symmetrical functions of space, i.e., $U_{11} = U_{10}$, the ratio U_F/U_{Li} can be determined from the measured ratio of intensities I_{11}/I_{10} .

In making the intensity measurements one must take account of the fact that the beams are not homogeneous in wave length but they contain a distribution (9) which is more highly dispersed in the (1, 1) than in the (1, 0) branches. The maximum of intensity on the plate in the (1,0) branches of the normal incidence patterns should fall, according to these considerations, at a distance S from the central spot equal to $0.408 l$, where l is the distance between the crystal and the plate. The calculated position of maximum intensity in the (1, 1) branches is at $S = 0.589 l$.

The ratio of intensities at these two points of maximum intensity is found from (9), (10) and (15) to be

$$\left(\frac{dI}{ds}\right)_{11} / \left(\frac{dI}{ds}\right)_{10} = (U_{Li} + U_F)^2 / 6.3(U_{Li} - U_F)^2. \quad (16)$$

The actual measurements carried out by means of the photometric technique described in the previous paragraph give a value of this ratio of about 1/6 with the possibility of an error of 100 percent or more arising not only in the unreliability of the method of calibration but also from the faintness of the 1, 1 branches. Although this inaccuracy of measurement renders a quantitative determination of U_{Li}/U_F impossible, the assumption of spherical symmetry of the U 's leads to a small value of this ratio. The same conclusion results from a consideration of the great intensity in the 1, 0 orders where the contributions to the amplitude from the two ion types is 180° out of phase. From these measurements it is not necessary to conclude that the scattering power of an ion is definitely less in the 1,1 direction than in the 1,0 direction as Estermann and Stern found from the extremely small intensity which they observed in the (1,1) beams, although this conclusion would be necessary if a more accurate determination of the ratio (16) leads to a value greater than 1/6.

DIFFRACTION BY A SECONDARY LATTICE OF WIDE SPACING

In addition to the spectra which have been described, arising from the surface array of ions, another type of spectrum of very low dispersion appeared on the plates. This type of spectrum was first noticed on a plate exposed at

45° incidence in the 100 azimuth where it appeared as a slight smearing of the specular beam in the plane of incidence. Later the same phenomenon was noticed on the plates exposed at 45° incidence in the 110 azimuth and in this case the spectra took the form of a blurred *X* extending out from the specular beam. These features may perhaps be distinguished in Figs. 6 and 7. An exposure at grazing incidence in the 100 azimuth increased the dispersion in this spectrum as shown in Fig. 10 but failed to separate the maximum of the

Fig. 10. Secondary structure spectrum at grazing incidence.

wave length distribution from the specular beam. It has been pointed out⁷ that this spectrum indicates the existence of a secondary periodicity on the crystal surface parallel to the 100 planes in agreement with the theory of Zwicky.⁸ Work is now under way to increase the resolving power in this spectrum with the hope of measuring the constant of the secondary lattice.

The writer wishes to take this opportunity to acknowledge his indebtedness to Mr. C. K. Boyer and Mr. M. A. Roesch, both of the Drexel Institute, who have assisted in this work.

SCATTERING OF X-RAYS FROM GASES

BY E. O. WOLLAN

THE UNIVERSITY OF CHICAGO

(Received February 18, 1931)

ABSTRACT

Measurement of the intensity of scattering of x-rays by various gases has been made for scattering angles between 10° and 90° . Soller slits were used to get a well-defined scattering angle and matched filters of ZrO_2 and SrO were used to isolate the K_α lines of molybdenum. Intensity measurements have been made for hydrogen, helium, oxygen, neon and argon. All the measurements were put on the same scale by comparison of the intensity of scattering from the various gases with the scattering from hydrogen at 90° . This is equivalent to putting the intensities on an absolute scale since the scattering from hydrogen at 90° can be calculated with considerable certainty. Values of the structure factors for neon and argon were calculated and comparison made with those determined from wave mechanics for similar atoms.

INTRODUCTION

IN VIEW of Compton's¹ recent theory for determining the electron distributions in atoms from the angular distribution of intensity of x-rays scattered from monatomic gases it was thought desirable to get more complete experimental data.

Barrett² in 1928 published data for the scattering of x-rays from most of the gases included in this paper. He measured the intensity as a function of angle but no attempt was made to get absolute intensity measurements.

In the work reported here a more definite scattering angle has been obtained by the use of Soller slits, x-rays made homogeneous by the use of balanced filters have been used wherever the intensity permitted, and all the measurements have been put on the same scale by comparing the intensities from the various gases with that from hydrogen. This is equivalent to putting the intensity measurements on an absolute scale since the scattering from hydrogen at 90° can be calculated with considerable certainty.

APPARATUS AND PROCEDURE

The set-up is shown in the diagram Fig. 1. A molybdenum target x-ray tube was operated at 40 kv peak and 35 m.a. with full-wave rectification. The tube was immersed in oil in a lead box fitted with a lead glass front. A small celluloid window within 2 mm of the tube transmitted the primary beam with only a small reduction in intensity due to the 2 mm of oil. This arrangement

² C. S. Barrett, Phys. Rev. 32, 22 (1928). Measurements of the relative scattering of hydrogen and Argon have been made by Herzog but not with homogeneous radiation. G. Herzog Helvetica Phys. Acta 2, 169 (1929).

allowed the tube to be brought very near the spectrometer and the intensity was considerably greater than would have been possible with the tube in air.

The intensities were measured with an ionization chamber and a Compton electrometer with which currents of 5×10^{-15} amperes could be measured with a reproducibility of about five percent.

Fig. 1. Arrangement of apparatus.

The scattering chamber is shown in Fig. 2. It was made from a brass tube 5.5 inches in diameter, 3 inches high and having 1/8 inch walls. The top and bottom were 0.5 inch steel plates grooved and fitted with rubber gaskets and

Fig. 2. Scattering chamber.

held in position by three bolts as shown. The windows were of 0.7 mm celluloid 2 cm high. They were screwed down on rubber gaskets and picein wax used where it was found necessary. The base was fitted to the spectrometer table so it could be removed and replaced without affecting the readings. The top contains a gauge, an oxygen tank connection, a needle valve for the chamber and a side tube for evacuating the chamber and the leads. The chamber

was partially filled with sealing wax as shown in Fig. 1, and lined with lead. This cut the volume to about 250 cc and acted as a shield for the diffusely scattered x-rays.

The chamber was found to be very satisfactory as pressures of 200 pounds were used with a leak of only a few percent per week and the corrections for scattering from the evacuated chamber were almost negligible.

Reference to the diagram will show the arrangement of the chamber and the slit system. Soller slits were used to collimate the primary as well as the scattered beam. These slits allowed a maximum angular divergence of less than 2° in the horizontal plane. Slit S_1 was 3 mm wide and 1 cm high. Slit S_2 was 1 cm high and could be varied in width to 1.5 cm. Besides defining the

Fig. 3. Transmission through ZrO_2 and SrO filters. Fig. 4. High pressure mercury pump.

scattering angle the second slit served the additional purpose of determining the scattering volume. With this slit remaining constant the scattering volume was proportional to $\sin \phi$. The height of the slits S_1 and S_2 made the actual scattering angle slightly larger than indicated on the spectrometer circle. It was necessary to make correction for this on the readings between 10° and 30° .

The $K\alpha$ lines of molybdenum were separated out by the balanced filter method.³ A filter of ZrO_2 containing about 0.025 gm per cm^2 was balanced by a filter of SrO so that less than five percent of the radiation corresponding to the difference of these filters lay outside of the range between the K critical absorption edges of Zr and Sr. A curve showing the transmission by these

³ P. A. Ross, Phys. Rev. **28**, 425 (1926).

filters is shown in Fig. 3. The shaded portion represents the difference of the transmission by the two filters. The filters were additionally tested by measuring the absorption coefficient of aluminum which gave a straight line when $\log(I_0/I)$ was plotted against thickness. It is very important that these filters be well balanced so that reliable corrections for absorption can be made when elements like argon are compared with oxygen.

Since some of the gases were originally at atmospheric pressure it was necessary to construct a pump to put them into the chamber at the desired pressure. Fig. 4 shows the construction of the pump. The cylinders were of seamless steel tubing with welded bottoms and top and connecting tube. The rest was constructed mainly from iron pipes and connections. The vertical pipe was cut through at two places and a glass tube waxed inside to make the mercury level visible. With valve *B* closed and all the others open the system

Fig. 5. Curve I hydrogen, Curve II helium.

could be evacuated through valve *D*. Closing valve *D* and breaking the tip in the glass container by means of the electromagnet, the gas expanded into the upper cylinder of the pump. By closing valves *C* and *F* the gas could be forced into the scattering chamber by applying the oxygen tank pressure at valve *E*. With repeated pumping it was necessary to draw the mercury back into the lower container by applying the vacuum pump at *F*.

HYDROGEN

The hydrogen used in this experiment came from a tank especially prepared and analysed by Burdett Oxygen Company and found to have less than 0.1 percent oxygen and CO_2 and 0.07 percent water vapor by volume. After scattering measurements had been made on the gas the density was measured by weighing and no additional impurities were found to be present. The scattering chamber connected directly to the hydrogen tank, was evacuated together with all the leads, flushed out several times and filled to about 200 pounds pressure. It was then placed in position on the spectrometer table

and the scattered intensity measured from 10° to 90° . Even at 200 pounds pressure, however, it was necessary to use general radiation in place of the balanced filters. Curve I, Fig. 5 shows the scattering per electron corrected to $\lambda=0.71\text{\AA}$ plotted against ϕ . On the basis of the classical theory of scattering the value of $S \equiv I_s/ZI_e$ for hydrogen would be unity at 90° . The fact that practically all the intensity scattered at 90° from hydrogen is modified will make the experimental value at this angle slightly lower than unity. The Breit-Dirac relation may then be used

$$S_{\text{class}} = S_{\text{mod}} \{1 + \gamma \text{ vers } \phi\}^3. \quad (1)$$

Placing for 90° $S_{\text{class}}=1$, we have thus, $S \equiv S_{\text{mod}} = (1 + \gamma \text{ vers } 90^\circ)^{-3}$. For $\lambda=0.71\text{\AA}$, $\gamma \text{ vers } 90^\circ=0.0243$, whence $S=0.91$.

The data included in table I are all based on a value of S for hydrogen equal to 0.91 at 90° . To get the classical values of S Eq. (1) must be used.*

TABLE I. *Scattering per electron. $\lambda=0.71\text{\AA}$.*

Angle	Hydrogen	Helium	Oxygen	Neon	Argon
10°			8.05	8.55	13.90
15°	1.27	1.45	4.90	6.87	10.65
20°	1.10	1.34	2.96	5.16	8.50
25°	1.03	1.27	2.00	3.85	6.35

80°	0.92	0.92	1.01	1.18	2.10
90°	0.91	0.91	0.96	1.06	1.95

In so far as the scattering per electron from hydrogen is known, the scattering from other gases can be put on an absolute basis by comparison with it. Since the intensity of scattering from hydrogen is weak and difficult to measure it was first carefully compared with oxygen which was then used as a secondary standard of comparison.

COMPARISON OF OXYGEN AND HYDROGEN

Oxygen and hydrogen were compared several times at 90° using general radiation and pressures of about 200 lb/sq. in. for both gases. This involves a large correction for absorption for an unknown wave-length. To make this correction the intensity of scattering was plotted as a function of pressure. The decrease in scattering per gm at 200 lb/sq. in. over that at small pressures was taken as the absorption correction.

Comparison of hydrogen at 200 pounds pressure with oxygen at 40 pounds pressure, taking account of the difference in pressure and making only a very slight absorption correction, gave results in very close agreement with those of the first method.

* Equation (1) gives the classical value only when all the scattered radiation is modified. In the case of oxygen, neon and argon the unmodified radiation must also be considered. Compton (ref. 1) has shown how the classical value of S can be gotten in this case.

The hydrogen curve was corrected to a wave-length of 0.71A by a method shown by the curves of Fig. 6. The curves are: I, hydrogen with general radiation; II, oxygen with general radiation; and III, oxygen taken with $\lambda=0.71\text{\AA}$ and arbitrarily fitted to the other oxygen curve at 90° . From these curves the intensity of scattering from hydrogen for $\lambda=0.71\text{\AA}$ was determined.

Fig. 6. Curve I hydrogen (general radiation), Curve II oxygen (general radiation), Curve III oxygen (filtered radiation, $\lambda=0.71\text{\AA}$).

HELIUM

The helium came in liter containers at atmospheric pressure and was introduced into the chamber by means of the mercury pump described above. The pressure used was about 115 lb/sq. in. A number of sets of readings were taken and the intensity compared directly with hydrogen. The intensities of scattering from hydrogen and helium at 90° were found to be equal within the experimental error. Curve II, Fig. 5 shows the scattering per electron from helium corrected to $\lambda=0.71\text{\AA}$ in the same manner as for hydrogen.

In introducing the helium into the chamber about 0.9 percent of air by volume entered as an impurity. This was found to be the case by measurement of the density after the readings had been taken. Correction was of course made for this and would not lead to any appreciable error because the scattering from air could easily be measured. The data for hydrogen and helium are in very close agreement with the results obtained by Barrett. Although he obtained no excess scattering from hydrogen his data only extended to what corresponds to $\phi=30^\circ$ on the above curve.

NEON

Neon was also obtained in liter containers at atmospheric pressure and was put into the scattering chamber with the aid of the mercury pump.

The intensity measurements were made with filtered radiation and a number of sets of readings taken. In order not to have to evacuate and refill the chamber repeatedly, a sheet of celluloid was used for an intermediate comparison. Comparisons of the intensity from neon were made with the celluloid scatterer and then the chamber was evacuated and filled with oxygen and the comparisons with the celluloid scatterer again made. Corrections were made for the different absorption coefficients, and the results are shown in curve IV,

Fig. 7. $\lambda = 0.71\text{\AA}$. Curve I hydrogen, Curve II helium, Curve III oxygen, Curve IV neon and Curve V argon.

Fig. 7. The scattering per electron from neon at 90° is very nearly that from oxygen. The neon curve begins to rise at larger angles than does the oxygen curve, a difference similar to that between hydrogen and helium.

ARGON

The argon used in these measurements was obtained in a tank with about 0.3 percent impurity. The chamber could be readily filled to any desired pressure directly from the tank. This gas, however, presented greater difficulties than the other gases since its absorption coefficient is so much larger. Fig. 8 shows the relation between intensity and pressure for argon and oxygen. Curves I and II represent respectively the measured intensity from argon and oxygen; curves IV and III represent the values after correction for absorption

has been made. To make the corrections as small as possible and still get sufficient intensity from both oxygen and argon pressures of about 40 to 50 lb/sq. in. were used.

In the case of argon, the comparison of intensity with oxygen was done directly by taking a number of readings with one gas and then refilling the chamber with the other gas with the x-ray tube in operation during the process. Several of these comparisons were made and the pressures varied somewhat to make the absorption corrections more certain.

It is noticeable that in argon the scattering per electron is considerably larger than for the other gases. This would correspond to a greater electron density near the center of the argon atom.

Fig. 8. Curves I and II represent respectively the measured intensity from argon and oxygen curves. Curves IV and III represent the values after correction for absorption has been made.

ERRORS

The largest errors involved in measuring the scattering per electron would probably be those of comparing the scattering from one gas with that of another. In the case of the comparison of the intensity of scattering from hydrogen with that from oxygen the probable error from the mean was about 1 percent. It is likely that there are other errors such as uncertainty of wavelength, measurement of pressure and corrections for absorption which would also amount to about 1 percent. This would mean that the scattering from oxygen would probably be correct to about 2 percent. In comparing neon and oxygen, considering the probable error already mentioned, the uncertainty

in the neon data would be of the order of 3 percent. In argon the large correction for absorption would probably increase the uncertainty to about 4 or 5 percent. In the case of hydrogen and helium the probable error of any point of the curve was about 2 percent.

STRUCTURE FACTOR

Calculation of the structure factors for neon and argon have been made from the relation given by Compton

$$F = Z \left\{ \frac{S - 1}{Z - 1} \right\}^{1/2} \quad (2)$$

where S is the classical value of the scattering per electron, Z is the atomic number and F the structure factor. The values thus calculated are given in Table II. In order to make comparisons between these data and the structure

TABLE II. *Structure factor.*

ϕ	$\left(\frac{\sin \phi/2}{\lambda} \right)$	Neon		Argon	
		S_{class}	F	S_{class}	F
10°	0.123	8.55	9.16	13.90	15.63
15°	.190	6.87	8.08	10.65	13.53

90°	.995	1.17	1.37	2.05	4.49

factors calculated from crystalline reflection it is necessary to correct the latter for the effect of thermal agitation which does not affect the intensity of x-rays scattered from gases.

Some very interesting comparisons have been made by James and others^{4,5} between the crystal reflection data at low temperatures and the structure factors calculated from Hartree's wave mechanics solution of the charge distribution in the K^+ , Cl^- and Na^+ ions. Making temperature corrections and assuming the existence of zero point energy they get structure factor curves which are in good agreement with the theoretical curves.

The values of F from Table II are plotted in Figs. 9 and 10 together with F values from wave mechanics taken from the above mentioned papers.

In Fig. 9 the solid line represents the F curve for Na^+ calculated from wave mechanics and the broken line represents the F values for neon. From a consideration of equation (2) the reason for the apparently large inaccuracies in

⁴ R. W. James and Brindley, Proc. Roy. Soc. A121, 155 (1928).

Fig. 9.

Fig. 10.

the values of F when S is nearly equal to unity can be seen. For neon at $(\sin \phi/2)/\lambda = 1.00$ an error of 2 percent in S gives rise to an error of 9 percent in F .

A more significant comparison between theory and experiment is shown in Fig. 10. The curve represents the average of the F values for K^+ and Cl^- determined from wave mechanics. The circles give the F values from Table II for argon. The agreement is seen to be very satisfactory.

As has recently been shown by Compton⁶ a comparison of these data with that determined from reflection from a crystal of KCl and corrected to 0°K gives a good experimental check of the existence of zero point energy.

CONCLUSION

These data furnish a significant check of Compton's recent theory of the intensity of x-rays scattered from gases and the use of these data for the determination of electron distribution in atoms. The agreement between the F curves of argon and those determined from wave mechanics and also from crystal reflection should give more confidence in the use of these methods for determining the distribution of charge in the atom.

A comparison of the F curves determined by these three methods is also a further check on the existence of zero point energy.

Calculation of the electron distribution curves from these data are now in progress.

In conclusion the author wishes to express his appreciation to Professor A. H. Compton, who suggested this problem, for his continued assistance in its solution.

INTERACTION OF X-RAYS WITH BOUND ELECTRONS

BY AUSTIN J. O'LEARY

COLUMBIA UNIVERSITY

(Received February 28, 1931)

ABSTRACT

I. Change of wave-length of scattered x-rays. A previous analysis of scattered x-rays in this laboratory by means of the double crystal spectrometer showed fine structure in both the unmodified and modified lines. These fine structure lines were interpreted as being due to absorption of an amount of energy equal to the binding energy of the electrons in the scattering substance. Since then, other experimenters have failed to observe this phenomenon in scattered x-rays. The earlier work has been repeated using measuring apparatus having greater stability and sensitivity but with experimental conditions for producing the scattered radiation as nearly as possible like those of the earlier experiments. No fine structure was found though a line of intensity greater than 10 percent of molybdenum $K\alpha_1$ unmodified could have been detected.

II. Change of wave-length without scattering. A change of wave-length ascribed to this type of phenomenon without scattering has been reported by B. B. Ray and R. C. Majumdar. A number of experiments have been performed in an attempt to detect a change of wave-length of this type due to partial absorption of molybdenum $K\alpha_1$ and copper $K\alpha_{1,2}$ characteristic rays in the K -level of carbon. No indication of a modified line was found though a line of smaller intensity than that of the lines reported could have been detected. Two possible sources, other than a change of wave-length, are suggested which may give rise to lines of the type reported.

I. CHANGE OF WAVE-LENGTH OF SCATTERED X-RAYS

DISCUSSION. Spectroscopic analyses have in general shown that when monochromatic x-rays are scattered by matter, the scattered radiation consists of two wave-lengths.¹ An unmodified line appears, having the same wave-length as the incident radiation and a modified line for which the wave-length separation from the unmodified is given by the Compton theory of scattering by free electrons and is

$$\delta\lambda = h/mc(1 - \cos \phi) \quad (1)$$

where h is Planck's constant, m the mass of an electron, c the velocity of light and ϕ the angle of scattering. A theory of scattering by bound electrons was proposed by A. H. Compton¹ in 1924. For the special case in which the recoil electron has zero kinetic energy, the theory predicts wave-length changes given by

$$\delta\lambda = \frac{\lambda^2}{\lambda_s - \lambda} \quad (2)$$

where λ is the wave-length of the incident radiation and λ_s the critical absorption wave-length of the level from which the bound electron is ejected.

¹ A. H. Compton, X-Rays and Electrons, Chapt. IX.

An analysis of scattered x-rays in this laboratory by means of the double crystal spectrometer which gave greater resolution than was hitherto possible with the single crystal methods, gave results which indicated fine structure in both the unmodified² and modified³ lines. The change of wave-length for the fine structure lines found in the unmodified characteristic molybdenum $K\alpha_1$ x-rays scattered at 90° by carbon, beryllium, and aluminum, agreed with that given by Eq. (2). In the case of beryllium, an "anti-Stokes" line was observed but no line in the position of $K\alpha_1$. Similar fine structure lines were reported in the modified radiation scattered by carbon at 155° and beryllium 163° , the wave-length change being given by

$$\delta\lambda = h/mc(1 - \cos \phi) + \frac{\lambda^2}{\lambda_s - \lambda} \quad (3)$$

except that using the estimated angle of scattering, ϕ , the constant h/mc was found to be about 9 percent less than the theoretical value. These fine structure lines were no broader than in the unmodified in spite of the large divergence in ϕ .

Since then, Ehrenberg,⁴ Coster,⁵ and Kast,⁶ using single crystal spectrographic methods failed to observe this reported phenomenon. More recently, the question of scattered radiation was investigated by Bearden,⁷ and Gingrich,⁸ using double crystal spectrometers without finding any indication of fine structure. Bearden analyzed copper $K\alpha_{1,2}$ and silver $K\alpha_{1,2}$ scattered by graphite and aluminum, and Gingrich, molybdenum $K\alpha_{1,2}$ scattered by graphite. They each observed the $K\alpha_{1,2}$ modified lines and found the wave-length separation from the unmodified to be accurately given by Eq. (1), the constant h/mc agreeing with the theoretical value within experimental error.

About the same time, the author repeated the earlier work done in this laboratory using measuring apparatus having greater stability and sensitivity but with experimental conditions for producing the scattered radiation as nearly as possible like those of the earlier work. A brief description of the experiments is given in the following.

Apparatus and method. A double crystal spectrometer of the type developed here, with both crystals set for first order reflection, was used to analyze the scattered radiation. Two slits, 43 cm apart, 15 mm high, and 7 mm wide, defined the direction of the scattered beam with a third slit between the crystals. Power was supplied at 125 volts and 500 cycles to a three kilowatt oil-immersed transformer and the high potential current rectified by means of two kenotrons and a large condenser. The voltage was read on an electrostatic voltmeter.

The ionization chamber consisted of two aluminum cylinders, 10 cm long and 4 cm in diameter, one at positive and the other at negative potential, suspended inside a grounded brass box. The central collecting rods in each were connected together and to the lead from the insulated quadrants of the electrometer. There are thus two ionization chambers connected so that the ionization currents in the two are in opposite directions and tend to balance each other. The leak in each chamber due to natural ionization was almost zero. To minimize the irregularity in the electric field produced by the grounded case, an aluminum cap was placed over the end of each cylinder with a window 2 cm high and 1 cm wide corresponding to a similar pair of windows in the grounded case. The x-ray beam entered one window while in front of the other was placed a small radio-active source behind a shutter. The chamber was filled with methyl bromide to absorb the rays.

The sensitivity of the electrometer was 11,000 mm per volt at 1 meter. The capacity of the system as measured with a string electrometer was 38 e.s.u. distributed as follows: 10 e.s.u. each for the ionization chamber and electrometer with the remaining 18 e.s.u. in the shielded lead wires between the two.

The method of measurement was as follows. The shutter was adjusted until the ionization current produced by the radium source just balanced that due to the background radiation. Rocking curves of the unmodified $K\alpha_{1,2}$ scattered rays were taken by timing the drift over a definite part of the scale. The width at half maximum of these curves was always between 20 and 25 seconds. Then a careful search was made to detect the existence of any other lines by insulating the grounding key for a definite time, say 10 minutes, for each setting of the second crystal and noting the drift if any during that time. Compensation for large backgrounds is unsatisfactory but for the small amount of background radiation present in these experiments, the method proved quite successful. The stability of the system was remarkably good, the drift from the zero position never being greater than 3 divisions during the 10 minutes for each reading.

Scattering from carbon at 90° . A cylindrical tube 6.5 cm in diameter with a molybdenum target was placed just out of line of the slits so that no radiation scattered by the glass could pass through. The tube operated steadily at 62 milliamperes and 45 kilo-volts. Both graphite and paraffin blocks were used to scatter the x-rays and were placed along side of the tube so that the average angle of scattering was about 90° with a fairly large divergence. When paraffin was used, a stream of cold air was blown against it continuously to keep it from being melted by the heat from the tube. In no case was there any indication of a line other than the unmodified $K\alpha_{1,2}$ lines though the method was sufficiently sensitive to detect a line of intensity greater than 10 percent of the unmodified $K\alpha_1$ line. With the radium source removed, readings were taken with and without the carbon, everything else remaining the same. The ionization current was zero with the carbon removed, showing that all the x-rays entering the ionization chamber came from the carbon.

Carbon at 150° , beryllium 154° . A tube was built with molybdenum target and graphite scattering element inside as closely similar as possible to the tube used in the original investigation⁹ of fine structure in the Compton effect. The focal spot was 5 mm wide and 9 mm long and faced a small graphite block supported about 2 cm from the center of the spot. This gave a large divergence in scattering angle, the average being about 150° with a plus or minus divergence of about 15° . A similar tube had a beryllium scattering element with an estimated scattering angle of $154^\circ \pm 18$. The anode in each tube was tilted sufficiently toward the scattering block to insure against any possibility of direct radiation from the molybdenum target and was out of line of the slits so that no radiation from the copper anode itself could come through. This was checked by a photographic method. Curves for the $K\alpha_{1,2}$ lines scattered by graphite were similar to those found for 90° scattering, with no indication of fine structure. An unmodified line of very small intensity was observed from beryllium with no indication of an "anti-Stokes" line. A curve for the modified radiation was not taken in either case but a search was made in the position where the fine structure lines were originally observed without finding any indication of them. The modified radiation apparently formed a very broad hump as would be expected from the divergence in scattering angle.

II. CHANGE OF WAVE-LENGTH WITHOUT SCATTERING

Discussion. A change of wave-length ascribed to this type of phenomenon has been reported by B. B. Ray⁹ at zero angle of scattering, his conclusion being that a change of wave-length of x-rays on traversing matter does occur but without change of direction. He passed x-rays from a metal tube with tungsten filament through carbon soot and air and photographed the transmitted radiation with a Siegbahn spectrograph with calcite crystal. Besides the lines to be expected, several broad and diffuse lines appeared each time on the photographic plate and were interpreted as being due to a change of wave-length of the characteristic lines caused by absorption of an amount of energy equal to that necessary to raise an electron from the K -levels of carbon, nitrogen, and oxygen, to a higher level or remove them from the atom with zero velocity. Lines due to a similar absorption in the L -levels would be expected but could not have been detected with the apparatus. A variety of characteristic wave-lengths was used, all showing the same effect. R. C. Majumdar,¹⁰ working in the same laboratory, has reported a similar effect due to partial absorption of characteristic x-rays in the L_1 level of aluminum.

The following considerations indicate the factors which are important in testing the existence of this phenomenon in the presence of continuous radiation. Suppose monochromatic radiation of frequency ν , and intensity I , falls on a thickness of matter d . Assuming the particular type of absorption mentioned above, the amount of radiation emerging from the matter with

⁹ B. B. Ray, *Nature* **125**, 746 and 856 (1930); *Nature* **126**, 399 (1930); *Zeits. f. Physik* **66**, 261 (1930).

¹⁰ R. C. Majumdar, *Nature* **127**, 92 (1931).

modified frequency $\nu' = (\nu - \nu_k)$ where ν_k is the critical absorption frequency of the K -level, would be:

$$I' = kIe^{-\mu'd} \left\{ \frac{e^{(\mu' - \mu)d} - 1}{\mu' - \mu} \right\} \quad (4)$$

where μ is the linear absorption coefficient for radiation of frequency ν , μ' that for radiation of frequency ν' and k the linear absorption coefficient for this particular type of absorption in the K -level. The absorption due to modification of the frequency ν' itself has been neglected. Taking $\mu = \mu'$, which is approximately true, (4) reduces to

$$I' = kId e^{-\mu d}. \quad (5)$$

This is a maximum for $d = 1/\mu$ which would be the optimum thickness to use if no continuous radiation were present but this is not the case in the experiments under discussion. The continuous radiation is absorbed in the usual way though it is not affected to any extent by the type of absorption under consideration and if I_1 is the incident intensity of the continuous in the region of frequency ν' , then its intensity on emerging is $I_1 e^{-\mu d}$. Thus the ratio R , of the modified line to the background in its neighbourhood, which determines the contrast on the photographic plate is:

$$R = kdI/I_1 \quad (6)$$

and is directly proportional to the ratio I/I_1 and the mass of absorbing material. Conversely, knowing the amount of absorption produced by the absorbing material and the ratios I/I_1 and R , one gets the ratio of the intensity of an observed modified line, or of one which might be observed, to the intensity of the incident radiation producing it. This is given by

$$\frac{I'}{I} = R \cdot \frac{1}{I/I_1} \cdot e^{-\mu d}. \quad (7)$$

To test the existence of this phenomenon, the following requirements should be observed:

- (1). The mass of material producing the effect should be as large as possible. This is, of course, limited by the time of exposure and the intensity of the radiation.
- (2). The ratio I/I_1 should as far as possible be a maximum. This is determined for the most part by the operating voltage which should be high since the ratio increases with the voltage. Impurities in the target reduce this ratio and also extraneous scattered radiation if the plate is not properly shielded.
- (3). To eliminate errors, photographs should be taken with and without the absorbing material in place before concluding that any lines observed are produced by its presence.

When a fixed crystal method is used, with a single narrow slit to give resolution and the x-ray beam having the necessary divergence in angle for

reflection of different wave-lengths, each wave-length comes from a different part of the target and errors may arise if the distribution of intensity over the target is not uniform. A pin-hole and a narrow-slit photograph of the target of one of the x-ray tubes with coil filaments used in this laboratory is shown in Fig. 1 and shows clearly the image of the filament coils on the target. Similar photographs of the targets of many other tubes were taken and showed widely different patterns, the particular distribution of intensity depending on the shape and position of the filament, filament cup, and anode. In no case was the distribution of intensity uniform. After reflection of the x-rays from a crystal, the characteristic lines appear on a background having the same pattern as that given by a narrow slit photograph of the target. If the distance from the narrow slit to the photographic plate is short enough, in comparison with the distance to the target, lines, not much broader than the characteristic lines, might appear on the plate and be erroneously interpreted. The tube used by Ray was of the heated filament type and it is possible that the lines observed by him, in every case broad and diffuse, were really due to lines in the target which accidentally appeared in a position where they might be given the interpretation he gave them. Also if the narrow slit is not close to the crystal, each wave-length is reflected from a different part of the crystal and there is the possibility of error due to imperfections in the crystal face. No statement was made as to whether or not photographs were taken with and without the absorbing material in place or other precautions taken to eliminate the possibility of such errors.

In the discussion Ray has assumed, without explaining how he arrived at the figure, that the intensity of the new lines, as compared with that of the primary, is only of the order of one in 400 or 500. However his photographs show that the intensity of these new lines above the background is at least as intense as the background (i.e. $R \geq 1$) and since the ratio of the intensity of the primary line to the background (I/I_1) is not likely greater than 50, Eq. (7) requires that the amount of absorbing material must have been sufficient to absorb 90 percent of the incident rays. The mass of absorbing material has not been given but it is unlikely that the amount of nitrogen and oxygen in which the rays were absorbed, was sufficient to produce this amount of absorption. In such case, the intensity of these lines, as compared with that of the primary, would be greater than that given above.

The experiments described in the following were carried out in an attempt to observe a change of wave-length of this type due to partial absorption of molybdenum $K\alpha_1$ and copper $K\alpha_{1,2}$ characteristic rays in the K -level of carbon.

Absorption of molybdenum $K\alpha_1$ in carbon. The change of wave-length predicted for x-rays which suffer absorption of the type considered was given by Eq. (2). For molybdenum $K\alpha_1$ absorbed in the carbon K -level this change would be about 11X.U. The modified wave-length would have a reflection angle from a calcite crystal 6.5 minutes greater than $\text{Mo}K\alpha_1$.

An x-ray tube with molybdenum target, thin glass window, and line focus, was operated at 25 milliamperes and 52 kilovolts peak voltage. Two slits,

0.05 mm wide and 76 cm apart, defined the x-ray beam. A calcite crystal mounted on a spectrometer table with a crystal rocking device reflected the rays to a photographic plate, placed at a distance of 2.4 meters and carefully

Fig. 1. Pinhole and narrow slit photograph of the target of an x-ray tube with coil filament showing the image of the filament coils on the target.

shielded from scattered radiation. This formed a system with high resolving power. The $K\alpha_1$ and $K\alpha_2$ lines were separated by a distance of 3.5 mm on the plate. Compressed lamp black was used to absorb the x-rays and was placed

Fig. 2. Photograph taken with molybdenum target, carbon absorbing material and crystal rocking device to reflect radiation in the neighborhood of a line which would be produced if $\text{Mo}K\alpha_1$ were partly absorbed in the K -level of carbon.

Fig. 3. Microphotometer curve of one of the plates similar to that shown in Fig. 2.

in front of the slit nearest the tube. It was found experimentally that the lamp black absorbed 85 percent of $\text{MoK}\alpha_1$ and that the ratio I/I_1 was 57.

After the crystal had been adjusted and the positions for reflection of $K\alpha_1$ and $K\alpha_2$ carefully determined, the method of procedure was as follows: With the carbon in place, short exposures of $K\alpha_1$ and $K\alpha_2$ were taken to give two reference lines on the plate. $K\alpha_1$ was usually exposed for about 15 minutes and $K\alpha_2$ 30 minutes so that the two lines would have approximately the same intensity. The crystal was then turned through an angle of 6.5 minutes from the setting for $K\alpha_1$ and the crystal rocking device set so that the crystal was rocked over a range of 4 minutes, covering 2 minutes on each side of this central position. Exposures were then taken for periods between 65 and 95 hours.

One of the photographs is shown in Fig. 2. The plates were projected on a screen under high magnification and microphotometer curves of two plates were taken but in no case was there any indication of a modified line. One of the microphotometer curves is shown in Fig. 3. A line of intensity 50 percent greater than the intensity of the background could easily have been observed. By Eq. (7), the intensity of such a line, as compared with that of the incident primary radiation, is one in 750.

The double crystal spectrometer was also used in a search for this modified wave-length. Direct radiation from a molybdenum tube, operating at 7 milliamperes and 37 kilovolts, was passed through the compressed lamp black. The ratio I/I_1 in this case was 75 and a line of intensity 15 percent greater than the continuous radiation could easily have been detected but no indication of such a line was found. In this case then, the intensity of a line that could have been observed as compared with that of the primary is, by equation (7), one in 3000.

Absorption of copper $K\alpha_{1,2}$ in carbon. The change of wave-length predicted for copper $K\alpha_1$, undergoing this particular type of absorption in the K -level of carbon, is about 55 X.U. and the reflection angle from a calcite crystal for this modified wave-length would be 33 minutes greater than for $K\alpha_1$. In this experiment the crystal rocking method was not used. Pin-hole and narrow slit photographs of two tubes with copper targets showed them to be unsuitable for a fixed crystal method. One target however showed a band of uniform intensity which was suitable for the purpose provided the rest of the target was blocked out. This was done by means of two slits 20 cm apart. The slit nearest the lead box was 0.04 mm wide and the width of the other slit and the position of the tube, were adjusted until the radiation coming through formed a beam of uniform intensity with a divergence of about 44 minutes.

The tube was operated at 30 milliamperes and 52 kilovolts peak voltage. The carbon used was a uniform slab of graphite of a thickness which absorbed 70 percent of the $K\alpha$ rays. It was interposed in the beam at the slit nearest the tube. The photographic plate was placed 75 cm from the crystal and was carefully shielded so that no radiation could strike it except that from the crystal.

The central positions of the crystal for reflection of $K\beta$ and $K\alpha_{1,2}$ were determined. Then with the graphite in position short exposures were taken of $K\beta$ and $K\alpha_{1,2}$ and a 24-hour exposure taken with the crystal set at an angle 33 minutes greater than the central position for reflection of $K\alpha_1$. Photographs were also taken without the graphite in place and were exactly similar to those taken with. In no case was there any indication of a line. The method was however not entirely satisfactory since each wave-length was reflected from a slightly different portion of the crystal and the band on the plate was somewhat patchy due to imperfections in the crystal face. One of these photographs is shown in Fig. 4.

Fig. 4. Photograph with carbon absorbing material and fixed crystal, using the radiation from only that portion of a copper target which gave uniform intensity. Narrow slit was 25 cm from crystal.

Fig. 5. Photograph similar to that shown in Fig. 4 except that narrow slit was close to crystal.

This objectionable feature was eliminated from the next set of photographs. The slit nearest the tube was reduced in size to 0.04 mm. In order that the divergence in angle from the small portion of the target giving uniform intensity, be large enough to give a band of the desired width on the photographic plate, the distance between slits was reduced to 5 cm and the tube moved up as close to the opening in the lead box as safety would permit. The width of the slit nearest the tube, and the position of the tube, were adjusted until the radiation coming through was only that from the portion of the target which gave uniform intensity. The short distance between slits made this difficult but it was finally accomplished. The divergence in angle of the beam was this time about 28 minutes. Each wave-length was reflected from closely the same part of the crystal and conditions were very favorable for observing a modified line.

Photographs were taken with and without the carbon in place as an added precaution against error, the time of exposure varying between 20 and 35 hours. One of the photographs is shown in Fig. 5. A microphotometer curve

of the band on the same plate is shown in Fig. 6. In every case the band was perfectly uniform with no indication of a line. A line of intensity of the order of one in 800, as compared with that of the primary, could easily have been detected.

Another set of photographs was taken using the radiation from the whole target. The distance from the narrow slit to the tube was small enough in comparison with the distance to the plate that any lines in the focal spot

Fig. 6. Microphotometer curve of band on plate shown in Fig. 5.

would appear broad enough on the plate that they would not be confused with the characteristic lines. One of the photographs is reproduced in Fig. 7. On the original, three broad and diffuse lines can clearly be seen in the position marked *X* due to lines in the focal spot which might cause error, were not their true origin known. The tungsten lines are due to evaporation from the filament and the nickel lines from the nickel used in spot welding the

Fig. 7. Photograph taken with fixed crystal, no absorbing material, and narrow slit close to crystal, using radiation from the whole copper target. Three broad and diffuse lines due to lines in the target are marked by an *X*.

filament cup. Photographs were again taken with the carbon absorbing material in place and showed no indication of a modified line due to absorption.

III. SUMMARY OF RESULTS

An analysis, by means of the double crystal spectrometer, of characteristic molybdenum $K\alpha_1$ x-rays scattered by carbon and beryllium, has failed to show

the existence of fine structure lines due to absorption of an amount of energy equal to the binding energy of the electrons in the scattering substance. The method was sufficiently sensitive to detect a line of intensity greater than 10 percent of molybdenum $K\alpha_1$ unmodified. This is in agreement with the results of all other experimenters since the fine structure was first reported.

An analysis of x-rays transmitted through carbon has failed to show a similar change of wave-length without scattering, as certain lines observed by Ray and Majumdar were interpreted. For molybdenum $K\alpha_1$ absorbed in carbon, a line of intensity of the order of 1 in 750, as compared with the intensity of the incident primary radiation, could have been detected with the single crystal method, and a line of the order of only 1 in 3000 with the double crystal spectrometer. For copper $K\alpha_{1,2}$ absorbed in carbon, a line of the order of 1 in 800 could have been detected. In discussing his results, Ray assumed that the intensity of the new lines as compared with the intensity of the primary, was of the order of 1 in 400 or 500. Thus the present experiments were sufficiently sensitive to detect a line of considerably less intensity. Two possible sources are suggested which may give rise to lines similar to those observed by Ray and ascribed to this absorption phenomenon.

In conclusion, the author wishes to express his indebtedness to Professor Bergen Davis for his interest in this work and for full privileges in his laboratory, and to the authorities of Columbia for a University Fellowship.

PHOTOELECTRIC PROPERTIES OF COMPOSITE SURFACES
AT VARIOUS TEMPERATURES AND POTENTIALS

BY DIMITER RAMADANOFF

DEPARTMENT OF PHYSICS, CORNELL UNIVERSITY, ITHACA, NEW YORK

ABSTRACT

Experiments designed to determine the variation of photoelectric current with temperature and plate potential for barium photoelectric cells are described. The technique used in making the cells is also given. A new method, employing interrupted illumination, a transformer coupled amplifier and a cathode ray oscillography, is developed for measuring the photoelectric current. In this way the thermionic current and currents of slow response are completely eliminated and only the a.c. component of the photo-current is amplified.

Experimental results. With constant plate voltage the photoelectric current increases gradually with temperature and at about 600°C is nearly twice as large as the current at room temperature. As the temperature however is raised from 600°C to 750°C the increase in photoelectric current for steady illumination is 100-fold while for interrupted illumination it is only 17-fold. The smaller increase in the latter case may be explained in view of the elimination of all sluggish currents produced by light in some secondary way. While the two curves for steady and interrupted illumination are similar in appearance, the latter has a maximum at 560°C which resembles very much a resonance peak.

The increase or decrease in photoelectric sensitivity with temperature for composite surfaces consisting of barium and oxygen on platinum may be explained by the diffusion of barium or oxygen on the surface. The increase in saturation voltage of the potential-current curves with temperature may likewise be explained by an increase in the contact potential brought about by a change in the work function.

INTRODUCTION

THE variation of photoelectric current with temperature for both oxides and pure metals has been studied by a number of investigators. Merritt¹ found that the photoelectric current obtained by illuminating the oxide-coated filaments of Western Electric audion bulbs increased in some instances 1400 times as the temperature of the filament was raised from that of the room to dull red heat. Large increases of photoelectric current with temperature for filaments coated with various oxides were also reported by Koppius,² Crew,³ Berger,⁴ Newbury,⁵ and others. Similarly for pure metals Du Bridge⁶ and Warner⁷ using platinum and tungsten respectively have measured an increase in the photoelectric current with temperature. In all of these

⁷ A. H. Warner, Phys. Rev. 33, 815 (1929).

instances however, both the oxide-coated and the pure metal filaments were poor photoelectric and good thermionic emitters and consequently a number of difficulties were encountered. The photoelectric current at room temperatures was small, while at the higher temperatures the thermionic current was large and in most cases masked the whole photoelectric phenomenon. Moreover in the investigations referred to the photoelectric current was measured with no regard to time response, for which Lawrence and Beams⁸ have reported a value of 3×10^{-9} second. Sluggish currents which may have been present with the photoelectric current are attributed to the true photocurrent. In this connection Bodemann,⁹ who has studied the photoelectric emission from filaments coated with the oxides of Ba and Ca at various temperatures, has named the increase in photoelectric current with temperature "addition current." This "addition current" he explained as due to the action of light on the negative space charge adjacent to the cathode. According to this view the "addition current" is to be regarded as nothing else than an increase in the thermionic current. Such currents however should be expected to have considerable time lag and are hardly to be regarded as true photoelectric currents.

The present investigation was undertaken for the purpose of studying the variation of the photoelectric current with temperature for barium photoelectric cells with both continuous and interrupted illumination. The barium cells were constructed in a manner similar to that described by Case.^{10,11} It was felt by the author that the barium cells were particularly suited for the study of the above mentioned phenomena not only because they were remarkably sensitive to ordinary visible light, but also because Case¹⁰ has already observed a 100-fold increase in the photoelectric current as the temperature of the cell was raised to just under dull red heat. The determination of the variation of the photoelectric current with temperature with and after eliminating all sluggish currents with rapidly interrupted illumination and proper filter circuits, forms the chief endeavour of this investigation.

APPARATUS

a. **Vacuum system.** The vacuum system consists of two liquid air traps, a two-stage mercury diffusion pump and a Cenco oil pump. No stopcocks were used on the high vacuum side. The McLeod gauge which was made entirely of glass is sealed between the liquid air traps and the mercury diffusion pump. The high vacuum side was made as short as possible with tubing of large diameter. Pyrex glass was used for the whole system and for convenience it was mounted on a rigid metal frame. This latter arrangement permitted a complete torching of the entire high vacuum side before the photoelectric cells were made.

b. Photoelectric cells. In the experiments to be described later several cells of slightly different construction were used. The most photoelectric typical cells are shown in Fig. 1 and Fig. 2. The glass of the cell in Fig. 1 is made of Pyrex and quartz joined together by means of a graded seal. No cement joints were used at any time with the photocells. In this particular cell the anode *F* consists of an oxide-coated Western Electric filament which was spot-welded to two tungsten leads. A thin platinum strip *P*, about 3 mm wide and 2.5 cm long, was similarly welded to another pair of tungsten leads, and served as cathode. These latter leads were made of two different sizes of tungsten wire. The finer leads were so selected as to reduce the cooling at the ends of the platinum strip which was heated by passing a current through it

Fig. 1. Diagram of photoelectric cell made of Pyrex and quartz joined with a graded seal.

Fig. 2. Photograph of a typical photoelectric cell made entirely of Pyrex glass.

from a storage battery. Provision was made to measure the potential drop across the platinum strip in order to determine its temperature. For this purpose two fine platinum filaments were welded across the plate and the center pair of tungsten leads. All tungsten wires were sealed directly through the Pyrex.

No efforts were spared in thoroughly outgassing the cells before the photo-sensitive material was deposited. Three electric ovens were used to bake out photocells together with the traps and the few centimeters of adjoining tubing. The temperature of the ovens was kept constant at 550°C for more than 24 hours. In the meantime the McLeod gauge and the remaining glass on the high vacuum side were thoroughly torched. During the bake out, the filament *F* and the plate *P* were heated several times to yellowish-red colour.

Great care was also used in preventing any mercury vapor from getting into the cell. While the cell and the trap next to it were kept at 550°C , the oven of the second trap was removed and liquid air applied. Liquid air was then applied to the next trap, and finally the oven of the cell was removed. In making some of the cells a charcoal trap immersed in liquid air was used next to the cell to improve the vacuum still further. In most cases however the burning of thoriated tungsten filaments was found to be most satisfactory. With all these precautions taken, the pressure was not greater than 10^{-7} mm of Hg.

During the process of making the photoelectric cells the functions of the electrodes are reversed. The filament F is heated to a temperature of about 1100°C or more and is used as a source of thermionic current. At the same time the platinum strip P is used as anode and its potential with respect to the filament is gradually increased to 400 volts or more. For several minutes the thermionic current is very small, but as soon as the filament is "activated" or "broken down," the thermionic current increases greatly and the plate voltage and filament temperature have to be reduced until the emission current is limited to a safe value. Then by varying the plate voltage from 200 to 700 volts for various filament temperatures a condition is finally reached when barium or oxygen, or both begin to evaporate from the filament and deposit on the plate. Soon the plate becomes coated with a very thin layer of deposit which has a brownish appearance. The plate so coated is remarkably sensitive to light and is used as the emitter of photoelectrons, while the filament serves as collector. That the evaporated material is barium and oxygen on platinum seems very likely in view of the recent work of Becker¹² who found that metallic barium evaporates from an activated oxide-coated filament if the temperature is not too high and if the emission current is small. He also found that oxygen evaporates if the temperature is high enough and if the thermionic current is limited not by space charge but by emission. Since the conditions under which the photoelectric cells were made correspond to those described by Becker it seems very likely that oxygen and barium evaporated either simultaneously or consecutively. In such a case one would expect the sensitivity of the cell to vary, in analogy with the thermionic emission, with the relative position of barium and oxygen with respect to the platinum. As will be seen later this seems to be the case in most of the experiments. If the oxide-coated filament is heated during the making of the cell to a very high temperature barium oxide evaporates. A cell which was made in this way gave no measurable current with the sensitive galvanometer in use.

At the present time there seem to be two different opinions as to the mechanism of production of barium from an oxide-coated filament. One view maintains that the oxide dissociates by a thermal reaction, while the other view favors the production of barium through electrolysis of the oxide. In this connection it may be of interest to mention that a photoelectric cell can be made by merely heating the oxide-coated filament i.e. without applying

¹² J. A. Becker, Phys. Rev. 34, 1323 (1929).

any voltage. Under this condition however the "breaking down" of the filament is rather slow and the temperature to which the filament should be heated is much higher. The result is that mostly barium oxide evaporates and the cell so made is rather insensitive to light.

The filaments of most of the photoelectric cells were coated with oxide by rubbing barium nitrate crystals on a red hot platinum-iridium ribbon, or by dipping the ribbon several times in a solution of barium nitrate. These filaments were more desirable than the commercial type because the oxide coating consisted mostly of barium oxide with traces of strontium and calcium oxides. The photoelectric cells which were made with these filaments were sensitive, not only to the ultraviolet light but also to visible light. This latter feature was particularly desirable because it made the use of the quartz mercury arc unnecessary.

Fig. 3. Disk used to interrupt the light falling on the photoelectric cell.

It was found best to make the photocells after they are sealed off. If a cell is made while on the pumps its sensitivity decreases considerably in the course of time. This shows how detrimental traces of gases are to the sensitive material.

c. Source of illumination. As already mentioned the cells which were made with the Western Electric oxide-coated filaments were sensitive only to the ultraviolet light and therefore a quartz mercury arc was used for a light source. In all cases the total radiation from the light was allowed to fall on the cell. The intensity of the light remained remarkably constant after the lamp had reached its operating temperature.

¹³ For a detailed description of the disk, the amplifier and their use in connection with the photoelectric cells and the cathode-ray oscillograph see: "A Method of Studying the Effect of Temperature on Photoelectric Currents," D. Ramadanoff, R. S. I. 1, 768 (1930).

For the interrupted illumination¹³ an incandescent lamp was used. The filament of a 500-watt projection lamp was focused on the platinum strip of the cell. Between the cell and the source were situated a water cell, a shutter, and a revolving disk. The disk shown in Fig. 3 has twenty holes around its periphery. The shape of the holes is of the form $y = \sin^2 x$. It is easy to see that the light passing through these holes, as the disk revolves at constant speed, will vary sinusoidally and will give approximately a sinusoidal photoelectric current superimposed on a d.c. current. Each hole of the disk gives a complete cycle of the a.c. wave.

d. Measuring instruments and method. The photoelectric current was measured with two different sets of apparatus both of which are shown diagrammatically in Fig. 4 and Fig. 5. Two galvanometers having current sensitivities of 2.96×10^{-10} and 3.4×10^{-9} respectively were used. The difference

Fig. 4. Circuit diagram of photoelectric cell and galvanometer used to measure the current produced by steady illumination.

in the galvanometer deflections obtained with the light on and off were recorded as true photoelectric currents. In most cases the thermionic current was not balanced because the photoelectric current was large and was read with no difficulty. One of the photoelectric cells which was used in the experiments gave $0.592 \mu\text{a}$ saturation current with the plate cold, when the light from 150-watt lamp was focussed on the cell. It is evident from the brief description of the circuit that with the galvanometer only the total current due to light can be measured. Sluggish currents which may be due to light in some secondary way cannot be distinguished from the true photocurrents which are characterized by a very short time response.

The circuit in Fig. 5 was designed to eliminate the thermionic current and any sluggish currents which may be present, and to amplify only the true photocurrents.¹³ After two stages of amplification the current is impressed on one pair of plates of a "Bedell-Reich Stabilized Oscilloscope," a visual cath-

ode-ray oscillograph. The deflections of the cathode spot indicate on the fluorescent screen not only the wave shape of the current but also its magnitude. From measurements of the amplitude of the voltage wave the photo-current can easily be determined. A photograph of the a.c. wave as it appeared on the screen is shown in Fig. 6. In this particular case a disk with circular holes was used and therefore the wave shape of the photoelectric current is not sinusoidal.

Fig. 5. Circuit diagram of photoelectric cell, amplifier and cathode-ray oscillograph used to measure the current produced by interrupted illumination.

The temperature of the photoelectric material was varied by passing various currents through the strip. By measuring the potential drop across the platinum strip, it was possible to determine its change in resistance and therefore its temperature. At the higher temperatures an optical pyrometer was used as a check. During the photoelectric measurements the heating cur-

Fig. 6. Photograph of a.c. wave as it appeared on fluorescent screen.

rent was not interrupted since it was found that the oscilloscope deflections were the same whether the heating current was on or off provided that the temperature of the strip did not change when the photoelectric current was measured. The oscilloscope was particularly useful for eliminating this difficulty since the response of the cathode spot is practically instantaneous. Such an observation would have been impossible with the ordinary galvanometer or electrometer. It is of interest to notice that this result is contrary to the hypothesis of Shenstone¹⁴ who suggested that the change in photoelec-

¹⁴ A. G. Shenstone, *Phil. Mag.* 45, 918 (1923).

tric sensitivity was due to changes in the metal which were produced by the current flowing through it.

EXPERIMENTAL RESULTS

A. MEASUREMENTS MADE WITH GALVANOMETER*

a. **Potential-current saturation curves.** Fig. 7 shows the variation of photoelectric current with potential applied between the electrodes when the light intensity is kept constant and the photoelectric surface is at room temperature. The low saturation potential and the reproducibility of the photoelectric current with both increasing and decreasing potentials is typical of all photoelectric cells used in the experiments. This latter feature is clearly indicated on the curve with large and small circles, the large circles being used for increasing potentials.** It is also easy to see from this curve that the

Fig. 7.

photoelectric current saturates as well as can be expected of a cell with a composite surface. In the experiments the plate potential was increased to 300 volts which is about 40 times the saturation potential and produces a gradient between the electrodes of more than 1000 volts per cm. But even at these high potentials the photoelectric current remained substantially constant.

In Fig. 8 is shown a family of saturation curves for constant illumination and for different temperatures of the photoelectric surface. The values of the photoelectric current for increasing and for decreasing potentials are so closely identical that they are represented by single curves. The thermionic current at the temperatures at which the curves were obtained was either small or zero. The saturation potential of all three curves increases with

* Under this heading the photoelectric current is defined as the difference in galvanometer deflections with the light on and off. In all cases the total radiation from the lamp was used.

** This notation is used for all curves.

temperature, i.e., the saturation points are shifted to the right. This experimental evidence is just the opposite of what has been reported by Crew³ who found that the saturation potential decreases as the temperature of the photoelectric surface is increased. That the shift should be as in Fig. 8 is evident from the fact that the contact difference of potential changes with a change in the work function. If the thermionic current however is large and the emission is limited by space charge then the increase in saturation potential with temperature will be greater and will be due partly to the increased space charge.

Fig. 8.

From the curve in Fig. 8 it is also evident that the photoelectric current increases with temperature. This increase in emission can be accounted for qualitatively by the relative position of barium and oxygen with respect to the platinum. The experiments which were performed to obtain these and other curves seem to indicate that the decrease in activity of the photoelectric material at room temperature is due to the negatively charged oxygen ions which have diffused to the surface on top of the barium layer. Since the photoelectrons come from the barium the strong surface field of the oxygen will tend to hinder the emission. But as the temperature of the plate is increased, more and more barium diffuses to the surface and exchanges place with the oxygen. Beyond this point any further increase in temperature

should not increase the emission. As will be seen later temperature-current curves were obtained which tend to show that this is probably the case.

Another possible explanation is that the light acts not only on the barium layer but also on the negative adsorbed oxygen ions and changes them to neutral atoms. Under this condition the photoelectric and thermionic emission will increase with light. In this connection Bodemann⁹ seems to maintain that the total increase in the photoelectric emission with temperature is due to the action of light on the negative space charge and he calls this increased current "addition current," which in reality is nothing else than an increase in the thermionic current. It is hard to believe however that the total increase in current due to light is thermionic, because currents which are produced indirectly by the action of light on a negative space charge

Fig. 9.

should be expected to have considerable time lag. As will be seen later experiments were performed to prove this point by the use of rapidly interrupted illumination.

A group of saturation curves which in all respects are similar to those in Fig. 8 are shown in Fig. 9. These curves however were obtained with a different photoelectric cell the anode of which was built in the form of a squirrel cage by welding fine thoriated tungsten wires on two nickel rings. The filament wires were spaced two mm apart and could be heated to incandescence by passing current from one ring to the other. In this way the anode served not only as collector but also as a "getter."

b. Variation of photoelectric current with temperature at constant plate potential. The curve in Fig. 10 brings out many interesting points which were not evident from the previous curves. In spite of the fact that this curve was taken when the total radiation of the mercury arc shone on the cell, its general appearance has a striking resemblance to the curves reported by War-

ner⁷ for pure tungsten with monochromatic illumination. The curve shows that at 800°C the photoelectric current reaches saturation and is at this temperature about 100 times greater than the photoelectric current at room temperature. The fact that the emission increases only slightly until a temperature of 600°C is reached, seemingly confirms the hypothesis that the increased activity is due to the diffusion of barium to the surface. It is particularly significant, in view of the low melting point of barium (850°C), that the greatest increase in photoelectric current occurs between the temperatures of 600°C and 750°C.

Fig. 10.

B. MEASUREMENTS MADE WITH CATHODE RAY OSCILLOGRAPH

a. Variation of photoelectric current with temperature at constant plate potential. In this group of experiments three photoelectric cells were tested and found to exhibit the same general characteristic. The curve in Fig. 11 was obtained by varying the light intensity sinusoidally with a frequency of 1000 cycles per second. The thermionic current, the d.c. component of the fluctuating photoelectric current, and all sluggish currents were completely filtered out. Only the a.c. component of the photoelectric current was allowed to pass through the amplifier. The sluggish currents were noticeable in the measurements only when the frequency of the interrupted light was

reduced to a few cycles per second. The data for the curve in Fig. 11 were obtained by measuring the amplitude of the a.c. wave on the fluorescent screen of the cathode ray tube. This curve is very similar to that shown in Fig. 10 except that the maximum and minimum values differ by a factor of 16 instead of 100. The peak at 560°C suggests a resonance phenomenon and was reproducible with both increasing and decreasing temperatures as shown by the large and small circles on the curve. The curve further shows that the optimum emission occurs at 750°C . Above this temperature the photoelectric emission decreases gradually. This decrease may be caused either by the diffusion of more barium ions which increase the surface concentration be-

Fig. 11.

yond that necessary for the optimum emission, or else by the reappearance of oxygen ions. It is doubtful if this decrease is caused by the evaporation of barium or oxygen ions since thin adsorbed layers will adhere to the platinum surface at high temperatures much better than thick, heavy coatings.

It is of interest to obtain potential-current curves as in Fig. 8 and Fig. 9 with interrupted illumination. It is of particular interest to determine what effect the sluggish currents will have upon the long wave-length limit of the photoelectric surface used. At the present time the apparatus is not sensitive enough to permit such measurements.

DISCUSSION

The increase in photoelectric emission with temperature from composite surfaces containing barium and oxygen on platinum cannot be explained

satisfactorily by surface gas contamination. The activity of such surfaces depends not only on the surface concentration of metallic barium and oxygen, but also on the relative position of the two. It is unlikely that the thin adsorbed layers of oxygen and barium will leave the surface without using very high temperatures which will distill off the photoelectric material and ruin the cell. Most of the oxygen on the surface due to its strong electron affinity is negatively charged. The barium which diffuses on the surface at the higher temperatures changes the intensity and the distribution of the surface fields and as a result changes the work function. This change in work function produces a change in the contact differences of potential which manifests itself in an increase of the saturation potential with temperature if the thermionic current is small. When large thermionic current limited by space charge is present the increase in saturation potential with temperature is caused also by the increase in space charge.

Any increase in thermionic current which may be caused by the heat rays of the light source or by the influence of the light alone in some secondary way should not be regarded as a true photoelectric current. The experiments with the oscillograph show definitely that part of the increased emission due to light at the higher temperatures is not caused by such secondary effects but is due to an increase in the photoelectric current. This finding is contrary to the results obtained by Bodemann. The increased photoelectric current is independent of the frequency of light interruptions for the range used from 500 to 1000 cycles per second.

The author is deeply indebted to Professor Ernest Merritt for suggesting the problem and for his many valuable suggestions and helpful criticism, and to Professor Frederic Bedell for his general interest in this investigation and for providing the Oscilloscope and other facilities in connection with the work. He also gratefully acknowledges the benefits derived from discussions with Dr. J. A. Becker and Professor H. A. Barton. For the construction of the glass apparatus thanks are due to Mr. H. W. Banta.

THE ENERGY OF DISSOCIATION OF MERCURY MOLECULES

By J. GIBSON WINANS

DEPARTMENT OF PHYSICS, UNIVERSITY OF WISCONSIN

(Received March 5, 1931)

ABSTRACT

The absorption spectrum of mercury vapor in the Schumann region showed three apparently continuous bands with maxima at wave-lengths 1849, 1808, and 1692. The 1849 and 1692 bands appeared without the 1808 band in the emission from an electrodeless discharge through mercury vapor. The absorption spectrum in the region 1900-1804 is correlated with a pair of potential energy curves for Hg_2 . From these curves, the energy of dissociation of Hg_2 is 0.15 volts.

INTRODUCTION

THE problem of the energy of dissociation of mercury molecules is particularly interesting because, as far as chemical evidence is concerned, mercury molecules do not exist. For example c_p/c_v for mercury vapor is 1.666, the value for a purely monatomic gas. Also the molecular weight of mercury vapor equals that of liquid mercury.¹ Nevertheless mercury molecules exist in both the excited and unexcited states as evidenced by the presence of bands in the absorption and emission spectra of mercury vapor.²

The binding force between two mercury atoms must be similar to that between two helium atoms since both have a closed outer shell containing two paired s electrons. So far three types of binding for diatomic molecules have been proposed; ionic as in NaCl , exchange forces as in H_2 , and polarization or van der Waal's forces. The binding between neutral mercury atoms can not be ionic, and Heitler and London³ have shown that the exchange forces between helium-like atoms must be repulsive if the Pauli exclusion principle holds. There remain only the polarization forces to hold the mercury molecule together. The analysis of Eisenschitz and London⁴ has shown that the polarization forces may, at large separations be greater than the exchange forces and produce a definite equilibrium when the exchange forces are repulsive. Mercury molecules are probably of this type.

Values for the energy of dissociation of mercury molecules have been obtained by Koernicke⁵ and Mrozowski.⁶ Koernicke, following the work of Franck and Grotrian,⁷ measured the change in total intensity of the mercury

band at 2540 with superheating and calculated the energy of dissociation of Hg_2 as 1.4 kg. cal./mol. or 0.06 volts. Mrozowski measured the total intensity of fluorescence in mercury vapor at different positions along the direction of the exciting light. He obtained the absorption coefficient of saturated mercury vapor at different temperatures for several exciting wave-lengths. Assuming this coefficient proportional to the number of Hg_2 molecules, he calculated D for Hg_2 as 17 kg. cal./mol. Koernicke's and Mrozowski's values differ by a factor 12. The two methods will be discussed in detail in a later paper.

The results of the present investigation give a value for D for Hg_2 which lies between the two above mentioned but is quite different from either. The method is the same as that used to obtain D for Zn_2 and Cd_2 .⁸ The value of D comes from an interpretation of the absorption region in the vicinity of the resonance line $1^1\text{S}-2^1\text{P}$. This line comes at wave-length 1849 for mercury.

APPARATUS AND PROCEDURE

The absorption spectrum of mercury in the region 3000–1550 was photographed with a small vacuum fluorite spectrograph on Schumann plates. The absorption cell, shown in Fig. 1, was made of fused quartz. The windows were

Fig. 1.

very thin to give increased transparency and hemispherical in shape to withstand atmospheric pressure. The cell was heated in an electric furnace. A hydrogen discharge tube served as a source of continuous light.

For photographing the emission spectrum of mercury, the cell of Fig. 1 was waxed to a tube leading to the spectrograph, a wire wrapped around each end, one wire grounded and the other connected to a low-voltage Tesla coil (leak chaser). When the tube was heated by a bunsen burner, a brilliant mercury discharge was obtained. CO bands from a discharge through air were used as standards for wave-length measurements.⁹

RESULTS

The absorption spectra taken with increasing pressures of mercury vapor (Fig. 2) show first the atomic line 1849 which broadens rapidly, then a continuous band with a maximum intensity at 1808 Å (Fig. 2 No. 1) and finally another continuous band with maximum at 1692 (Fig. 2, No. 2), Fig 3 is a microphotometer record of Fig. 2 showing the 1692 band. Fig. 2, No. 2 shows how, at increased pressure the 1808 band is broadened principally toward

⁸ J. G. Winans, *Phil. Mag.* 7, 555 (1929).

⁹ T. Lyman, *Astrophys. J.* 23, 204 (1906); "The Spectroscopy of the Extreme Ultraviolet," p. 114.

longer wave-lengths and the absorption region surrounding 1849 broadened toward shorter wave-lengths as far as the 1808 band but no farther, and toward longer wave-lengths beyond 2200 Å. The lack of intensity below 1690 in No. 1 Fig. 2 was due to short exposure and not to absorption.

Fig. 2.

Fig. 3.

In the emission spectrum from the electrodeless discharge (Fig. 2, No. 3), the band surrounding 1849 and the one at 1692 were observed but not the one at 1808. The distribution of intensity in the 1692 band was the same in emission and absorption (Fig. 3).

TABLE I.

Description	Wave-length	Vacuum wave-number
Absorption maximum	1691.4	59123
Emission maximum	1692.1	59097
average	1691.8	59110
Absorption maximum	1808.0	55311
*Short wave limit	1804.2	55427

* The wave-length was measured at the point where the photographic blackening from the source had been reduced to one half.

Table I gives a summary of results. Wave-lengths previously given (Phys. Rev. 36, 1020(1930) should be corrected to agree with Table I.

DISCUSSION

The continuous bands at 1808 and 1692 do not coincide with atomic transitions and are observed only at pressures much greater than that needed to show the atomic line 1^1S-2^1P . They are therefore attributed to molecules of mercury and these molecules are assumed to be diatomic. The characteristics of these bands as described above can be correlated with a set of potential energy curves for the Hg_2 molecule.

The band at 1808 was observed in absorption but not in emission in the electrodeless discharge. In the spectra of atoms, absorption lines are sometimes missing in emission because they are absorbed by the vapor surrounding the source. This can not be the case for the 1808 band; since, from the

order of appearance of the bands with increasing pressure, the absorption coefficient of the missing band 1808 lies between that of the two bands at 1849 and 1692, both of which were observed in emission. A probable reason for the non-appearance of 1808 in emission is that the Hg_2 molecule is dissociated upon absorption of this wave-length. If this is true, the curves of potential energy as a function of nuclear separation must have definite relative positions. According to the Franck-Condon principle, the nuclei of a molecule do not change their separation appreciably during an electron transition. If curves of potential energy and nuclear separation are plotted for the excited and normal molecule, allowed transitions are represented by vertical lines connecting the two curves. For interpreting absorption spectra, one assumes a Boltzmann distribution of molecules in the vibrational states of the normal molecule, so that the lowest vibrational state with $1/2$ quantum of energy is the most thickly populated. The most intense part of an absorption band should be represented by vertical lines through the points of the normal mole-

Fig. 4.

cule curve, corresponding to this lowest energy. If absorption of the 1808 band results in dissociation of an Hg_2 molecule, the potential energy curves must have relative positions like either *c* and *a* or like *c* and *b* in Fig. 4. If positions *c* and *a* are correct, after absorption of 1808, (transition B) the nuclei find themselves with sufficient potential energy to dissociate into one excited and one normal atom. This is the usual interpretation given to a photo-chemical dissociation. If curves *c* and *b* are correct, the nuclei simply lose all attraction for each other upon absorption of 1808, and find themselves free to drift apart. In either case the band 1808 should be observed in absorption but not in emission.

If the original assumption that absorption of 1808 means dissociation is correct, it is not difficult to decide which of the two relative positions shown in Fig. 4 must be right. From analogy with He_2 , which is found to exist only when excited, the energy of binding in the excited mercury molecule is probably greater than that in the normal molecule. In practically all molecules which have been studied, greater energy of binding is associated with

smaller nuclear separation at the minimum of the potential energy curve, so that curves c and b should be required for Hg_2 . If curves c and a were correct, with increase of pressure and temperature and corresponding increase in the number of normal molecules in higher vibrational states, the 1808 band (B , Fig. 4) should broaden toward both longer and shorter wave-lengths corresponding to transitions from points g and d . This does not agree with the observation that the 1808 band broadened almost entirely toward longer wave-lengths. On curve c and b , however, we see that 1808 represents the longest vertical distance between the two curves and absorption from points g and d would give a broadening toward longer wave-lengths only.

Further we can also explain the very interesting fact that the absorption region surrounding 1849 reaches a short wave limit coinciding with that for the 1808 band, but reaches no definite long wave limit. Consider two mercury atoms making a collision. Their mutual potential energy would follow the curve for the normal mercury molecule (estimated as curve c , Fig. 4). If they absorbed light during a collision, the energy absorbed would correspond to vertical lines between the two potential energy curves of Hg_2 , and since they come to rest at point g , Fig. 4, and move more slowly at point d than at o , the positions g and d would be more probable positions for the absorption of light. This would represent wave-lengths slightly greater and slightly less than that of the atomic absorption line 1849. Now suppose the number of colliding atoms which absorb light to be greatly increased, one should observe absorption from points c and o . This would mean a continuous broadening of the 1849 line toward both longer and shorter wave-lengths but it would reach a limit on the short wave side coinciding with the limit for the 1808 band. This exactly describes what was observed. Of course, it is not sure that the short wave limit of 1849 exactly coincides with that of 1808 since the observed limit comes from a superposition of both. It is, however, significant that the 1849 band does not broaden beyond 1804 on the short wave side but broadens beyond 2200 on the long wave side.

We have correlated a set of curves such as b and c , Fig. 4, with three observations; the appearance of 1808 in absorption but not in emission, the broadening of the 1808 band toward longer wave-lengths with pressure, and the peculiar broadening of the 1849 band with pressure.

From Fig. 4 it is easily seen that the energy of dissociation of the normal molecule is simply the difference in energy between the 1849 and the 1808 bands. This gives D for Hg_2 equal to 0.15 volts or 3.5 kg. cal./mol. This value is three times Koernicke's value and one-third of Mrozowski's. The three methods will be compared and discussed in a later paper.

PROPERTIES OF SOME ZINC, CADMIUM,
AND MERCURY BANDS

BY J. GIBSON WINANS

UNIVERSITY OF WISCONSIN

(Received March 16, 1931)

ABSTRACT

Zinc bands at wave-lengths 2139, 2064, and 2002 are shown to resemble the corresponding bands of cadmium and mercury in emission as well as in absorption.

THE absorption spectra of zinc, cadmium, and mercury each show three corresponding continuous bands which may be called *A*, *B*, and *C*. The wave-lengths at the maxima are given in Table I. It has been shown¹ that

TABLE I.

	<i>A</i>	<i>B</i>	<i>C</i>
Zinc	2139	2064	2002
Cadmium	2288	2212	2114
Mercury	1849	1808	1692

for cadmium and mercury the bands *A* and *C* appear in emission in an electrodeless discharge but not the band *B*. The present experiment was undertaken to see if the same thing were true for the zinc bands.

A quartz tube was evacuated and sealed off after having had some zinc distilled into it. Nicrome wires wrapped around the ends served as external electrodes. One electrode was grounded and the other attached to a small Tesla coil (leak chaser). When the tube was heated by blow torches to give a stream of zinc vapor through the tube, a bright discharge was obtained. In stagnant vapor the discharge was very weak. This may have been the result of impurities as observed by Wood and Voss² in mercury vapor. Spectra were photographed with nitrogen flowing through the spectrograph to eliminate oxygen.

The resulting discharge through zinc vapor showed band *A* with great intensity and with the maximum reversed, and showed also band *C*. No trace of band *B* was observed. These observations are the same as those on the corresponding bands for Cd and Hg.¹ An interpretation for one set of these bands will apply to all since the bands are shown to have the same properties. One interpretation¹ gives energies of dissociation of zinc, cadmium, and mercury molecules of 0.24, 0.20, and 0.15 volts respectively.

There was observed only one difference in the behavior of these bands relative to each other for the various elements. In the absorption spectra, the zinc bands *B* and *C* appeared with increasing pressure at practically the same pressure; the cadmium band *C* required about 1.7 times that required for band *B*, and the mercury band *C* needed about 5 times as much pressure as the mercury band *B* for equal intensities. This does not affect the interpretation given to the bands but it may indicate an interesting change in properties of similar elements with increasing atomic weights.

PERTURBATIONS AND PREDISSOCIATION IN THE S_2 BAND SPECTRUM

BY ANDREW CHRISTY AND S. MEIRING NAUDÉ
RYERSON PHYSICAL LABORATORY, UNIVERSITY OF CHICAGO

(Received February 27, 1931)

ABSTRACT

The S_2 bands belonging to the ${}^3\Sigma_u^- \leftarrow {}^3\Sigma_g^-$ transition have been photographed with relatively large dispersion in absorption and in emission between $\lambda 3500$ and $\lambda 2400$. Several perturbations have been found in the vibrational levels of the excited ${}^3\Sigma_u^-$ state. These became apparent when the quantum assignment of the band heads were determined. The following revised equation was found to fit the unperturbed heads:

$$\nu = 32250.9 + 429.5(v' + 1/2) - 2.75(v' + 1/2)^2 - 727.4(v'' + 1/2) + 2.91(v'' + 1/2)^2$$

Weak bands were observed (mainly in absorption) about 20 cm^{-1} to the violet of the heads in the $v'' = 0$ progression. These bands are believed to be due to another system. Perturbations of about $+17 \text{ cm}^{-1}$ have been found in the heads of the bands with $v' = 0, 2, 4$, which are presumably due to perturbations of the rotational levels near the band heads by another electronic state or perturbations in the $U(r)$ curve of the ${}^3\Sigma_u^-$ state. Perturbations found in the levels with $v' > 9$ are attributed to a ${}^3\Pi_u$ state which causes predissociation in these bands.

Predissociation. This phenomenon is discussed in terms of the Franck-Condon principle of transition probabilities. It is shown that the ${}^3\Pi_u$ continuous state which causes predissociation must intersect the $U(r)$ curve of the ${}^3\Sigma_u^-$ state at two points giving the two observed regions of predissociation. The relative transition probabilities for the radiationless jump in the two regions are discussed.

Dissociation. The energies of dissociation of the lower and upper states are found to be 4.45 and 2.07 volts. This gives 1.6 volts as the separation of the 3P and 1D states of the S atom.

I. INTRODUCTION

THE S_2 bands which extend from $\lambda 6000$ to $\lambda 2300$ have been studied by various investigators.¹ Rosen,² who gave the first quantum analysis of these bands, found that the band heads could be represented by the equation:³

$$\nu = 32290 + 427.1(v' + \frac{1}{2}) - 2.7(v' + \frac{1}{2})^2 - 727.4(v'' + \frac{1}{2}) + 2.91(v'' + \frac{1}{2})^2. \quad (1)$$

For this analysis he had a relatively small dispersion ($1 \text{ mm} = 300 \text{ cm}^{-1}$ in the ultraviolet) at his disposal.

³ This equation is the same as that given by Rosen except that the quantum numbers have been changed from n to $(v+1/2)$.

There are large discrepancies in the combination differences⁴ $\Delta G(v + \frac{1}{2})$ given by Rosen (cf. Table 15 of reference 2a) which should be the same within experimental error for any one row or column of his table. It may be concluded, therefore, either that his experimental errors were very large, which is possible since his dispersion was very small, or that the assignment of the vibrational quantum numbers to at least some of the heads, was wrong. The latter alternative is not so impossible as it may appear, since with larger dispersion in the present work it was found that many of the heads which Rosen measured as one, consist of groups of two or more heads. Furthermore, in the region above $\lambda 2900$ the spectrum is so complicated due to overlapping, as can be seen from our plates, that the heads with $v' < 8$ all may have been assigned incorrectly. Therefore it became necessary for us to determine the correct assignment of the band heads before proceeding with the rotational analysis of the bands. The latter has already been published⁵ and will be referred to here as I.

In the course of this investigation it was found that the irregularities in the $\Delta G(v + \frac{1}{2})$ values given by Rosen were due partly to an incorrect assignment of some of the band heads and partly to numerous perturbations in the vibrational levels of the upper state. The perturbations are larger than any that have been observed in the band systems of other molecules and therefore need special consideration.

The phenomenon of predissociation which Henri⁶ found to occur in the S_2 bands, has also been studied in relation to the vibrational analysis. The interpretation of this phenomenon as it is observed in these bands differs from that given by other investigators.

II. EXPERIMENTAL PROCEDURE

Since absorption spectra obtained at different temperatures offer the best means of studying the vibrational analysis, especially of the upper electronic state, a quartz absorption cell, having a length of 5 cm and a diameter of 2.5 cm was used. The cell was first baked out and sufficient distilled sulphur was added to give a vapor pressure of 12 mm⁷ at 450°C. The cell was heated electrically. Since the amount of sulphur in the cell remained constant throughout the investigation, the vapour pressure of the sulphur within the cell (above 450°C) was proportional to the temperature.

A hydrogen tube was used as continuous source.⁸

⁴ $\Delta G(v + \frac{1}{2}) = G(v + 1) - G(v)$ where $G = E_v/hc$ (cf. R. S. Mulliken, *Phys. Rev.* **36**, 623, 625 (1930)).

⁵ S. M. Naudé and A. Christy, *Phys. Rev.* **37**, 490 (1931).

⁶ V. Henri, *Structure des Molecules*, Paris 1925; V. Henri and M. C. Teves, *Nature* **114**, 894 (1924).

⁷ V. Henri (see Symposium of the Faraday Soc. on Molecular Spectra and Molecular Structure, Sept. 1929, p. 765) used 0.1 mg of sulphur in a 16 cc quartz tube at 600°C which gave him about the same S_2 vapour pressure.

⁸ The hydrogen tube used has been described previously: S. M. Naudé, *Phys. Rev.* **36**, 333 (1930).

The region between $\lambda 3500$ and $\lambda 2400$ was studied in absorption. The absorption plates were taken with an E1 Hilger spectrograph giving a dispersion varying from $1 \text{ mm} = 7.7\text{\AA}$ at $\lambda 3500$ to $1 \text{ mm} = 2.3\text{\AA}$ at $\lambda 2400$, as well as in the first order of the 21 foot Rowland grating, giving a dispersion of 2.6\AA per mm. Eastman 33 plates were used. The iron and copper arcs were used as comparison spectra, the wave-lengths of which were taken from Kayser's "Hauptlinien" and Shenstone's work,⁹ respectively. The copper arc was used mainly in the region below $\lambda 2800$ since the iron lines are very weak and too numerous in this region to serve as standards.

The wave-lengths of the band heads on the plates obtained with the E1 spectrograph were calculated with Hartmann's formula. The measurements of the band heads obtained with both instruments agreed within experimental error. This error was relatively large (about 2 cm^{-1}), because the band heads are not very well defined owing to their characteristic rotational structure. Below $\lambda 2792.8$ the heads are fuzzy due to predissociation which increases the error in this region to 5 cm^{-1} . Below $\lambda 2615$ the heads become very diffuse making the experimental error as large as 10 cm^{-1} .

The S₂ spectrum was studied in emission in the region between $\lambda 3500$ and $\lambda 2400$. The spectrum was excited by means of a Geissler tube described in I. The plates were taken in the first order of the 21-foot grating. Iron standard wave-lengths were used as comparison spectrum.

III. DESCRIPTION OF THE PLATES

Fig. 1a is a reproduction of the bands obtained in absorption. When the absorption tube is heated to about 450°C the maximum absorption occurs in the region between $\lambda 2741$ and $\lambda 2799$. Plates were also taken with the absorption cell at about 600°C and 750°C . With higher temperatures the maximum absorption is shifted to longer wave-lengths as is to be expected. For temperatures of the cell below 400°C (i.e., below the boiling point of sulphur) no bands appeared in absorption in the region investigated. In emission the maximum intensity lies in the region between $\lambda 3000$ and $\lambda 3500$. In this region the band heads are not clearly defined owing to the great amount of overlapping. This overlapping causes many clusters of lines to be formed on the plates in this region which are not easily distinguishable from heads. These intensity relations, both in absorption and in emission, can be understood with the help of the potential energy curve obtained from the vibrational and rotational analyses given in section VII below.

Below $\lambda 2792.8$ (cf. Fig. 1b) the absorption bands become diffuse. As can be seen from the plate, there are two regions in which the bands are diffuse to a different degree: first, between $\lambda 2792.8$ and $\lambda 2615$ and secondly between $\lambda 2615$ and $\lambda 2440$. The bands in the latter region are more diffuse than those in the former. In addition there seems to be a continuous absorption in the second region which reaches a maximum at $\lambda 2549$. Although indications of the rotational structure reappear below $\lambda 2440$ (cf. Fig. 1d) the bands are still more diffuse than in the first region.

⁹ A. G. Shenstone, *Phys. Rev.* **28**, 449 (1926).

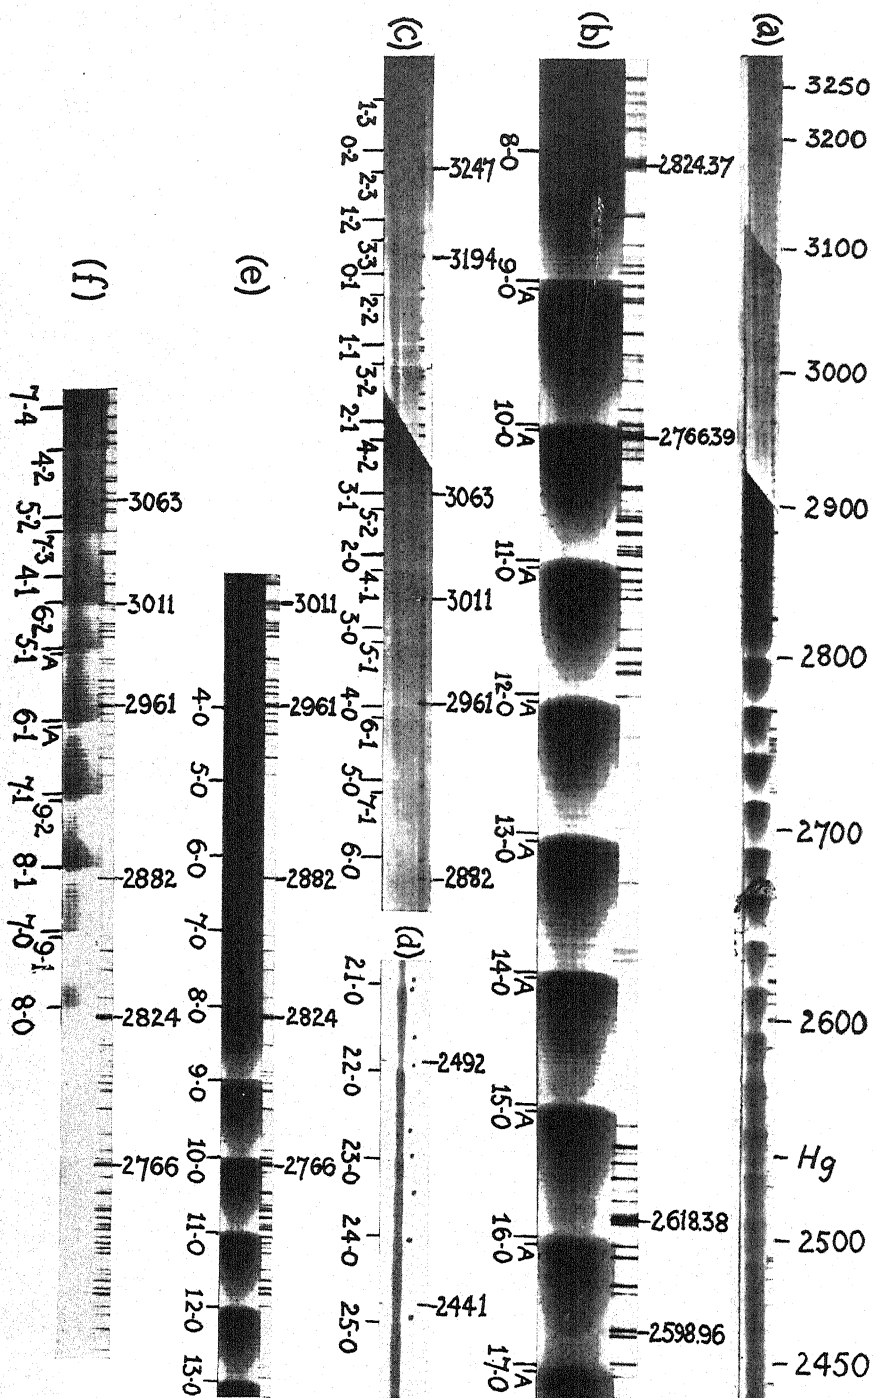

Fig. 1. (a) S_2 spectrum investigated in absorption. (b) Part of (a) showing the first region of predissociation between $\lambda 2792.8$ and $\lambda 2615.0$ and the first band of the second region below $\lambda 2615$. (c) Absorption spectrum obtained with sulphur cell at about 750°C . (d) Bands of the second region of predissociation showing indications of rotational structure. (e) Absorption spectrum obtained with sulphur cell at about 450°C . (f) Emission spectrum of S_2 .

By comparing (e) and (f) one sees that the bands which become diffuse in absorption due to predissociation do not appear in emission.

Accompanying the strong heads in absorption and about 20 cm⁻¹ to the violet of these lie a number of faint heads indicated by "A" in Fig. 1b. These heads Henri and Teves⁶ evidently accounted for as R heads, the strong heads being supposed to be formed by Q branches. It has been shown in I that the main system of bands is due to a $^3\Sigma^-_u \rightarrow ^3\Sigma^-_g$ transition. Furthermore, the authors have found that no Q branches appear in these bands. Therefore the weak heads are probably due to a different electronic transition.

IV. THE VIBRATIONAL ANALYSIS

The band heads obtained in absorption can be arranged now as shown in Table IA. One would expect the bands which appear at the lowest temperature in absorption to correspond mainly to those having $v''=0$. Hence the band heads which were measured on the plates corresponding to the cell temperature of about 450°C can be assigned to transitions for which $v''=0$ and $v''=1$, the former being much more intense. These bands lie within zone (1) (cf. Table IA). When the temperature of the cell was raised to about 600°C, the band heads with $v''=1$ became more intense and in addition the band heads for which $v''=2$ appeared. These bands lie within zone (2). Similarly at about 750°C the bands for which $v''=3$ appear in absorption as well as a few for which $v''=4$ and 5. These bands lie within zone (3).^{10,11} Most of these bands are indicated in Fig. 1c and 1e.

The consistent values of $\Delta G(v + \frac{1}{2})$ for any one column and row in Table IA prove the correctness of the assignment of vibrational quantum numbers to the various heads as brought out by changing the temperature of the absorption cell. Table IA reveals a number of irregularities in the values of $\Delta G(v' + \frac{1}{2})$ which will be discussed in section V. One would expect the $\Delta G(v' + \frac{1}{2})$ values to decrease regularly as v' increases. As is clear from Table IA, however, these values vary irregularly as v' increases.

The band heads measured on the plates taken in emission in the region $\lambda 3500$ to $\lambda 2800$ are given in Table IB. Most of the band heads observed in emission agree within experimental error with the absorption values. It is seen from Table IB that all the bands observed in emission have $v' < 10$.

The values of the vibrational constants ω_e and $\omega_e x_e$ given by Rosen^{2a} are essentially correct. He obtained the vibrational constants ω_e'' and $\omega_e'' x_e''$ of the lower state from the progression having $v'=3$ which was excited in fluorescence by the mercury line $\lambda 3132\text{\AA} = 31922 \text{ cm}^{-1}$. Further he derived the vibrational constants ω_e' and $\omega_e' x_e'$ for the upper state mainly from the absorption bands having $v' > 4$. However, most of the heads with $v' > 7$ measured by him are the weaker heads of the bands designated as A bands (cf. section III) which are discussed later. The differences between the weaker and the stronger heads are approximately constant (20 cm⁻¹) and hence the value

¹⁰ For the higher temperatures the absorption in the region between $\lambda 2800$ and $\lambda 2600$ becomes complete.

¹¹ By adding more sulphur to the absorption cell and increasing the temperature it would be possible to obtain the bands having $v'' > 4$ in absorption. This was not carried out as the above results were sufficient for our present purpose.

of ω_v derived from them is essentially correct. The dispersion used by Rosen was not sufficient to resolve these heads, and furthermore, when the vapour pressure of the sulphur in the absorption tube is increased, the weak heads become completely absorbed, and consequently one is liable to measure these as the main heads as Rosen apparently has done. This can be seen by comparing our assignment of vibrational quantum numbers to the various band heads with that of Rosen as is done in Table II. For wave-lengths greater

Note: The bracketed heads have been measured as one by Rosen.

than $\lambda 2926$ the absorption spectrum becomes complicated and consequently Rosen's results become less trustworthy. In this region it is impossible to correlate our results with those given by him. Owing to these errors in Rosen's assignment the vibrational constants of the upper state as well as ν_e should be changed as follows:

$$\nu_e = 32250.9 + 429.5(v' + \frac{1}{2}) - 2.75(v' + \frac{1}{2})^2 - 727.4(v'' + \frac{1}{2}) + 2.91(v'' + \frac{1}{2})^2. \quad (2)$$

The above mentioned faint absorption heads (cf. section III) which lie about 20 cm^{-1} to the violet of the $v''=0$ progression, have been observed only next to the main band heads having v' ranging from 8 to 20. Some of these heads are indicated by *A* in Fig. 1b. A few more weak heads have been found to appear in absorption and a few in emission which seem to belong to the same electronic transition as those marked *A*. These band heads are tabulated in Table III which gives a possible arrangement. This arrangement, however, is uncertain, since no more heads can be found, as they are relatively

weak compared with the bands of the main system and are overlapped by these bands. It is therefore impossible to determine whether the upper or the lower state is common to these two systems. This might be decided in case a series of experiments were performed in which the temperature in the cell was comparatively low and the pressure was increased gradually. In addition to these two systems of bands a large number of heads have been observed above $\lambda 3500$ which appear in emission. A special study of these bands, if possible with a low temperature source such as active nitrogen which would diminish the excessive overlapping of the bands, should be made in order to determine whether or not they belong to the ${}^3\Sigma_u^- \rightarrow {}^3\Sigma_g^-$ transition.

V. PERTURBATIONS

In the great majority of band systems which have been analyzed thus far the vibrational combination difference $\Delta G(v + \frac{1}{2})$ has been found to decrease regularly as the vibrational quantum number increases.¹² If in Table IA we compare the mean $\Delta G(v' + \frac{1}{2})$ values, we see that perturbations must

¹² It was observed by G. Nakamura in the NaH bands (Zeits. f. Physik 59, 218 (1930)) and by T. Hori in the LiH bands (Zeits. f. Physik 62, 352 (1930)) that the $\Delta G(v' + 1/2)$ values, instead of decreasing with v' , increase up to a certain value of v' and then decrease regularly. W. Weizel (Zeits. f. Physik 60, 599 (1930)) showed that this may be accounted for by uncoupling of the $p\sigma$ and $s\sigma$ electrons.

be present in the vibrational levels of the upper ${}^3\Sigma_u^-$ state. This is shown more strikingly if one compares the observed and calculated energy levels as shown in Table IV. The calculated values were obtained by passing the best graph through the observed $\Delta G(v' + \frac{1}{2})$ values, and then adjusting the value of the calculated $v'=0$ level until the best fit was obtained with the

NOTE: Our measurements below the $23 \leftarrow 0$ bands are very inaccurate, hence no comparison can be made for $v' > 23$. In considering the *O-C* values it must be remembered that the experimental error for the bands having $v' < 9$ is about 2 cm^{-1} and for $v' > 9$ probably greater (cf. section II).

experimental values. It is seen that the *O-C* values for $v'=7$ and 8 are zero within the experimental error. We know from I that the rotational levels for $v'=7$ and 8 are normal, whereas those for $v'=9$ are perturbed. From Table IV we see also that the vibrational levels $v'=7$ and 8 are normal and $v'=9$ seems to be displaced. It appears that the levels with $v'=0, 2, 4$ are perturbed by about $+17 \text{ cm}^{-1}$. From $v' > 9$ predissociation begins and it appears that practically all these levels are perturbed in varying degree. The perturbations for $v'=0, 2, 4$ as obtained by measuring the heads of the bands, might be due either to perturbations of the rotational lines near the heads or to perturbations of the vibrational levels.

Johnson and Asundi¹³ found that in the Cameron CO bands all band heads with $v'=1$ are displaced by 4.2 cm^{-1} . Rosenthal and Jenkins¹⁴ showed that all the rotational lines near the heads of these bands are perturbed, all the lines being displaced in the same direction, thus giving a displacement of the head and consequently an apparent displacement of the vibrational level. In the CN bands Rosenthal and Jenkins¹⁵ showed that the perturbations of the rotational lines occurring in some of these bands are due to the fact that certain rotational levels of the upper state have energies approximately equal

¹³ R. C. Johnson and R. K. Asundi, Proc. Roy. Soc. A123, 560 (1929).

¹⁴ J. Rosenthal and F. A. Jenkins, Proc. Nat. Acad. of Sciences 15, 896 (1929).

to the rotational levels of another state with the result that the two sets of levels are mutually perturbed, as we would expect from Kronig's theory.^{16,17}

It may be that the perturbations of the S_2 band heads for $v'=0, 1, 2, 4$ are of the same type, i.e. that all the rotational lines near the band heads are displaced in the same direction and that, consequently, the heads are displaced by about $+17 \text{ cm}^{-1}$. But in order that the alternate vibrational levels might be perturbed, we must assume the presence of another state having an ω which is approximately twice that of the $^3\Sigma_u^-$ state. If such a state were present, we would expect transitions between this and the normal state of the molecule. It may be, however, that some of the emission bands are due to such a transition.

The observed perturbations of the band heads with $v'=0, 2, 4$ may, be due to perturbations of the vibrational levels. In this case one would expect the $U(r)$ curve to be irregular and not a smooth curve as it seems to be for the electronic states of most other molecules. A similar type of perturbation to that observed in S_2 has been found by Jevons¹⁸ in the bands of CS, where the band heads having $v'=1, 2, 4$ were found to be displaced in the same way, the maximum displacement of the CS band heads being 7.4 cm^{-1} as compared with $+18 \text{ cm}^{-1}$ for S_2 . Moreover, by comparing the observed displacements of the R and Q heads from their calculated positions,¹⁹ Jevons concluded that the observed perturbations were due to perturbations of the vibrational levels.

Whether this type of perturbation as observed in the S_2 bands is due to rotational or vibrational perturbations or to a superposition of both can only be determined by studying the rotational structure of the S_2 bands having $v'=0, 2, 4$ with reference to the unperturbed bands. Owing to the great amount of overlapping of those bands in the S_2 spectrum, this study is impossible unless some other type of excitation (active nitrogen or fluorescence) will excite fewer and less extensive bands, and consequently give less overlapping. Although still difficult, this study may be carried out in the CS bands.²⁰

The perturbation present in the vibrational levels for $v' > 9$ may be due to the continuous state which causes predissociation and which is discussed in the next section. Although the probable error in the measurement of these diffuse bands ($v' > 9$) is large (cf. section II), consequently making it difficult to interpret correctly the observed minus calculated values, it may be pointed

¹⁶ R. de L. Kronig, *Zeits. f. Physik* 50, 347 (1928).

¹⁷ But cf. H. H. Hyman and C. R. Jeppesen, *Nature* 125, 462 (1930) and R. T. Birge and C. R. Jeppesen, *Nature* 125, 463 (1930). These investigators have found a perturbation in the $v''=0$ level of the normal state of H_2 , where presumably there could not be another interacting state present.

¹⁸ W. Jevons, *Proc. Roy. Soc. A* 117, 351 (1927-1928).

¹⁹ If both the R and Q heads were displaced by the same amount, one might attribute this displacement to a perturbation of the vibrational level. If, however, the two heads were displaced by different amounts, this displacement might be due to the perturbation of the rotational levels. Cf. also references 13 and 14.

²⁰ This investigation has been started by one of the authors (S.M.N.).

out that, whereas the level $v'=9$ seems to be displaced downwards, those above the intersecting curve ($v'=10-16$) seem to be displaced upwards which suggests some interaction between the corresponding $U(r)$ curves.

We know according to I from our rotational analysis of the 9-1 and 9-2 bands that the rotational levels of the $v'=9$ level are perturbed. In these bands we have found that the mean value of B_9' obtained from the $\Delta_2 F_9'$ graph is larger than the B_7' and B_8' .²¹ The fact that B_9' obtained from lower values of K is less than the values obtained from higher values of K (the factor $8D_e K^3$ has been considered) seems to indicate that the perturbation increases with K .

VI. PREDISSOCIATION*

It has been remarked in a previous section of this paper that there are two regions in this spectrum where the bands are diffuse. As can be seen from Fig. 1b the absorption bands are sharp²² up to $\lambda 2799.1$ ($v'=9, v''=0$).²³ To the violet of this point they become at first more and more diffuse, the maximum diffuseness being at about $\lambda 2741.0$ ($11 \leftarrow 0$). As we proceed toward shorter wave-lengths the bands become sharper. At 2615.0 ($16 \leftarrow 0$) the bands suddenly become much more diffuse, the maximum diffuseness of the second region being at $\lambda 2549.0$ ($19 \leftarrow 0$). From this point on the bands become less diffuse. Although the spectrum has been photographed down to $\lambda 2400$, the bands below $\lambda 2492$ are no sharper than those between $\lambda 2792$ and $\lambda 2615$, as can be seen from Fig. 1d. In the first region of predissociation ($\lambda 2799-\lambda 2615$), the bands although diffuse, still preserve some of their rotational structure, the diffuse lines merging into definite groups (cf. Fig. 1b). In the second region ($\lambda 2615-\lambda 2435$) the bands are completely diffuse, all group structure disappearing.

All the bands which are diffuse in absorption fail to appear on our emission plates (cf. Figs. 1e and 1f and also Table I).²⁴ No bands were observed in emission with $v'=10$, although the exposures were long enough to photograph these had their intensity been one tenth of that of the others. The non-appearance of these bands may be ascribed primarily to the small life time of the molecule in the vibrational levels of the $^3\Sigma_u^-$ state with $v'>9$, due to the transitions from these levels to those of another state with subsequent dissociation. The non-appearance of the $9 \rightarrow 0$ band may be explained by the fact that the transition probability from $v'=9$ to $v''=0$ is small. The

²¹ $B_v = B_e - \alpha_e(v+1/2)$. Hence B_v should decrease as v increases.

* The authors appreciate the discussions with Drs. J. L. Dunham and Carl Eckart about points brought up in this section.

²² When we use the expressions: bands are "sharp" or "diffuse," we actually mean that the rotational lines of the bands are sharp or diffuse.

²³ V. Henri gave $\lambda 2792.4$ as the wave-length at which the bands become diffuse (cf. reference 6). However, the band at $\lambda 2792.4$ (2792.8 according to our measurements) does not belong to the main system, i.e. $^3\Sigma^- - ^3\Sigma_u^-$, but to a weaker group of bands which are designated here as *A* bands and are given in Table IV. As will be shown in section VII, this wave-length has no special meaning.

²⁴ This fact was independently observed by H. H. van Iddekinge, *Nature* **125**, 858 (1930).

transition probability for $v' > 9$ to $v'' = 0$ is still smaller, hence these bands would be weak even if predissociation was not present.

Various investigators^{25, 26, 27} have given explanations of the predissociation, which occurs in this spectrum. Franck²⁵ showed that if we assume two intersecting curves as in Fig. 2A, we may expect transitions to take place at the point b with immediate dissociation of the molecule. The theoretical explanation based on wave mechanics, as given by Kronig²⁶ involves the same basic principles as those used by Franck. Kronig showed that the selection rules for radiationless transitions are $\Delta\Lambda = \pm 1, 0$; $\Delta\Sigma$ or $\Delta S = 0$; $\Delta J = 0$; and that transition can occur only between two $+$ (or $-$) rotational levels belonging to two electronic states that are both g or both u .²⁸ [It may be pointed out that the ordinary transition rules are $\Delta\Lambda = \pm 1, 0$; $\Delta\Sigma$ or $\Delta S = 0$; $\Delta J = 0, \pm 1$; $+$ (or $-$) levels to $-$ (or $+$) levels and g (or u) to u (or g) states (if equal atoms)]. The probability of a radiationless transition is proportional to $J^2/(E)^{1/2}$.²⁹ E is the energy difference between any level of the $^3\Sigma_u^-$ state and the line b, b' , b' being the dissociation energy of state a . The above formula would indicate that no transition is possible between the two intersecting curves below b . Hence we would expect predissociation to begin sharply and then decrease gradually as we reach the vibrational levels above the point b . However, in both the first and second region, predissociation begins suddenly and increases gradually to a maximum before it decreases.

The explanation given by Herzberg²⁷ for the observed predissociation in the S_2 bands is a further development of Franck's principle. According to Herzberg curve a^{30} cuts the $^3\Sigma_u^-$ curve at two points, c and b , as in Fig. 2B, corresponding to the two regions of predissociation. He points out that the bands of the second region may be more diffuse, first because in this region the bands will be overlapped by the continuum³¹ due to $^3\Sigma_g^- \leftarrow a$, and secondly, because at c the probability of predissociation will be greater, for at

²⁵ J. Franck and H. Sponer, *Nachricht Gesellschaft d. Wiss. Göttingen, Math.-Phys. Klasse*, p. 241 (1928); K. F. Bonhoeffer and L. Farkas, *Zeits. Phys. Chem.* 134, 337 (1927).

²⁶ R. de L. Kronig, *Zeits. f. Physik* 50, 347 (1928); 62, 300 (1930).

²⁷ G. Herzberg, *Zeits. f. Physik* 61, 604 (1930).

²⁸ The last rule as formulated by Kronig (cf. *Zeits. f. Physik* 62, 300 (1930)) is symmetrical to symmetrical, and antisymmetrical to antisymmetrical states. The $+$ and the $-$ levels here referred to are the "gerade" (g) and "ungerade" (u) rotational levels of Kronig (cf. *Zeits. f. Physik* 50, 351 (1928)) and Mulliken (cf. *Phys. Rev.* 36, 617 (1930)). The g and u used here refer to the "gerade" and "ungerade" electronic states of Hund as Π_u , Σ_g , Σ_u , etc. (cf. *Zeits. f. Physik* 51, 759 (1928)).

²⁹ The J^2 term in Kronig's formula enters only when the transition involves $\Delta\Lambda = \pm 1$. For a transition for which $\Delta\Lambda = 0$, the probability is independent of J . The dependence on J would indicate that within any diffuse band, the rotational lines would become more diffuse as we go away from the origin. The probability essentially depends upon J and not on J^2 since $J^2/(E)^{1/2} \propto J$. It is difficult to determine from our results whether or not the lines within a band become more diffuse as we go away from the origin.

³⁰ Herzberg points out that curve a may or may not have a minimum. His explanation fits either case equally well.

³¹ Fig. 3 shows that the most probable transition from the lower vibrational levels of the $^3\Sigma_g^-$ state is to the left of the upper curves.

this point the radiationless transition may occur before it is necessary for the molecule to complete half a vibration as it would at point *b*. It is highly improbable, however, that the overlapping continuum will make the bands appear more diffuse than they actually are. Furthermore, since the frequency of vibration is much larger than that of rotation, the fact that the molecule will have to complete half a vibration at *b* and not at *c* before it dissociates, can have no appreciable effect on the relative probability of predissociation of the bands in the two regions.

The first idea which suggests itself is that there may be two curves intersecting the $^3\Sigma_u^-$ curve, giving the two regions of predissociation. It may be well, therefore, to consider here the various possible states which may be present. It has been shown by us⁵ that the main system of bands which show predissociation is due to a $^3\Sigma_u^- \leftarrow ^3\Sigma_g^-$ transition, $^3\Sigma_g^-$ being the lower state. By a comparison with the Schumann-Runge bands of O₂ (cf. also section VII), one would expect the $^3\Sigma_g^-$ of S₂ to dissociate into two 3P atoms, and the excited state, $^3\Sigma_u^-$, into one 3P and one 1D atom. It is evident also from the $U(r)$ curves that the states which cause predissociation must dissociate into two normal atoms. By applying the results of Wigner and Witmer,³² one finds that the molecular electronic states resulting from similar atoms both in a 3P state are the following: $^1\Delta_g$, $^1\Pi_g$, $^1\Pi_u$, $^1\Sigma_g$, $^1\Sigma_g^-$, $^1\Sigma_u^-$, $^3\Delta_u$, $^3\Pi_u$, $^3\Pi_g$, $^3\Sigma_u^+$, $^3\Sigma_u^-$, $^3\Sigma_g^-$, $^5\Delta_g$, $^5\Pi_g$, $^5\Pi_u$, $^5\Sigma_g^+$, $^5\Sigma_g^-$, $^5\Sigma_u^-$. The state or states causing predissociation (curve *a* in Fig. 2B or Fig. 2C) must be among the above. But according to the rules given by Kronig¹⁶ for a radiationless transition, the only state in the above list which can interact with a $^3\Sigma_u^-$ state is a $^3\Pi_u$ state. Hence the state which causes predissociation must be a $^3\Pi_u$ state and must intersect the $^3\Sigma_u^-$ at two points as Herzberg assumed.²⁷ However, we have still to explain why the bands in the second region corresponding to *c* are more diffuse than those in the first.

It may be shown that Kronig's formula does not apply to the region *c*. In deriving his formula,³³ he assumed that the nuclear momentum of the molecule in state *a* (here identified as a $^3\Pi_u$ state) is constant. That is, he was dealing only with the flat portion of the curve, line *b b'* of Fig. 2A. If, however, the curve has no minimum³⁴ as in Fig. 2C the momentum will not be constant near either of the points *b* or *c*.³⁵

³² E. Wigner and E. E. Witmer, *Zeits. f. Physik* 51, 859 (1928).

³³ Kronig took as the wave function of state *a* an oscillatory function with a constant period, i.e., constant momentum.

³⁴ The $^3\Pi_u$ state may have a very shallow minimum. If it had a sharp minimum we would expect to find discrete bands either in emission or absorption due to a $^3\Pi_u \leftarrow ^3\Sigma_g^-$ transition. No such bands have been found although there is a region of weak continuous absorption beginning at about $\lambda 2600$ which may be ascribed to this transition. The group of bands designated in this paper as *A* bands are not due to this transition, for they are found in absorption after the point *c* has been passed.

³⁵ Since the $^3\Pi_u$ intersects the $^3\Sigma_g^-$ curve at *c*, we will have to suppose that although the interaction between the two atoms forming the $^3\Pi_u$ state is almost zero for very small distances of internuclear separation, when this distance is made still smaller, the repulsion between the two atoms is smaller than that in state $^3\Sigma_u^-$. (This will be the case if the electronic configuration of the $^3\Pi_u$ state resembles the united atom more closely than that of the $^3\Sigma_u^-$ state.)

In the tentative explanation given here we shall make use of the Franck-Condon theory³⁰ of transition probabilities between the two states $^3\Sigma_u^-$ and

Fig. 2A

Fig. 2B

Fig. 2C

$^3\Pi_u$. According to this theory the probability of a transition is greatest when

³⁰ E. U. Condon, Phys. Rev. 28, 1182 (1926).

the nuclear separation as well as the momentum remain unchanged during the transition. Since the slopes of the two intersecting curves are more nearly alike at the point c than at b , and furthermore remain closer together at the former point than at the latter, a transition from a discrete vibrational level whose energy is near that of c to the continuous curve will involve a very much smaller change in the nuclear separation at this point than at the point b . The ratio of the nuclear momenta in the neighbourhood of the two points is approximately the same in both cases. This can be seen from Fig. 2C. If we take two discrete vibrational levels E_1 and E_2 so that $E_1 - c = E_2 - b$, and consider the points on E_1 and E_2 having zero nuclear momentum it is quite evident that the difference of the nuclear separation for the former is much less than for the latter. For two other points on E_1 and E_2 having nuclear separations r_1 and r_2 so that $r_1 - r_c = r_b - r_2$ the ratios of the nuclear momenta in the former case will be about the same as in the latter. Hence the probability of the predissociation at the former point will be greater (therefore the rotational lines more diffuse) than at the latter point. Furthermore, since the two curves remain closer together near c , i.e. the second region of predissociation, we would expect more bands to be diffuse in the second region of predissociation than in the first. Finally, from the above explanation we would expect that, in both regions of predissociation, the bands tend to become more diffuse as we approach the points of intersection from either side.³⁷ These phenomena are exactly what we observed.

It has been stated in a previous section that the overlapping continuum reaches a maximum at $\lambda 2549$. This maximum could not be due entirely to transitions between the $^3\Sigma_g^-$ and the $^3\Pi_u$ states, for according to Fig. 3, the maximum probability of this transition should occur at $\lambda 2662$. We have also seen that the band at $\lambda 2549$ ($19 \leftarrow 0$) is the most diffuse band in this spectrum. Hence the overlapping continuum at this point must be due to the fact that the rotational levels for the $v' = 19$ are so diffuse as to be practically continuous.

For a quantum mechanical formulation of the results obtained by application of the Franck-Condon principle, we would make the step by step conversion from one to the other exactly as Condon has done for ordinary transitions.³⁸ One sees that the overlapping of the wave functions of the two states ($^3\Sigma_u^-$ and $^3\Pi_u$) is greater at c than at b since the internuclear distances (with zero nuclear momentum) on both curves are nearer the same in the neighborhood of the former point than of the latter. Therefore the two waves will tend to reinforce each other more at c than at b , giving a greater transition probability in the neighborhood of c .

³⁷ L. A. Turner (Am. Phys. Soc. Meeting, New York, Feb. 1931, Paper No. 12) refers to two types of predissociation. In one the broadening of the lines sets in suddenly at a definite wavelength and in the other it sets in gradually. The former is the type discussed by Kronig (cf. Fig. 2A) and is also approximated at point b of Fig. 2C. According to our interpretation the continuous curve at point b has almost the value of dissociation. Hence at this point one would expect the broadening of the lines to set in more suddenly than at point c .

³⁸ E. U. Condon, Phys. Rev. 32, 858 (1928), also Condon and Morse, Quantum Mechanics, pp. 168-170.

In the above discussion we were concerned mainly with the ${}^3\Sigma_u^- \longleftrightarrow {}^3\Sigma_g^-$ bands. The other system of bands which we have designated as *A* bands shows exactly similar characteristics. Whenever a band of the main system is diffuse the corresponding *A* band is also diffuse.

While this paper was being written Asundi³⁹ reported that in the presence of argon at high pressures, he was able to photograph the bands in emission

Fig. 3. Potential energy curves of the known states of the S_2 molecule. The ${}^3\Sigma_g^-$ and ${}^3\Sigma_u^-$ curves have been drawn using Morse's equation.

beyond the first limit of predissociation. If the mechanism of predissociation given by all thus far is correct, it is difficult to see what effect the presence of argon could have except that of increasing the population of the levels with $v' > 9$. Thus, although dissociation does take place there are still sufficient molecules present in these states to emit the bands with sufficient intensity to be observed.

VII. HEATS OF DISSOCIATION

In our previous paper⁵ we showed that the main system of S_2 bands is due to a ${}^3\Sigma_u^- \longleftrightarrow {}^3\Sigma_g^-$ transition, and is analogous to the Schumann-Runge bands of O_2 . We should, therefore, expect the normal ${}^3\Sigma_g^-$ state of S_2 to dissociate into two 3P atoms just as in the case of O_2 , and similarly the upper state ${}^3\Sigma_u^-$ to dissociate into a 3P and a 1D atom.

From the graph $\omega_e v$ for the ${}^3\Sigma_u^-$ state we obtain by linear extrapolation 2.07 volts for the heat of dissociation D' of this state.⁴⁰ Hence the total energy required to excite the molecule into the ${}^3\Sigma_u^-$ state and to dissociate it is:

$$\nu_e + D' = 3.98 + 2.07 = 6.05 \text{ volts.}$$

³⁹ R. K. Asundi, *Nature* 127, 93 (1931).

⁴⁰ Of the 2.07 volts the energy is known up to 1.01 volts and the rest is extrapolated.

The ${}^3\Pi_u$ level which causes the predissociation must also dissociate into two 3P atoms, since there is no other possible atomic state between the 3P and 1D states. From the description of the phenomenon of predissociation as observed in these bands given in section VI it is clear that the rotational lines of the bands, are sharp up to $\lambda 2792.8$ where they begin to become diffuse. The rotational lines immediately below $\lambda 2792.8$ which are diffuse in absorption correspond to transitions from the higher rotational levels in $v''=0$ to the corresponding levels of $v'=10$. These lines are diffuse because the rotational levels of $v'=10$ have energies which lie in the continuous energy range of the ${}^3\Pi_u$ curve (i.e. $>D''$). Since the lines near the head of the 10-0 band ($\nu=36101\text{ cm}^{-1}$) also are diffuse the energies of these lines are greater than D'' . The head of the 9-0 band is sharp so that its energy is less than D'' . In I, moreover, it was shown that the rotational lines of the 9-1 and 9-2 bands could be followed to $K\approx 30$. The line having $K\approx 30$ corresponds to an energy $35713\text{ cm}^{-1} + B_9K(K+1) \approx 36000\text{ cm}^{-1}$. This energy must be less than D'' otherwise the rotational lines could not have been observed in emission. D'' must therefore lie between 36000 and 36100 cm^{-1} . Therefore $D'' = 4.45 \pm 0.01$ volts.⁴¹ This value is in good agreement with the chemical value $103600\text{ cal} = 4.5$ volt obtained by Budde.⁴² By extrapolation of the ω_v/v graph for the ${}^3\Sigma_g^-$ state we ought to obtain the same value for its energy of dissociation D'' . But, as in the case of O₂, this extrapolation leads to a value of D'' which lies above the correct values for S₂ as obtained from predissociation.⁴³

Using the values of r_e' and r_e'' given in I and the values of ν_e , D' and D'' obtained above, we are able to draw the potential energy curves of the ${}^3\Sigma_g^-$ and ${}^3\Sigma_u^-$ states of S₂ using Morse's equation,⁴⁴ (see Fig. 3). Assuming the ${}^3\Pi_u$ curve to intersect the ${}^3\Sigma_u^-$ curve at about $v'=19$ and $v'=11$ according to section VI and to give two 3P atoms, we may draw this curve as shown in Fig. 3.

According to the above results the separation of the 1D and 3P atomic states must be $6.05 - 4.45 = 1.60$ volts. The value of this separation for O as given by Frerichs⁴⁵ is 1.95 volt and the corresponding separations in the Se and Te atoms as determined by McLennan and Crawford⁴⁶ are 1.2 and 1.3 volts. By interpolating we obtain 1.6 ± 0.1 volts for S which is in good agreement with the value given above;

The authors wish to thank Professor R. S. Mulliken for his interest and criticism in connection with this work.

⁴¹ G. Herzberg, *Zeits. f. Physik* **61**, 604 (1930) lays great stress on the fact that one can obtain only a maximum value of the energy of dissociation from predissociation data. From our interpretation of the phenomenon it is clear that a fairly accurate determination is possible for S₂.

⁴² Budde, *Zeits. f. Analyt. Chem.* **78**, 169 (1912).

⁴³ The linear extrapolation in this case will be very inaccurate as it is much greater than in the ${}^3\Sigma_u^-$ state.

NOTE ON MODES OF SPECTROGRAPH
SLIT IRRADIATIONDONALD C. STOCKBARGER AND LAURENCE BURNS
RADIATION MEASUREMENTS LABORATORY
MASSACHUSETTS INSTITUTE OF TECHNOLOGY

(Received February 26, 1931)

ABSTRACT

The mercury lines, 3650-63, have been photographed with very approximately coherent slit irradiation and with a number of different slit-widths. Maximum sharpness and resolution were obtained when the slit-width had a rather critical value. Multiple lines appeared when a multiple of the critical slit-width was used. Diffraction patterns appeared between the lines when the slit was made narrower than the critical value. A more detailed account of the research, of which this is but a small part, will appear later.

THE recent appearance of a mathematical paper by van Cittert¹ has prompted us to publish a small portion of the experimental results which we are accumulating in our study of spectrograph slit irradiation. Although the work has been in progress for nearly a year we do not feel justified in attempting to treat the subject in a general way until the entire program has been covered. The results presented will serve, therefore, merely as an indication of what we are finding, viz., that the width and shape of a line image are influenced to a large degree by the mode of slit irradiation.

We were led to undertake the research by difficulties encountered during the past few years in connection with such things as line absorption and intensity measurements. Evidently others have experienced similar difficulties.² Sometimes photographed lines appeared to have absorption cores when there were no assignable reasons for self-reversal. In one instance several lines seemed to suffer a shift of wave-length so great that no known agencies could account for it. Although the false effects could be eliminated usually through adjustment of the optical system, we felt that a systematic investigation should be made in order to remove the necessity for cut-and-try methods. Practically no help was found in the literature.

Van Cittert treats the two special cases, coherent and noncoherent monochromatic irradiation, in some detail and draws conclusions in regard to a few intermediate modes such as would be met in practice. Wadsworth³ and Schuster⁴ had already treated the completely noncoherent case but, as van Cittert suggests, a self-radiant slit which is sufficiently narrow is practically

¹ P. H. van Cittert, *Zeits. f. Physik* **65**, 547 (1930).

⁴ Schuster, *Ency. Brit.* Article on Spectroscopy; *Ast. Jour.* **21**, 197 (1905).

unattainable. Approximately noncoherent irradiation can be realized through the use of a very broad source or by imaging a source on the slit with a very large condenser lens. Departure from noncoherency of irradiation may lead to narrower lines but it can also seriously affect their shapes. In ordinary prac-

Fig. 2. Slit 3.5 divisions.

Fig. 3. Slit 4.5 divisions. Sharpness and resolution appear to be best with this slit width.

tice this departure may be considerable. For every mode of slit irradiation there exists a slit-width which should not be exceeded. This width being measured in wave-lengths, the correct setting for one spectral region is incorrect for another.

Fig. 4. Slit 9.5 divisions.

Fig. 5. Slit 12.5 divisions.

Fig. 6. Slit 14.5 divisions.

In general, we find our experimental results to be in qualitative agreement with van Cittert's mathematical analysis. We are including intermediate modes of irradiation, however, and consequently are finding different orders of effects and some effects not mentioned in his paper.

In the example selected for this note, the source was a low pressure quartz mercury arc placed 2.25 meters from the slit of a Hilger E2 quartz spectrograph. To narrow the beam of radiation an opaque screen with a window, about one centimeter in diameter, was mounted 25 cm in front of the arc. The arc and screen were carefully adjusted in position so that the radiation passed through the center of the collimator lens. This mode of irradiation, which approached the coherent case, was of such a nature that pronounced diffraction effects were observed, but it was not an extreme case. The 3650-63 lines were photographed with different slit-widths, and then the plates were examined with the aid of a recording microphotometer.

Figs. 1-10 show that maximum sharpness and resolution of the lines were obtained when the width had a rather critical value, viz., 4.5 divisions on the drum. At multiples of the critical width the lines tended to appear equally

Fig. 7. Slit 21.5 divisions.

Fig. 8. Slit 26.5 divisions.

Fig. 9. Slit 31.5 divisions.

Fig. 10. Slit 36.5 divisions.

multiple, e.g., a doubling occurred at twice the critical slit-width. For widths between multiples of the critical value the diffraction patterns were not as regular. The lines were often well resolved even when they appeared to be multiple. Below the critical width, however, the spaces between the lines were filled with a diffraction background of considerable density.

Evidently accurate estimates of the relative intensities would be difficult to make in some of the cases illustrated, either through measurement of areas or from reading maximum densities. Furthermore, very misleading information concerning true line shapes could easily be got from an examination of the images. The minima due to doubling might be misinterpreted as an indication of reversal. In extreme cases the diffraction patterns might even suggest fine structure.

We plan to present in much greater detail in a forthcoming paper the results of similar studies made with a number of modes of slit irradiation. Some of these modes give rise to doubling or trebling with wide separations between components.

THE MASSES OF O^{17} ¹

BY HAROLD C. UREY

DEPARTMENT OF CHEMISTRY, COLUMBIA UNIVERSITY

(Received March 9, 1931)

ABSTRACT

The rest mass of O^{17} is calculated from the known rest masses of N^{14} , He^4 , and H^1 and the masses due to the kinetic energies of He^4 , H^1 , and O^{17} as determined by Blackett and Harkins in the transmutation reaction $N^{14} + He^4 \rightarrow O^{17} + H^1$. The only assumptions involved are that the conservation of momentum and of mass-energy holds in these reactions. The masses secured in this way from seven sets of data do not agree within the probable limits of error for the experimental data. It is suggested that this is due either to the formation of O^{17} atoms of different masses and energies in this reaction or to the emission of gamma-rays during the collision. The former of these predicts discontinuous energy levels while the latter would probably cause the rest mass of O^{17} as calculated here to vary continuously. The relation of this calculation to the experiments of Bothe and Pose on the ranges of H particles from boron and aluminum is discussed.

BLACKETT² and Harkins and his coworkers³ have reported the presence of anomalous forked cloud tracks when α particles from thorium C and C' bombard nitrogen gas in a Wilson cloud-track apparatus. These forked tracks consist of the usual α -particle track up to the point of the fork; beyond this point there is one heavy track due to a heavy atom and one thin track having all the characteristics of the tracks of high speed hydrogen particles. These forked tracks are anomalous in that the kinetic energy is not conserved. Blackett has given a critical discussion of these tracks and shows that the range of the heavier secondary track is consistent with the assumption that it has an atomic number of 8 and a mass somewhere between 12 and 20 atomic weight units. It seems certain that only two particles are produced as a result of the collision between the α -particle and the nitrogen nucleus because only two tracks result and because these two tracks and the original α -particle track lie in one plane. The approximate conservation of mass requires that the heavy particle produced have an approximate atomic weight of 17 and thus that it be O^{17} . The subsequent discovery of this nucleus in atmospheric oxygen increases our confidence in the correctness of this conclusion.

These authors have secured the velocities of the He^4 , O^{17} , and H^1 nuclei (that of N^{14} is zero) and using Aston's values for the rest masses of He^4 , N^{14} and H^1 , it is possible to calculate the rest mass of O^{17} assuming the conserva-

tion of mass and energy. The mass of O^{17} is then easily seen to be given by

$$M_O = [M_{He}(1 - v_{He}^2/c^2)^{-1/2} + M_N - M_H(1 - v_H^2/c^2)^{-1/2}](1 - v_O^2/c^2)^{1/2}, \quad (1)$$

where M_O , M_{He} , M_N and M_H are the rest masses of the corresponding atoms in atomic weight units ($O^{16}=16$) and v_{He} , v_H and v_O the corresponding velocities. The velocities v_H and v_O are calculated from the angles between the direction of the original α -particle track and the directions of the oxygen and hydrogen tracks using the formulae

$$v_O = \frac{M_{He}}{M_O} v_{He} \frac{\sin \psi}{\sin(\psi + \omega)}, \quad v_H = \frac{M_{He}}{M_O} v_{He} \frac{\sin \omega}{\sin(\psi + \omega)}, \quad (2)$$

where ψ and ω are the angles between the α -particle track and the hydrogen and oxygen tracks, respectively. These formulae follow if the law of conservation of momentum holds for these collisions. The velocity of the α -particle is secured from the remaining range of the α -particle at the point of collision by using the well-known relation between range and velocity, $R = kv^3$.

Blackett used $M_{He}=4$, $M_H=1$ and $M_O=17$ in calculating the values of v_O and v_H and did not correct for the change of mass with velocity. Harkins probably used the rest nuclear masses (not the atomic masses) but did not correct for the change of mass with velocity. In making the calculations for M_O , $M_{He}=4.00107$, $M_H=1.00723$, $M_O=17$ have been used in securing preliminary values for v_{He} , v_H , v_O and M_O . Using these results values for $M_{He}(1 - v_{He}^2/c^2)^{-1/2}$, $M_H(1 - v_H^2/c^2)^{-1/2}$ and $M_O(1 - v_O^2/c^2)^{-1/2}$ were secured which were then used in repeating the entire calculation in order to correct for the change of mass with velocity and to use only the rest masses of the nuclei and not those of the atoms. These corrections changed the values of M_O by nearly a constant amount of 0.0007 at weight units and did not change the variations in M_O appreciably.

The probable errors in this calculation can be estimated more readily by expanding (1) in the form

$$M_O = M_{He} + M_N - M_H + \frac{1}{2} M_{He} \frac{v_{He}^2}{c^2} - \frac{1}{2} M_H \frac{v_H^2}{c^2} - \frac{1}{2} (M_{He} + M_N - M_H) \frac{v_O^2}{c^2} + \frac{3}{8} M_{He} \frac{v_{He}^4}{c^4} - \frac{3}{8} M_H \frac{v_H^4}{c^4} + \dots \quad (3)$$

Then substituting the values of (2) in (3) and neglecting the terms in v_{He}^4 and v_H^4 , we secure

$$M_O = M_{He} + M_N - M_H + \frac{1}{2} M_{He} \frac{v_{He}^2}{c^2} - \frac{1}{2} \frac{M_{He}^2}{M_H} \frac{v_{He}^2}{c^2} \frac{\sin^2 \omega}{\sin^2(\psi + \omega)} - \frac{1}{2} \frac{M_{He}^2 (M_{He} + M_N - M_H)}{M_O^2} \frac{v_{He}^2}{c^2} \frac{\sin^2 \psi}{\sin^2(\psi + \omega)}.$$

In the last term M_O can be set approximately equal to $M_{He} + M_N - M_H$ since this term is small and the equation then becomes

$$M_O = M_{He} + M_N - M_H + \frac{1}{2} M_{He} \frac{v_{He}^2}{c^2} \left(1 - \frac{M_{He}}{M_H} \frac{\sin^2 \omega}{\sin^2 (\omega + \psi)} - \frac{M_{He}}{M_{He} + M_N - M_H} \frac{\sin^2 \psi}{\sin^2 (\psi + \omega)} \right). \quad (4)$$

From this it is easily seen that the errors in the rest masses of He, N, and H introduce the same error in each calculation and that this is approximately Aston's error in the rest mass of N,¹⁴ namely ~ 0.0028 atomic weight units and that the error in the energy of the α -particle only affects the small quantity $M_O - M_{He} - M_N + M_H$. An error of one percent in the energy of the α -particle makes an error of only a few units in the fifth decimal place as will be seen below. A study of the effects of errors in ω and ψ on the mass shows that the error in ω is by far the more important because it is a small angle in the case of all the forked tracks measured by Blackett and because M_{He}/M_H (~ 4) is much larger than $M_{He}/(M_{He} + M_N - M_H)$ (~ 0.235) so that the error in the second term within the parenthesis of Eq. (4) is the important one. Blackett estimates his mean error of measurement of angles⁴ as about $10'$ providing the tracks are not curved and the angles are not near 90° , i.e., less than 75° . These conditions are fulfilled in the case of ω for every case except one in which the tracks are curved. The least laborious way for calculating this error was found to be a repetition of the calculation of M_O using $\omega + 10'$ instead of ω throughout. The probable error in M_O is then taken as

$$\Delta M_O = (\Delta M_1^2 + \Delta M_2^2)^{1/2}$$

where ΔM_O is the probable error of M_O and ΔM_1 and ΔM_2 are the errors produced by a one percent error in the energy of the α -particle and an error of $10'$ in ω , respectively.

The probable errors in Harkins' measurements cannot be estimated. The

track observed by Harkins and Shadduck⁵ is difficult to explain because both ω and ψ are obtuse angles so that the conservation of momentum is impossible and thus Eqs. (2) cannot apply, while the angles between the tracks are not reported in the case of the track observed by Harkins and Schuh.

The results of the calculations are listed in the Table I. Column 1 contains a symbol, B1, etc., indicating the first track of Blackett, etc. Altogether the data are complete for seven tracks.

DISCUSSION OF RESULTS

It is evident that the total variation of the calculated masses of O^{17} is very much greater than any reasonable estimate of the experimental errors. The lowest value is 0.00197 below the mean. It would be impossible to make a sufficient error in the kinetic energy of the α -particle to account for this error, for in order that this lowest value should agree with the 17.00300 value it would be necessary to assume that the energy of the α -particle was about 1/6 of that actually used in the calculation. The error in the measurement of ω necessary to account for this difference would be about 4° . Yet the track meets all of Blackett's requirements and the published track appears to be distinct and capable of exact measurement. The largest value is 0.00172 above the average. The angle ψ in this case is $78^\circ 52'$ and thus difficult to measure according to Blackett, but errors in this angle will make only small errors in M_O and thus there is no reason to believe that the mass calculated from this track is in error. Thus the conclusion that these values of the mass of O^{17} do not agree within experimental error seems justified and the preliminary average is not permissible.

The following ways of accounting for the discrepancies may be considered:

1. The oxygen atoms formed may not have the same mass and energy and the mass differences measure the energy-level differences of the O^{17} nucleus. If this is the case, one would expect γ -rays to be emitted by the O^{17} nucleus very soon after the collision.

2. γ -rays may be emitted during the collision process.

A decision between these possibilities is not possible on the basis of these experiments, nor, in fact, on that of the experiments of Bothe⁶ and Pose⁷ who have shown that the ranges of the H particles produced when α particles of uniform range bombard boron and aluminum respectively fall in discontinuous groups. The second assumption is the one usually assumed by workers in this field. I choose, however, to use the first, for it is more nearly in accord with the well established interpretation of collision phenomena of the external electron shells. Moreover, the time of collision is of the order of mag-

⁵ The figure drawn by these authors does not agree with the angles reported but the writer has been unable to reproduce their values for the velocities of O^{17} and H^1 by assuming different ways of defining the scattering angles.

⁶ W. Bothe, *Zeits. f. Physik* 63, 381 (1930).

⁷ H. Pose, *Zeits. f. Physik* 64, 1 (1930).

nitude of 10^{-21} sec. while the probability of emission of a quantum from the nucleus should be about 10^{15} so that the emission of a quantum during the collision is relatively improbable. The calculations in either case are subject to about the same errors due to neglect of the momentum of the quantum. An estimate of these errors can be made easily for the calculations as made here.

It is likely that the γ -ray quantum would be emitted within $\sim 10^{-15}$ seconds after the collision.⁸ During this time the O^{17} nucleus would move a distance equal to the diameter of one atom and thus the angle between the track of the excited O^{17} nucleus and the original α -particle track would not be the observed angle used in deriving equations (2), since the momentum of the quantum would deflect the track of O^{17} . To see how large an error this would make we shall consider the B4 track and assume that a quantum having energy equivalent to 0.00369 atomic weight units is emitted. This should give the greatest possible error. If this quantum were emitted in a direction parallel to the direction of the O^{17} nucleus, no change in the angle ω would result and thus no error be made in the calculation. If it were emitted perpendicular to the approximate plane of the three tracks, only a slight error would be made since the angle between the O^{17} and α -particle tracks would be changed but slightly. Finally if it were emitted in a direction perpendicular to the O^{17} track and in the plane of the three tracks, a maximum displacement of the O^{17} track would result. This angle is given by the relation

$$M_O v_O \sin(\Delta\omega) = 0.00369c$$

or

$$\Delta\omega \cong \frac{0.00369 \times 3 \times 10^{10}}{17 \times .454 \times 10^9} = 0.014 \text{ radians} = 50'.$$

A comparison with the calculated errors in M_O assuming an error of $10'$ in the measurement of ω shows that the maximum error possible in the B4 case is about ± 0.00038 . The error cannot be this large in any other case for the quantum cannot be as large as the quantum assumed here unless the rest mass of O^{17} is considerably less than 17.00135 which does not appear likely. Thus the actual spacings of the energy levels may be uncertain due to this effect by not more than 10 percent of their total separations from the lowest level. If the B2 collision does not produce a normal O^{17} nucleus, the maximum uncertainty increases in approximately direct proportion to the excitation energy and the uncertainty remains the same fraction of the excitation energy. The probable error would certainly be less, for the quantum may be emitted in a more favorable direction and the total excitation energy may not be emitted at the same time or in the same direction. The largest atomic

⁸ The probability of emission of a quantum is proportional to $\nu^2 a^2$ where ν is the frequency and a a length of the dimensions of the emitting system. Taking ν equal to about 10^5 times the frequencies emitted by atoms and a equal to 10^{-4} of the diameter of an atom, we see that this probability will be 10^7 times that of an atom which is known to be $\sim 10^8$.

weight difference of 0.00369 is equivalent to 0.003584 or 3.4×10^6 electron-volts.

Altogether these estimates of possible errors lead to the conclusion that the B1, B5, B3, and B6 values may all be due to one energy level but that B4 and B2 are due to the formation of O^{17} nuclei of different masses. Finally the B7 track may be disregarded because of the uncertainty arising from the curved tracks. Three masses separated by about equal differences are indicated by the data as shown in Table II. The data are too meager and

TABLE II.

Track	M_{\odot}	Av. M_{\odot}	ΔM_{\odot}

the uncertainty too great to regard these differences as certain, but equally spaced vibration levels due to a proton (or neutron) vibrating relative to an O^{16} residue of the O^{17} nucleus immediately comes to mind as a possibility.

Bothe's and Pose's experiments showing discontinuous ranges of H particles agree with the assumption of discrete energy levels in the heavier nucleus as they have indicated.⁹ If the range of the α -particles is uniform as was the case in their experiments, and if the energy of the heavier nucleus is small as compared with that of the hydrogen nucleus, discrete ranges of H particles will occur, the higher range particles occurring when a nucleus of low energy is formed. These conditions are not fulfilled by Blackett's data for the energy of the α -particles are not sufficiently uniform. It is of interest, however, to note the rough agreement between this data and the data of these authors. Table III shows the atomic weight of O^{17} as calculated, the kinetic energies

of the α -particle, and of the H and O^{17} nuclei, the velocity of the H nucleus and its range in air calculated from the formula, $R_H/R_{He} = v_H^3/v_{He}^3$. The

⁹ E. Rutherford and J. Chadwick, Proc. Camb. Phil. Soc. 25, 186 (1929) conclude that the variation of Blackett's data is outside experimental limits of error, but do not calculate the masses of O^{17} as is done here.

kinetic energies are expressed in atomic weight units per gram molecule (at. wt. of $O^{16}=16$). The energy of the O^{17} nucleus is considerably smaller than that of the hydrogen nucleus except in the case of the B6 track. The shortest range H nucleus is indeed that of the B4 track and the longest that of the B2 track as expected. The irregularities of the ranges as compared to the calculated masses of O^{17} can be seen to be due to the variations in the kinetic energies of the α -particles or of the O^{17} nucleus.

Bothe and Becker¹⁰ have detected the emission of γ -rays from lighter elements during the disruption of the nucleus in agreement with the expectations of this calculation and the interpretation of the results. They report, however, that the γ -radiation in the case of nitrogen gas bombarded with α -particles from polonium is very weak. This does not contradict the prediction of γ -rays in the collisions observed by Blackett, for they are all due to α -particles of considerably longer range (6.24 to 7.79 cm) than those from polonium.

On the basis of this calculation the atomic weight of O^{17} cannot be greater than the minimum value calculated, namely, 17.00135 ± 0.0028 if the atomic weight of O^{16} is taken as 16.000.

PROPAGATION OF LARGE BARKHAUSEN DISCONTINUITIES

BY K. J. SIXTUS AND L. TONKS

GENERAL ELECTRIC COMPANY, SCHENECTADY, NEW YORK

(Received February 28, 1931)

ABSTRACT

Large Barkhausen discontinuities have previously been observed by Forrer and by Preisach in nickel wires and hard-drawn wires of the nickel-iron series respectively under stress. A prediction that these discontinuities occur in form of a propagation along the wire, starting at a nucleus, has now been substantiated. In the experiments an additional local field was used to start the propagation at a definite point on the wire, which was in a uniform magnetic field, and the velocity was determined by measuring the short time interval elapsing between the passage through two search coils around the wire. With a fixed value of tension on the wire, the velocity v was found to vary approximately linearly with the applied uniform field H , so that $v = A(H - H_0)$. A is the slope of the velocity-field characteristic and H_0 is called the *critical field*. Measured velocities range from 500 to 40,000 cm sec⁻¹. H_0 varies with composition, amount of cold working, and with the stress applied to the wire. Increasing tension reduces the critical field over the greater part of the Ni-Fe alloy composition range. The behavior of H_0 with increasing and decreasing tension shows the presence of elastic hysteresis. A is nearly constant for changes in tension, in diameter of wire, for composition of wire, and is the same for a strip. Its value is approximately 25,000 cm sec⁻¹ gauss⁻¹.

The existence of eddy currents limits the speed with which magnetism can penetrate the wire. A rough calculation of this time gives values in the neighborhood of 10⁻² sec. Thus a discontinuity travelling at 10⁴ cm per sec. occupies a length of some 100 cm on the wire. This was substantiated both by measurements of the peak voltage induced in a search coil and by oscillograms taken of the induced voltage. The observed passage times agree well with the theoretical penetration times.

The constancy of the v - H slope for wires of different diameters is believed to indicate that the velocity depends upon surface phenomena rather than volume phenomena. The velocity would thus be determined by conditions existing near the front edge of the discontinuity where the penetration is still slight. The critical field is believed to represent a threshold value of magnetic field which must be exceeded at all points of the wire before reversal of magnetism can occur. The excess of the impressed field over the critical is nullified during propagation by the fields arising from the eddy currents. A possible picture of the discontinuity is one in which the reversal occurs within a minute distance of an approximately conical surface in the wire, the edge of the base of the cone forming the front of the wave.

The explanation advanced by Preisach for the asymmetric hysteresis loops found if one limit of the magnetization cycle was reduced has been extended. In this case magnetic inhomogeneities act as nuclei. Mechanical distortion introduces inhomogeneities of another type which also lead to the very easy formation of a nucleus. The phenomena found with torsion are more complicated than for tension. In some cases the slope of the v - H lines shows appreciable variation with direction of twist. The results of tests with various compositions of the nickel-iron series are described using both tension and torsion, but no new relations to other properties of these alloys can be given so far. Identifying H_0 with coercive field, R. Becker's theory has been compared with our results. It appears that in most cases increased elastic tension and increased cold working stresses shift H_0 in opposite directions.

1. LARGE BARKHAUSEN DISCONTINUITIES

SINCE the discovery of the Barkhausen effect, it has been a well-established fact that a great part of the change in induction in a ferromagnetic when subjected to a varying field, is made up of discontinuous changes. These ordinary discontinuities can only be observed after amplification and are not detectable by the ballistic method. Large discontinuities were first observed by Forrer¹ in 1926 in the hysteresis loop of a strained nickel wire. Later Preisach² showed that wires of Ni-Fe alloys under the influence of any stress (tension, torsion, bending) gave large discontinuities in a longitudinal field. In some cases these discontinuities were equal to almost the whole change in induction between saturation in the two directions.

If one tries to picture the manner in which such a magnetization discontinuity occurs, one is struck by the difficulty of accounting for a simultaneous reversal in the whole length of a fine wire. This consideration led Langmuir to predict that the magnetization first reversed at one point in the wire, forming a nucleus, and that the two boundaries which were thus formed then travelled along the wire with a finite velocity which probably depended on the magnetic field strength and the elastic strain. This prediction has been well substantiated by the experiments which will be described in what follows. A preliminary report of this work has appeared in the *Phys. Rev.* **35**, 1441 (1930).

2. THE PROPAGATION OF MAGNETIZATION

Several investigations on the propagation of magnetic waves have been carried out.³ The method used has been the same in all cases. An iron wire or bar was subjected to an alternating magnetic field at one point and the phase shift and maximum value of induction a certain distance away were measured. Zenneck⁴ proposed a theory for the observed effects, based on the assumption of eddy currents as a determining factor, and postulated the equivalence of electric and magnetic waves propagating along a ferromagnetic conductor. But the velocities corresponding to the observed phase shifts differed within a wide range (10^3 to 10^5 cm/sec), the whole phenomenon appeared to be very complex, and no effort was made to relate theory and experiment to each other.

The problem appears simpler in the case of the propagation of a single discontinuity, particularly a 100 percent discontinuity, by which is meant one in which the reversal of saturation is complete. In such a case we are dealing with a medium of finite conductivity and permeability unity but capable of reversing its magnetization at a point under a certain critical local condition.

⁴ T. Zenneck, *Ann. d. Physik* **9**, 497 (1902).

This local condition is defined by two variables, the state of elastic strain and the magnetizing force.

It was thought that general energy considerations might enable us to make an attack on this problem. A change of intensity of magnetization ΔI in a field H represents an available energy density of $H\Delta I$. This must at least exceed the energy dissipated by the eddy currents accompanying the magnetization wave.⁵ These losses can be estimated as follows. The whole change of magnetization intensity, ΔI , is assumed to occur in a

Fig. 1. Illustrating the induction of eddy currents by a moving magnetic discontinuity.

thin plane slab, S , moving with velocity v as shown in Fig. 1. The time integral of the e.m.f. induced in an annular volume dw of radius r will be that due to the change in flux, $\Delta\phi$, inside that ring, that is,

$$\int F dt = \Delta\phi/c = \pi r^2 \cdot 4\pi\Delta I/c \quad (1)$$

where F is the e.m.f. induced in dw and c is the ratio of units. The chief contribution to this integral will occur while the discontinuity is within a distance of dw which is comparable with its radius r . Accordingly, instead of $\int F dt$, where F is the e.m.f., we may write $F\Delta t$, approximately, where $\Delta t = 2r/v$. Applying this to Eq. (1), we have

$$F = 2\pi^2 r v \Delta I / c. \quad (2)$$

Since F is acting for a time Δt the eddy current loss in dw is $F^2 \Delta t dr dl / 2\pi r \rho$ where ρ is the specific resistance. Combining with Eq. (2) and integrating, the energy loss per unit length of wire of diameter a is found to be $E = (4/3)\pi^3 a^3 v (\Delta I)^2 / \rho c^2$. The magnetic energy available is $E_m = \pi a^2 H \Delta I$. Equating the two we find for the velocity

$$v = (3/4\pi^2) \rho c^2 H / a \Delta I \quad (3A)$$

in magnetic units or

$$v = 0.76 \times 10^8 \rho H / a \Delta I \quad (3B)$$

in practical units.

⁵ This reasoning obviously neglects any elastic energy changes which may occur.

Another calculation based on what appeared to be a less favorable hypothesis at the time was made by Dr. H. Poritzky. The assumption that the magnetization change occupies a length, λ , of the wire, long compared to a , gives

$$\Delta t = \lambda/v.$$

Reasoning as before, it follows that

$$v = (1/2\pi^2)\rho c^2 H \lambda / a^2 \Delta I \quad (4A)$$

in magnetic units, or

$$v = 0.51 \times 10^8 \rho H \lambda / a^2 \Delta I \quad (4B)$$

in practical units for this case.

3. APPARATUS

Theory of method. In measuring rectangular hysteresis loops of the same type as published by Preisach, it was noticed that the field strength at which the large discontinuity occurred, which will be called the *starting field*, was variable within a few percent in successive experiments. Since the occurrence

Fig. 2. Schematic diagram of circuit for velocity measurements.

of the large discontinuity depends upon the spontaneous formation of a nucleus, as described in Section 1, this erratic behavior can either mean that one nucleus was itself starting erratically or that different points along the wire were acting as nuclei. To control the creation of a nucleus an "artificial nucleus" was made by locally increasing the field strength by means of a current through a small magnetizing coil which created a local adding field. If then the homogeneous field, which will be called the *main field*, was set at a value

below the starting field, the large discontinuity could be initiated by applying the local adding field. The change in magnetization then begins at this point and propagates into the homogeneous part of the field where its velocity can be determined in the following way. If we place two search coils around the wire at a known separation, the discontinuity in travelling along the wire will produce successive voltage surges in these coils. If their time interval be measured, the velocity can be calculated.

Design of apparatus. The main field (Fig. 2) was furnished by a helix of 65.5 cm length containing 1200 turns of copper wire of 0.051 cm diameter, wound on a glass tube. Thus the uniform part of the field is given by $H = 23.0 i$ (i being the magnetizing current in amperes). The decrease in H 23 cm from the middle of the coil is 0.5 percent. At first a liquid resistance allowing continuous variation of current was used, but later on a slide-wire resistance was found to give a sufficiently gradual variation.

The wire under investigation was held in the axis of the coil and could be subjected to tension or torsion or both in the same way as described by Preischach. The tension was read by a spring balance and the twist by a pointer connected to the wire. The wire was surrounded by a capillary glass tube so as to permit its easy replacement with the search coils in place.

Each search coil consisted of 5000 turns of copper wire of 0.008 cm diameter. Since the length of the winding was 0.65 cm and the inner and outer diameters were 0.4 and 1.8 cm respectively, the voltage induced in them could not be proportional to the change in flux in one point on the wire, but gave an average over a distance comparable with the outer diameter (i.e., approximately 2 cm). The coils were wound on hard rubber spools and could be moved separately along the capillary tube by means of strings connected to them, and their positions could be read by pointers fastened to the strings and sliding along a scale. In most cases their separation was kept at 20 cm, each being 10 cm from the center of the main field.

The additional local field was produced by a coil of 10 turns of copper wire of 0.051 cm diameter, wound on a spool which was also movable along the wire. Generally the adding coil was placed at a distance of 24 cm from the middle of the main field.

Time-measuring arrangement. For measuring the time interval between the voltage impulses induced in the two search coils by the passing discontinuity, a vacuum tube device (Fig. 3) was built. This system, which is similar to the one used by Turner for his Kallirotron amplifier,⁶ has two stable states of current distribution, if voltages and resistances are properly adjusted. In State 1, plate current is flowing only in Tube I and there is no measurable plate current in Tube II; in State 2, current is flowing only in Tube II and there is no current in Tube I. To explain this let us assume that both tubes carry current. If a negative voltage impulse is now applied to the first grid, the plate current in Tube I decreases and in turn reduces the potential drop in R_I , which makes Grid II more positive. The plate current in II there-

⁶ L. B. Turner, Radio Review 1, 317 (1920).

fore rises, causing an increasing potential drop in R_{II} , and since this drop furnishes the grid bias for Tube I the grid voltage in I becomes still more negative. This cumulative action proceeds until practically no current is flowing in I, while the plate current in II has its full value. The current may now be shifted back to Tube I by applying a sufficient negative voltage to the grid of Tube II. Since the minimum value required increases as the resistances R_I and R_{II} are increased, the sensitivity of the circuit is under control. Two UX-112A tubes were used.

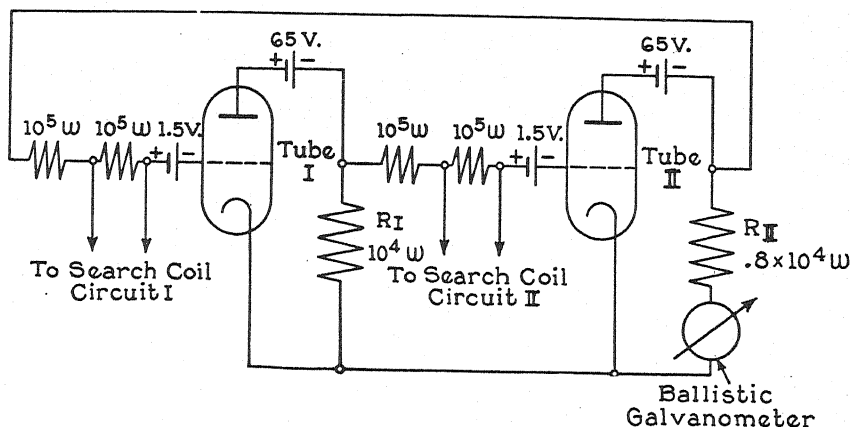

Fig. 3. Time-measuring circuit.

In making a time interval measurement this circuit was put into State 1 and a negative voltage impulse excited by Search Coil I was applied to the grid of Tube I. This shifts the current over to Tube II. After a time interval t the impulse from Search Coil II impressed on the second grid stops the current in Tube II. Thus the quantity of electricity which has passed through Tube II is a measure of the time t between the impulses. This quantity was measured by a ballistic galvanometer so that t was given by

$$i_P t = C\theta \quad (5)$$

where i_P is the plate current, C the ballistic constant of the galvanometer, and θ its deflection.

This relation was checked by means of a pendulum which opened two contacts in succession. Each contact was joined in series with a battery and the primary of a transformer, and the secondaries were connected respectively to the grids of Tubes I and II of the timing circuit. The opening of the contacts thus produced voltage impulses on the grids. The pendulum was calibrated by using a known condenser discharging through a known resistance. The time interval found from the pendulum calibration agreed with those calculated from Eq. (5). This means that the shift of the current from one tube to the other occurs in a time short compared with the time intervals to be measured.

The negative voltage impulse applied to tube I had to exceed a certain

minimum value (for given voltages and resistances in the timing circuit) but if it were too large, the current, after shifting to II, failed to return with the negative impulse on II. Thus it was necessary to keep the impulses within a certain range. The timing circuit was so adjusted that impulses of 1 volt operated it, and this voltage was obtained independently of the magnitude of the voltage induced in a search coil in the following way: The impulse from each search coil was amplified by a two-stage resistance-coupled amplifier whose output was impressed on the grid of a thyatron⁷ as shown in Fig. 4. The sudden rise of plate current, from 0 to 100 m.a. in the present circuit, being independent of the voltage impressed on the grid, always gives the same voltage of approximately 1v. across the secondary of the transformer in

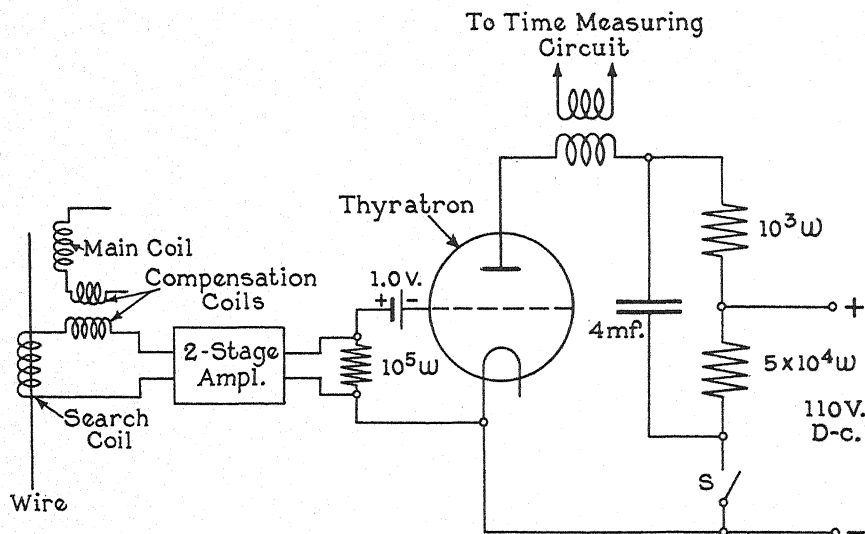

Fig. 4. Thyatron relay.

the plate circuit. The 4- μ f condenser and 50,000-ohm resistance made it possible to stop the discharge in the thyatron by simply closing the switch *S*, thus setting the circuit for the next impulse.

The maximum voltages induced in the 5000 turn search coils were of the order of 0.1 v. The amplification of the amplifiers used was about 120. As the grid bias of the thyatrons was so adjusted that positive impulses of about 1 v. would start the discharge, both thyatrons were started before the voltage impulse reached its maximum (See oscillograms Figs. 11 and 12). The whole

⁷ A thyatron is a three element tube containing a small amount of mercury. The cathode of the one used was oxide coated. In a thyatron which is initially carrying no current, current does not start to flow as long as the grid potential is less than a certain value. As soon as the grid voltage exceeds this critical value, however, the full plate current begins to flow, and from this moment on the grid has no further influence on this current. By using a proper value of grid bias this tube can be used as a relay, as in Fig. 4, or as a peak voltmeter. See: A. W. Hull, Hot-Cathode Thyatrons, *Gen. Elec. Rev.* **32**, 213, (1929) and **32**, 390 (1929); A. W. Hull and I. Langmuir, *Proc. Nat. Acad. Sci.*, March 1929; A. W. Hull, *Trans. A.I.E.E.* **47**, 753 (1928).

arrangement, it was found, worked satisfactorily down to time intervals of 0.5×10^{-3} sec, since all time constants were kept as low as possible.

Hysteresis loops. Hysteresis loops were taken with the magnetizing coil and one search coil (Fig. 2). The latter was connected to a ballistic galvanometer (Leeds and Northrup Type HS No. 2285d) with a sensitivity as used of 1425 Maxwell/Sc. div. and a period of 30 sec. The direct effect of the magnetizing coil on the search coil was compensated as usual by a mutual inductance.

4. VELOCITY MEASUREMENTS

Composition and treatment of specimens. The wires used in our experiments were made from ingots of electrolytic nickel and Armco iron plus 0.25 percent manganese to make the alloy ductile. The ingots were swaged and then drawn down to 0.10 cm diameter, sometimes to 0.076 cm, with annealing. From this diameter the wires were cold drawn to 0.038 cm. The per-

Fig. 5. Hysteresis loops for a wire under different tensions. Wire of 0.038 cm diameter from ingot No. 32, 15 percent Ni-Fe (only half of the total loop is shown).

centage of Ni was determined for each wire investigated by chemical analysis. In this section we shall deal mainly with alloys of between 10 and 20 percent Ni since these show the phenomena of propagation very markedly. In Section 11 the results with wires of other compositions will be considered briefly.

The wires were aged by stretching them for about 1 hour with loads near to the elastic limit, because more consistent results were obtained in this way. The aging load was never exceeded by the tensions used in the course of an experiment. Incidentally, in these hard drawn wires the breaking point lies only slightly beyond the elastic limit.

Effect of tension on hysteresis loops. Fig. 5 shows hysteresis loops for a wire of 15 percent Ni Fe and 0.038 cm diameter (cold drawn from 0.076 cm)

under different tensions. These loops are of the same type as the ones observed by Preisach. With no load only the ordinary Barkhausen discontinuities occur and these cannot be detected by the galvanometer. With rising tension the formation of large discontinuities begins until with high tension a great part of the whole change between negative and positive saturation occurs in one single discontinuity. The maximum magnetizing field was in all cases 34.5 gauss. The curves show that for increasing tension the remanence

Fig. 6. Velocity-field curves for a wire under different tensions. Wire of 0.038 cm diameter from ingot No. 14, 14 percent Ni-Fe.

increases until it equals 100 percent saturation as exactly as we could measure. The coercive field on the other hand is reduced by increasing tension.

Velocity measurements. A complete set of velocity measurements covered both variation of tension and of magnetic field. This was accomplished by finding the relation of velocity to field at each of a series of values of tension. In this series the tension was increased from zero to a maximum and then decreased again. At any one tension the starting field (see Section 3) was determined so that it might serve as an upper limit to the fields which could be used in the velocity determinations. The main field was then set at a value be-

low this, and the propagation was started by sending a current through the adding coil. The velocity of propagation was obtained from the throw of the ballistic galvanometer in the timing circuit and the known separation of the coils.

The results for a wire, 14 percent Ni-Fe, 0.038 diameter, are given in Fig. 6 for several values of tension between 38 and 92 kg/mm², the range in which large discontinuities were found. These curves exhibit some very striking features. They are, except in two cases, straight lines and are approximately parallel to each other. The higher the tension the further are the curves shifted to lower field strengths. The failure of the curves taken with decreasing tension (marked "Decr.") to coincide with the curves taken with increasing tension (marked "Incr.") shows the presence of elastic hysteresis which was observed directly by stress-strain measurements. When the wire which had undergone the stress cycle described was allowed to "rest" without tension for an hour, it reverted almost completely to its original condition, so that approximately the same cycle could be reproduced.

Observations of velocity were made down to velocities as low as possible but in many cases the experimental points could not be measured below 1000 cm/sec. In this neighborhood the discontinuity, after passing the first coil, often failed to reach the second one. In view of the linearity of the curves it is quite reasonable to suppose that the failure to propagate at low velocities does not arise from any inherent limitation in the mechanism of propagation but rather from irregularities in the wire which, influencing relatively small portions of the material, are unable to affect seriously a discontinuity propagating under more favorable conditions. For this reason the curves have been extrapolated to zero velocity, and the intercept with the H -axis has been interpreted as the limiting field in which propagation at a velocity approaching zero would occur in an ideal wire. This field will be called the *critical field* and will be designated by H_0 .

The behavior of the v - H curves with respect to the elastic hysteresis mentioned is peculiar in that the successive curves with decreasing tension instead of lagging with respect to the "Incr." curves, as they would if H_0 were a function of elongation, show the opposite behavior. This could be due to two types of response in the wire, one an immediate elastic response, and the other a slower and limited plastic yield. A lowering of H_0 by the elastic strain combined with an increase of H_0 with plastic deformation would account for the phenomenon observed. (See Section 12).

Judging from their general character, the curves may best be represented by an empirical formula of the type

$$v = A(H - H_0) \quad (6)$$

where v is the velocity of propagation, and A is the slope of the line which was within 25 percent of a value of 25,000 cm sec⁻¹ gauss⁻¹.

When the velocity was measured over subdivisions of the usual 20 cm and over other portions of the wire still within the uniform 46 cm of field, this

velocity was found to be always the same for the same conditions in the cases where the v - H characteristics were straight lines. When these characteristics were curved, however, the velocity showed some variation. This suggests that the curvature arises in some way from a variation in the state of the wire along its length.

One of the cases in which the characteristics showed the greatest curvature was that of the wire whose hysteresis loops were shown in Fig. 5. These characteristics are reproduced in Fig. 7 as an example of the greatest deviation from the simple relations usually found.

The above tests were originally made with a view to testing the constancy of the velocity of propagation. Another test consisted of varying the position and intensity of the adding field. It was found that for a certain position of

Fig. 7. Velocity-field curves for a wire under different tensions. Wire of 0.038 cm diameter from ingot No. 32, 15 percent Ni-Fe.

the adding coil a certain minimum current was required to start the discontinuity, but that this minimum varied in successive trials. The average of this minimum at each of several successive points along the wire was found to vary considerably, exhibiting maxima and minima even in the homogeneous part of the field. The velocity of propagation was independent of both position and magnitude of adding field as long as this field did not add to the uniform field between the search coils appreciably.

The magnitude of the discontinuity is nearly constant over the homogeneous part of the field; only at very low velocities do large differences at different points appear. Since large differences at the same point in successive trials were also found, we can only conclude that the behavior is erratic at low velocities.

It is significant to note that the general effect of the aging process referred

to at the beginning of this section is to increase the critical field but to leave the slope of the characteristic in most cases unchanged. This suggests that while the critical field depends on the strain state of the wire, the slope depends on other factors.

5. COMPARISON OF EXPERIMENTS AND THE EDDY-CURRENT THEORY

It is now possible to make a direct comparison of the velocities appearing in Fig. 6 with those calculated from the eddy current formulas derived in Section 2. For 15 percent Ni-Fe $\rho = 30 \times 10^{-6}$ ohm cm and using an average value of H of 5 gauss and an average value of ΔI of 2400, Eq. (3B) gives $v = 250$ cm sec $^{-1}$ compared to velocities well exceeding 10^4 cm sec $^{-1}$ in many cases. A discrepancy in the other direction might well have been explained on the basis that the magnetic energy was only partially available for conversion into eddy currents. Eq. (4B), however, permits of velocities greater than those given by Eq. (3B) roughly in the ratio that λ exceeds a . Actually, the observed velocity of 10^4 cm sec $^{-1}$ would require a ratio $\lambda/a = 60$. But how could a transition 60 times as thick as the diameter of its front characterize the definite self-propagating phenomenon we were observing?

At least, the formulas gave experimental hints and also served to emphasize certain features of the velocity-field characteristics. We have already remarked that these characteristics do not pass through the origin so that v is not proportional to H . This might be an indication that, for some reason, the magnetic energy available is not $H\Delta I$ but $(H - H_0)\Delta I$ so that on this hypothesis

$$v = 0.51 \times 10^8 \rho \lambda (H - H_0) / a^2 \Delta I \quad (7)$$

On the other hand, such reasoning would increase λ/a over ten-fold since $H - H_0$ is some 0.4 gauss compared to the 5 gauss assumed for H at $v = 10^4$ cm sec $^{-1}$.

A comparison of velocity-field slopes with ΔI (or ΔB as in Fig. 8) shows no such correspondence as indicated by Eq. (3B) and a check of slope against wire diameter gave the values of slope shown in Fig. 9. The wires used were of 10 percent Ni-Fe and were cold drawn from 0.102 cm to the different diameters. Over a three-fold range of diameters, namely, from 0.020 to 0.061 cm the observed slopes, taken for one wire at different tensions or for different wires, lie scattered in the range 2 to 3×10^4 cm sec $^{-1}$ gauss $^{-1}$, and show no evidence of an increase in slope with a decrease in diameter. The 0.071 cm diameter slope is probably not comparable with the rest because the magnitude of the discontinuity gradually decreased as it proceeded along the wire.

The successively smaller wires have been subjected to successively greater amounts of cold working thus raising the question as to how comparable the results can be on this account. It has been pointed out, however, (Section 4) that the aging process has a marked effect on the critical field but almost none on the v - H slope. And later it will be seen that annealing wires of various diameters, succeeded by cold drawing to a uniform size, again yields specimens having different values of H_0 but approximately equal v - H slopes. Thus the

differences in cold working are probably of no significance as regards our present conclusions.

Fig. 8. Magnitude of the discontinuity and velocity as functions of field and tension. Wire of 0.038 cm diameter from ingot No. 14, 14 percent Ni-Fe.

The evidence against the eddy-current theory which we considered to be most convincing was given by the following experiment. A wire of 0.254 mm

Fig. 9. Slope of velocity-field curves for wires of different diameters. Wires from ingot No. 24, 10 percent Ni-Fe.

diameter was rolled down to a strip 0.076 mm thick and 0.53 mm wide. Although the influence of eddy currents is, of course, reduced considerably in

comparison with the round wire, the v - H slopes measured for the strip fall in the same range as the slopes found for wires.

At this stage in the investigation we found ourselves in the position of observing magnetic discontinuities travelling with such high velocities that for the phenomenon to be energetically possible this "discontinuity" must occupy a length on the wire of at least 60 times and perhaps 750 times (if energy available is $(H - H_0)\Delta I$) the wire radius. The proof that this actually occurs is a result of the measurements on the voltage induced in the search coils and of the oscillograms of the wave shape which are described in the next two sections.

6. VOLTAGE MEASUREMENTS

We have already mentioned the fact that the voltages induced in the search coils are of the order of several tenths of one volt, but we should expect much higher voltages on the basis of a plane wave front. Let us make the assumption that the total change in flux, $\Delta\phi = 47$ lines (for a change in induction of $\Delta\phi = 40,000$ gauss) in a 0.038 cm wire, produces a voltage in the coil during the time Δt , which the jump needs to travel a distance equal to the diameter (2 cm) of the coil. That will give us an average value of voltage to be expected, and the maximum voltage might be much higher than this. Now $v = 10^{-8}n\Delta\phi/\Delta t$ where v is the voltage induced in a coil of n turns. Taking $n = 5000$, and $\Delta t = 2 \times 10^{-4}$ sec (for a velocity of 10,000 cm/sec), we obtain 11.8 volts as a lower limit for the peak voltage. The existence of any such voltages would have rendered the use of amplifiers in the original velocity measurements entirely unnecessary. It therefore became of interest to eliminate this large discrepancy by direct voltage measurements.

In our determinations a thyatron circuit, similar to the one shown in Fig. 4, was used as a peak voltmeter. By adjusting the grid bias in several trials, a bias value was found at which the single impulse just started the discharge. The difference between the known critical voltage and the applied bias is the peak voltage of that impulse. The voltage induced in a 200-turn search coil was amplified by two screen-grid stages, giving a uniform amplification of 120 in the frequency range between 30 and 10^4 cycles/sec. While a single search coil permits the measurement of the voltage peak only, it was thought that two search coils with variable separation and connected in series-opposition would allow a rough determination of the wave shape itself to be made simply by plotting the observed peak voltage against coil separation. A more detailed analysis made after numerous measurements had been taken shows that this experiment would give the same apparent wave-front shape for a variety of actual shapes.

Thus in Fig. 10 the shape of the curves which were obtained in this way is roughly that to be expected from the method used, leaving as significant features only the voltage maximum attained and the least separation of the coils which gives that maximum. The former yields the maximum rate of change of flux, the latter the distance from wave front to this point in the wave.

The curves of Fig. 10 depict measurements made with different values of main field, that is, with different velocities. Over a 3-fold range of velocities the maximum is seen to come between 4 and 6 cm from the beginning, and the plot to the right shows that the peak voltage is proportional to the velocity. This indicates that the discontinuity retains an approximately constant shape as its velocity changes.

Although the two-coil method fails to give the wave shape near the wave front it is reliable beyond the voltage maximum. This region was explored by connecting the coils in series-addition (the negative peak voltage with the series-opposition connection could also have been used) but as the oscillograms taken subsequently cover the same range in greater detail these results will not be given.

Fig. 10. Amplified peak voltage induced by the discontinuity in two search coils connected in series-opposition. Voltage amplification 120 times. Wire of 0.038 cm diameter from ingot No. 14, 14 percent Ni-Fe.

A comparison between the voltages induced in two coils of 200 and 5000 turns, respectively, was made to make sure that the internal capacity of the coils was not reducing the coil voltages. The ratio of voltages found, namely, $0.023/0.59 = 0.039$, so nearly checks the turn ratio as to prove that any such effect is negligible in these experiments.

7. OSCILLOGRAMS

Further information concerning the nature of the discontinuity was obtained from oscillograms of the voltage induced in a search coil. The circuit connections were made in this order: 5000-turn search coil to high resistance potentiometer to amplifier to oscillograph. The potentiometer was used to obtain a suitable oscillograph deflection in each case. The amplifier had 3-resistance-coupled stages. The oscillograph was of the Blondel type. The vibrator used to reproduce the voltage had a sensitivity of 1.45 m.a./mm and a natural frequency of 1000 cycles/sec. Figs. 11 and 12 show the amplified voltage wave superimposed on the plate current of the last tube for a wire of 14 percent Ni-Fe and 0.038 cm diameter under a tension of 92 kg/mm². In

Fig. 11 the discontinuity is traveling at a rate of $17,000 \text{ cm sec}^{-1}$ in a field of 4.25 gauss, in Fig. 12 the velocity is 7000 cm sec^{-1} in a field of 3.91 gauss. We note the steep rise of the voltage and the long tail with many irregularities. But in interpreting these curves we have to bear in mind that the resolution of the method is limited by three factors. First, there is the limited space resolution of the search coil, a factor also present in the method employed in Section 6. It has already been estimated that this limit is of the order of 2 cm for the 5000-turn coil used. But of more importance here is the second factor, the limited time resolution of the oscillograph vibrator. The maximum in

Figs. 11 and 12. Amplified voltage induced in a 5000-turn search coil by the discontinuity. Velocities: Fig. 11, $17,000 \text{ cm sec}^{-1}$ (see Table I, Osc. No. 29); Fig. 12, 7000 cm sec^{-1} (see Table I, Osc. No. 28).

Fig. 11 occurs only $0.68 \times 10^{-3} \text{ sec}$ after the beginning of the deflection. Since the period of the vibrator is 10^{-3} sec , the oscillograms can give us no useful information concerning the fore-part of the wave.

The two factors mentioned are of little importance as regards the general shape of the tail of the wave, but here the third factor enters, the fact that the voltage surge produces a charge on every inter-stage condenser, which discharges comparatively slowly. This appears in the zero shift occurring in the oscillograms. In this connection it is interesting to note that the peak voltages were about 25 percent lower than those found in the preceding section, undoubtedly on account of the second factor.

The area under the oscillogram curve is proportional to the total change in flux through the search coil. The area when measured (allowing in any reasonable way for zero shift) gave a value of flux change only a few percent less than that found ballistically, Section 3. Thus the third factor can be estimated with fair accuracy.

It is essential to know which features of the wave are characteristic of a propagating discontinuity in general and which arise from special local conditions. Successive oscillograms at the same point are identical except for small variations in the details. Oscillograms taken at different points along the wire show greater variation in the minor discontinuities, but the total

Fig. 13. Change of induction with time (upper part) and penetration of induction into the wire. (The shaded area represents the portion of the wire which has changed direction of magnetization). The radial dimensions are magnified 675 times with respect to the axial dimensions.

duration of the wave and for the most part the main structure, involving perhaps two or three major peaks, are preserved.⁸ The main structure is unaltered if the main field is changed so that the wave velocity is different.

Incidentally, the oscillograph was used to obtain a check on the velocity measurements made with the timing circuit by recording the impulse from the two search coils connected in series at a known separation. The agreement was exact.

Since the integral of the voltage curve from its beginning gives the total flux change in the wire up to the corresponding time, an oscillogram enables us to plot this flux as a function of distance along the wire if we make use of the known velocity. In addition to the plot of the integral in Fig. 13, we have

⁸ In the single experiment made, the voltage maximum decreased with distance travelled by 20 percent in the central 20 cm of the main field, although ballistic measurements have shown in general that the magnitude of the whole discontinuity remains unchanged.

shown the change as progressing from the surface of the wire inward, assuming that each element of the wire completely reverses magnetization instantaneously.⁹ The existence of eddy currents definitely requires that the progress of the change shall be inward, and the instantaneous reversal is plausible if a quantum phenomenon is involved.

Such an analysis applied to the oscillogram of Fig. 11 gives Fig. 13. In this particular case the jump was 97 percent of saturation reversal, and as shown, the 3 percent deficiency has been localized at the axis of the wire. The justification for this is not clear-cut but has some basis in the consideration that the orienting forces are probably least at the axis.

The most striking feature is the experimental demonstration of the fact that the wave occupies a length of some 100 cm in the 0.038 cm wire, a length of the same order of magnitude as calculated in discussing Eq. (7). The comparison of experiment with theory will, however, be based on time of passage rather than length of discontinuity for two reasons. First, because the oscillograph measures time directly and second because the formulas developed in Section 2, being based fundamentally on skin-effect considerations have to do with the time required for a magnetic field to penetrate to a certain depth. They are not concerned with conditions at other points relatively large distances away. On this basis, the only possible interpretation of these formulas is in terms of the time required for the change at a single cross-section to complete itself. Eq. (3) has been definitely found to be inapplicable. Eq. (4), as modified in Eq. (7), gives for this time,

$$\delta t = \lambda/v = 1.96 \times 10^{-8} a^2 \Delta I / \rho (H - H_0) \quad (8)$$

Table I sets forth our most representative comparisons between the directly observed times required for the discontinuity to pass (Column 5) and

TABLE I. Comparison between the experimental and calculated times of penetration.

the times calculated from Eq. (8) (Column 6). The small numerical value of the ratio of these two (Column 7) constitutes a satisfactory check in view of the manner of deriving Eq. (7), and the constancy of this ratio for velocity

⁹ In this connection see Section 8.

ratios of 3.5 to 1 lends strong support to the fundamental correctness of the calculation. Unfortunately, simultaneous velocity and oscillograph measurements on wires of other diameters have not been made so that the dependence of δt on a has not yet been checked.

The question as to whether the whole hysteresis loss is an eddy-current loss or whether appreciable transfer to heat occurs through magnetostrictive vibrations, quantum transitions, and possibly other mechanisms, has never been conclusively answered. The present results, however, furnish a very strong indication that at least for large Barkhausen discontinuities only a small fraction $(H-H_0)/H$ of the magnetic loss goes into eddy currents.

The possibility presents itself that the remaining energy appears as magnetostrictive energy. An experiment in which we tried to detect either a momentary or permanent change in length of the wire accompanying a reversal gave a negative result. The accuracy was not quite good enough, however, to be able to reject this hypothesis definitely.

In view of the large penetration times found by us, it becomes of some interest to inquire just what Preisach (reference 2, p. 778) was measuring when he detected harmonics to 10^7 cycles/sec in a stretched wire subjected to a 6000 cycle magnetizing field. It is impossible to say conclusively in the absence of definite data, but it may be pointed out that in 0.5×10^{-7} sec. 0.01 cm of wire surface to either side of a nucleus can reverse by propagation and that the increase of field in that time interval may well cause a large number of magnetic elements to reverse spontaneously, thereby becoming nuclei. The combination of propagation and nucleus formation may easily cause the reversal of an appreciable fraction of the surface of the wire during this time. On this basis the reversal time of a nucleus or any small portion of the wire may be far less than the minimum fixed by Preisach's experiment.

8. THE NATURE OF THE DISCONTINUITY

Experiments have enabled us to outline roughly the flux distribution in the discontinuity, Fig. 13, and an eddy-current theory has been advanced which gives the penetration time. The only results, however, so far obtained which throw the slightest light on the longitudinal velocity are those which show that the slopes of the v - H curves for different size wires and even for the strip are all approximately the same. This indicates that the velocity, which corresponds to a given $H-H_0$, being independent of cross-section, is determined only by conditions existing within a small distance of the surface. Since the front edge of the wave lies in the surface, we have been led to the view that the forces at the wave edge determine the velocity, the rest of the wave penetrating the wire as fast as eddy currents allow. It seems plausible to assume that the force required to reverse an element of the wire is H_0 itself or is directly related to it. On such a basis a too-rapid progress of the wave would either give rise to eddy currents or alter the wave configuration near the front in such a way as to reduce the force at the wave front below the minimum reversing value. In this case no new elements could reverse until eddy

currents had decreased or later portions of the wave had advanced sufficiently to reestablish the minimum field.

Any theory must take cognizance of the electromagnetic field set up by the discontinuity. As a solution of Maxwell's equations for the discontinuity shown in Fig. 13, travelling at a high velocity, seems to be extremely complicated at the best, the attempt might be made to disentangle the various factors for the simpler case of very low velocities. As a first step we shall assume as an approximation that the shape of the wave is independent of velocity in the experimental range and remains constant in the limit as $v \rightarrow 0$. It may then be possible to make a first order calculation of magnetic field arising from eddy currents for low velocity and assume that this remains valid at the highest velocities measured. The proportionality of peak voltage to velocity and the approximate shape constancy found by experiment themselves strongly suggest that first order effects are the important ones.

Let us tentatively assume that Fig. 13 indicates the nature of a discontinuity travelling from right to left with magnetization reversing from positive to negative. Both unchanged and reversed portions of the medium present north poles to the wave front with the result that it is a surface of magnetic charge of pole strength m per unit area, m being given by

$$m = \Delta I dy/dx \quad (9)$$

where y is the depth of the discontinuity below the wire surface at a distance x back from the front edge. This distribution of magnetism, supposed stationary, gives rise to an almost radial magnetic field from the discontinuity surface outward. An approximate calculation of this field can be made on the assumption that $y \propto x$. For the 100 cm discontinuity in the 0.038 cm wire with ΔI equal to 3240, Eq. (9) gives

$$m \sim 3240 \times 0.019/100 = 0.62$$

whence the radial field near the front edge is

$$H_r = 4\pi m = 8 \text{ gauss.}$$

A field of this magnitude would not allow the elements which are completing their reversal to align themselves axially, but a little consideration will show that their deviation from axial alignment need be very little in order to annihilate the internal poles. Referring to Fig. 14 showing the discontinuity FF' travelling with velocity v , it is readily seen that if the intensity of I_2 in the reversed domains forms the same angle with FF' as the original intensity I_1 , there is no pole development in the wire. The angle β , being twice α , will thus be about $2 \times 0.019/100 = 3.8 \times 10^{-4}$ radians which is a negligible deviation from perfect alignment. Finally, this deviated I_2 can be joined to the axial I_2 which is supposed to exist when the discontinuity has completely passed with a discrepancy only of the order of $(3.8 \times 10^{-4})^2$.

In this representation the reversal of intensity occurs within a distance equal to the thickness of a domain, but it is also possible to picture the transition as being much less abrupt. The one condition to be fulfilled, established

by the requirement that no internal poles develop, is that the intensity of magnetization be solenoidal throughout the wire, or, mathematically, that $\nabla \cdot I = 0$. This means, of course, that we can imagine tubes of intensity drawn in the wire and that all poles develop on the surface. A little consideration

Fig. 14. Compensation of internal poles.

shows that this surface distribution of pole strength is given by the oscillograms. Fig. 15a shows two possible configurations of intensity tubes for an iron-nickel strip with idealized surface distribution. Only half the strip is shown. As represented, the tubes are of equal strength and therefore terminate at the surface in equal poles as given by equal partial areas under the

Fig. 15. a. Possible configuration of lines of intensity in a strip. b. Detail of reversal region.

distribution-of-magnetism curve. I_1 can join I_2 either via the sharp dashed bend or via the smooth curve. The former corresponds to Fig. 14, the latter to a more gradual transition.

The interesting feature of this transition is that it cannot occur as a uniform progression. Referring to Fig. 15b, which gives the detail of Fig. 15a, it

is seen that such a progression would mean a continually increasing rotation of I from domain to domain in going from m to n . This in turn would require that the intensity of all domains along pq be parallel. Now it is evident that a tube of intensity expands between rs and pq , both of which represent surfaces normal to the tube. Since I is solenoidal, I at pq must be less than I at rs , which is incompatible with detailed parallelism of the domains. But if we abandon the idea of uniform progression and suppose that as the reversal region mn begins to traverse any small volume (large compared to a domain) certain of the domains scattered throughout it reverse before others, then no such inconsistency arises.

The representation of the discontinuity just given has only been recently devised and no calculation of the fields arising from eddy currents in the neighborhood of the front edge has been made. It seems quite possible, however, that they may be comparable with $H - H_0$. In that case we shall have reached the simple viewpoint that the excess magnetic field over H_0 is just that necessary to overcome the opposing eddy current field.

The velocity would thus be dependent upon the surface magnetization in the neighborhood of the wave front, the length λ of the discontinuity is in turn the product of this velocity and the calculable penetration time δt . Both λ and ΔI , as well as a , then fix the average pole strength of the surface. But what in turn establishes the surface distribution of magnetism? That must probably await a detailed solution.

9. THE EFFECT OF INHOMOGENEITIES IN THE WIRE

Magnetic inhomogeneities. The magnetic and mechanical uniformity of the wire is of utmost importance with respect to large Barkhausen discontinuities. The importance of the first factor has been pointed out by Preisach in the experiment in which he varied the limits of the hysteresis cycle. We now look at it from a new viewpoint reached through our knowledge concerning the propagation. In all the preceding experiments the cycle of magnetization was carried as far as ± 34.5 gauss. Later we performed an experiment somewhat similar to Preisach's. In successive cycles the positive field strength limit was decreased as indicated in Fig. 16. On the negative side the limit was always at 34.5 gauss. We note that reduction of the maximum field on the positive side reduces both starting field and the magnetization change at the succeeding jump. In the limiting case, if the maximum positive field used is that required to cause the jump, the succeeding negative starting field is little less than the critical field for this wire.

The explanation for this lies in the following. The usually small change in induction which occurs after a large discontinuity is irreversible and contains smaller Barkhausen discontinuities. Thus in not carrying the cycle to saturation on the positive side, we have failed to turn a number of elementary magnets into the positive direction. These particles set up fields in the negative direction and thus act as nuclei where a discontinuity may start. The bigger such a nucleus is, i.e., the higher the field it produces, the lower the starting field which we have to apply in order to start propagation. We should expect

Fig. 16. Effect of varying one limit of the hysteresis loop. Wire of 0.038 cm diameter from ingot No. 32, 15 percent Ni-Fe.

Fig. 17. Influence of a bend in the wire. A. Apparent hysteresis loop of the bent portion. B. Hysteresis loop of unbent portion.

that the starting field could never be less than the critical field, since we found this to be the lower field limit for propagation. In experiment this expectation was not quite confirmed since the lowest observed starting field in some cases was lower than the critical field. But the deviation in no case amounted to more than a few percent.

Mechanical inhomogeneities. In a special case the range of field strength, within which propagation could be observed in a 14 percent Ni-Fe wire of 0.038 cm diameter and under 62 kg/mm² tension was found to be 4.25 to 4.65 gauss. This wire was bent in its middle to a semicircle of 2.5 mm radius (the wire being strained far beyond its elastic limit in doing this), was then straightened out again and was finally put under the same tension as before. After this treatment the starting field coincided with the critical field at 4.25 gauss so that propagation could not be obtained. This behavior can be explained by the fact that the bent part has a magnetization curve different from the rest of the wire as shown by curves *A* and *B* of Fig. 17. Curve *A* was taken in the usual way with a search coil placed at the bent portion of the wire. The hysteresis curve so obtained gives a change of induction just below the starting field which is even less than the actual because of the flux leakage arising from the shortness of the bent portion. Thus when the critical field of the normal wire is reached, a considerable part of the bent portion has already changed magnetization and again those elementary particles, which point in the field direction, act as nuclei to start propagation.

Another example of the same type of phenomenon is the fact that hand-drawn wires have starting fields which lie only slightly above the critical field. The irregularity of hand drawing undoubtedly creates "weak nuclei" just as the bending did. Since a low starting field makes it impossible to measure the higher speeds of propagation, machine drawn wires were used in all experiments.

In all but one early experiment the wire projected from both ends of the magnetizing coil so that it extended into regions of comparatively low field strength. In that experiment, however, a short wire terminating within the homogeneous part of the field was used. This wire was clamped to copper wires with brass fastenings and was put under tension. The ends of the wire where it was clamped were not under the same strain as the middle part. Accordingly they did not have rectangular hysteresis loops and acted as weak nuclei.

From these experiments we can conclude that the upper limit of the propagation range is fixed by the non-homogeneity of the wire. The greatest range observed extended from 3.20 to 4.75 gauss in the case of a 14 percent Ni-Fe wire under combined tension and torsion. To the higher field value there corresponded a velocity of 40,000 cm sec⁻¹, which is the highest one measured so far.

10. TORSION

Preisach obtained great discontinuities in magnetization also when he applied torsion to a wire. In this case, too, we found that the magnetization

propagated in the same way as in the case of tension. We also observed a parallel shift of the velocity field lines to the left for increased twist in the range between 8 and 20 percent Ni-Fe, but we obtained much greater variations with respect to slope than in the case of tension. Fig. 18 taken for a 0.038 cm, 25 percent Ni-Fe wire shows this behavior very clearly. For this particular wire it made a great difference whether the twist was applied clockwise or counter-clockwise and if tension was added still another slope was found. All these curves were perfectly reproducible which shows that the

Fig. 18. Velocity-field curves for torsion and combined tension and torsion. Wire of 0.038 cm diameter from ingot No. 19, 25 percent Ni-Fe. The black dots represent check points.

strains were elastic. (The black dots in Fig. 18 were taken after the direction of applied torsion had been changed several times.) As another wire from the same lot did not exhibit this dependence of slope on direction of twist, it is probable that internal strains have an important influence on the slope in the case of torsion. More work on wires having different strain distributions has to be done before the observed effects can be explained.

The data for these cases are insufficient as yet for checking the application of Eq. (7).

11. WIRES OF DIFFERENT COMPOSITION

Nickel iron wires of 3, 5, 8, 10, 12, 14, 15, 20, 25, 35, 40, 55, 60, 78, 80, 90 and 100 percent nickel content have been examined. We were able to obtain large discontinuities (i.e., of more than 80 percent of the double saturation value) with *tension* only in the ranges 8 to 25 percent and 55 to 78 percent.¹⁰ From 5 percent down and from 80 percent up no large discontinuities could be observed and with 35 and 40 percent only small jumps of about 1/10 of the double saturation value appeared under tension. These jumps were very erratic and probably only included a short length of wire at a time so that velocity measurements with these compositions were impossible. Throughout the remainder of the range the v - H slope did not deviate much from an average value of $25000 \text{ cm sec}^{-1} \text{ gauss}^{-1}$, but the effect of tension on the critical field varied profoundly. Between 8 and 20 and at 78 percent increasing tension reduced the critical field H_0 , but at 55 and 60 percent it increased H_0 . At 25 percent there was a pronounced reversal in the dependence of H_0 on tension. Up to a certain value of tension H_0 increased with increasing tension; after passing this value the critical field decreased again.

Torsion produced large discontinuities over the entire range between 8 and 100 percent Ni-Fe, and the great variations in v - H slope already mentioned as existing in the 8 to 20 percent interval were found to be present over this wider range, varying between the values 10^4 and $6 \times 10^4 \text{ cm sec}^{-1} \text{ gauss}^{-1}$. There were no simple relations between either composition or amount of twist and critical field. The v - H characteristics were occasionally curved, but no more frequently than in the case of tension.

No experiments have been carried out on the propagation in wires under an elastic bending force.

12. THE CRITICAL FIELD

Some of our experimental results allow comparison with a theory recently advanced by R. Becker¹¹ which has already been applied successfully to the case of nickel under tension.¹² Becker introduces the close and important relation between the magnetic and elastic state of materials by the assumption that the direction of magnetization in each Weiss domain is determined by the stress tensor in that domain in the absence of an external field. The theory enables him to derive hysteresis loops for these districts for different initial angles between magnetization and applied field.

For the limiting case of anti-parallelism between magnetization and field, this theory yields a rectangular hysteresis loop for which the coercive field is given by

$$H_C = 8SAI_m$$

¹⁰ Preisach (p. 755) has already pointed out that the upper limit coincides with the composition at which magnetostriction and accordingly the effect of tension on magnetization change sign.

¹¹ R. Becker, *Zeits. f. Physik* **62**, 253 (1930).

¹² R. Becker and M. Kersten, *Zeits. f. Physik* **64**, 660 (1930).

where $S \sim 1$ is a factor calculated from magnetostriction, A is the elastic deformation of the domain and I_m is the saturation intensity of magnetization. With exact antiparallelism, however, the force couple exerted by the impressed field is zero, with the consequence that the domain may conceivably retain its position of unstable equilibrium even for values of H exceeding H_C . It is interesting that the Ni-Fe wire as a whole exhibits this behavior. On this basis the critical field H_0 is to be identified with the coercive field H_C , while the somewhat erratic starting field corresponds to the indeterminate field at which the equilibrium of the Weiss domain may be destroyed.

As a matter of fact, the wire only approximates to a single Weiss domain, both because of the peaks evident in the oscillograms and because of the fact that for fields only slightly greater than H_0 the reversal of the wire is incomplete (as may be seen in Fig. 8), indicating that the coercive force for certain portions of the wire exceeds H_0 . It is possible that the ΔI vs H curves in

Fig. 19. Critical field for wires of different diameter. All Wires cold drawn from annealed wire 0.102 cm diameter from ingot No. 14, 14 percent Ni-Fe.

that figure give the proportion of the wire for which H exceeds the coercive field.

Becker's formula, when applied to our conditions, yields values more than 10 times higher than those observed by us and predicts in the case of iron and low nickel-iron alloys for which S is positive, an increase in H_C with increasing elastic deformation A . In our experiments with Ni-Fe wires of 8 to 20 percent nickel content, we observed just the opposite relation. This is shown clearly by Fig. 19 in which the reciprocal of tension is plotted vs. the critical field for different diameters. In a certain range of tensions we obtain almost a linear relation between $1/T$ and H_0 ! In his second article Becker recognizes this difficulty.

Fig. 19 allows of one other comparison with experiments made by Becker and Kersten. The critical fields obtained for wires of different diameter for the same stress are quite different. Since all wires were cold drawn from 0.102 cm, the explanation lies in the different amounts of cold working the wires have suffered. The more cold working, the greater are the internal strains,

and the higher the coercive force. In their experiments with nickel wires Becker and Kersten are able to obliterate differences in internal strain conditions entirely by application of high tension and they can account for this satisfactorily by assuming that hard drawing produces only longitudinal strains in the wire whose influence disappears in the limiting case of high applied tension.

In our case, however, this does not occur, for even with tension near to the breaking point, the coercive forces are still considerably different for wires subjected to different amounts of cold working. This is illustrated by

Fig. 20. Critical field at 62 kg/mm² tension for wires with different amounts of cold working. All wires of 0.038 cm diameter from ingot No. 22, 20 percent Ni-Fe.

Fig. 20 which shows the critical field for wires of 0.038 cm diameter annealed at the diameters shown and then cold-drawn. Even with 62 kg/mm² tension, the coercive force varies between 3.3 and 6.8 gauss. It may well be that radial and associated ring strains introduced by cold working play an important role in determining the coercive force. On the other hand, Becker and Kersten's results on stretched Ni wires where only continuous and reversible changes are present show that any radial strains can be neglected. Further investigation of propagation in thin strips may give additional information regarding the role of strains in this connection, as the strain structure is probably much simpler in rolled strips than in drawn wires.

Among the various possibilities which present themselves for extending this work we intend to refine the oscillographic method further and to use that method on different sized wires and strips and also on composite strips (strips with a surface layer only of Ni-Fe) with the hope of obtaining a more detailed picture of the magnetic discontinuity. We also intend to examine the effect of temperature change both on nucleus formation and propagation velocity.

We appreciate the interest which Professor R. Becker has shown in this work, and we wish to express our gratitude to Dr. I. Langmuir who, as we have said, not only foresaw the magnetic propagation, but has also given many suggestions and much advice.

FERMI-DIRAC STATISTICS APPLIED TO THE PROBLEM
OF SPACE CHARGE IN THERMIONIC EMISSIONBY RUSSELL S. BARTLETT
YALE UNIVERSITY

(Received March 2, 1931)

ABSTRACT

This paper develops mathematically the state of an electron gas in equilibrium with a plane electrode when the electron gas obeys the Fermi-Dirac rather than the classical distribution law. For a part of the range of integration graphical methods were found necessary, but fortunately a change of variable leads to a solution, shown graphically, which is independent of the temperature and of the nature of the emitting electrode. Thus a single graphical integration can be applied to any emitting surface at any temperature, giving the density, electric intensity, and potential at any desired distance from the surface. A simple extension of the theory makes possible the calculation of the thermionic current between plane electrodes. Numerical examples are given, and the validity of the assumptions is discussed briefly.

WHEN Schottky¹ first proposed that the thermionic work function could be explained by the attraction of an escaping electron to its electric image in the surface, he discussed at some length the possible effects of space charge and "structure effects," and finally concluded that other forces were small compared to the image force. Recently Waterman and the author² have questioned this conclusion, and have suggested that, at least under certain conditions, possibly always, space charge and structure effects are more important than the image force.

Schottky, assuming the image force to be correct, and assuming a Maxwell distribution of electron velocities, was able from measured electron emission currents to calculate the concentrations of the electron atmosphere at all points outside the metal and found it so rarefied that space charge could be neglected. This extension of the image force from a region out from the surface where it can be confirmed experimentally down towards the surface through a region where it could not be expected to be valid appears to be unjustifiable. The alternative treatment by space charge analysis, which is to be developed in this paper, is certainly not free from criticism. In particular, it is necessary to apply Poisson's equation to an electron gas, thus assuming a continuous distribution of electricity which certainly does not exist. On the other hand it would appear, as is pointed out in a previous paper by Waterman and the author, that the choice of suitable statistics may in part avoid that difficulty. In any case the space charge method of attack seems justified close to the surface where the image force certainly breaks down. In order to

¹ Schottky, *Phys. Zeits.* **15**, 872 (1914).

² Bartlett and Waterman, *Phys. Rev.* [2] **37**, 279 (1931).

shed more light on this question certain calculations have been carried out, assuming that the electron concentration is controlled by space charge alone.

EQUILIBRIUM. CLASSICAL DISTRIBUTION LAW

After the manner of Fry,³ Langmuir,⁴ and others, consider a stream of electrons emerging from an infinite plane electrode with initial velocities distributed according to some law. The electrons outside the surface of the electrode will induce a charge on the electrode tending to draw the electrons back to it. There will be a potential distribution outside the metal surface through which the electrons move, those with higher initial velocities normal to the surface getting further out before they are turned back.

With no external field and no neighboring electrode, we may write an expression for the charge density at any point in potential space.

$$\rho = 2e \int_{(2V\epsilon/m)^{1/2}}^{\infty} \frac{f(v_0)}{v} dv_0 \quad (1)$$

where $f(v_0)dv_0$ gives the number of electrons emerging from the surface per square cm with initial velocities normal to the surface lying between v_0 and $v_0 + dv_0$, while v represents the normal velocities of these electrons at the point in question. Clearly

$$v_0^2 - v^2 = \frac{2V\epsilon}{m}. \quad (2)$$

Using Poisson's equation we get

$$\frac{d^2V}{dx^2} = -4\pi\rho = -8\pi e \int_{(2V\epsilon/m)^{1/2}}^{\infty} \frac{f(v_0)}{v} dv_0. \quad (3)$$

Multiplying both sides by $2 dV/dx$ and integrating in the usual manner gives

$$\left(\frac{dV}{dx}\right)^2 = 16\pi m \int_{(2V\epsilon/m)^{1/2}}^{\infty} v f(v_0) dv_0. \quad (4)$$

We cannot proceed further without knowing the distribution law of velocities expressed in $f(v_0)$. For the classical case

$$f(v_0) = n_0 \frac{mv_0}{kT} e^{-mv_0^2/2kT} \text{ or } f(v_0) = N_0 \left(\frac{m}{2\pi kT}\right)^{1/2} v_0 e^{-mv_0^2/2kT}, \quad (5)$$

where n_0 is the number of electrons passing through a square centimeter of the surface per second, and N_0 is the number of electrons per unit volume at the surface. Then

$$\left(\frac{dV}{dx}\right)^2 = 16\pi m N_0 \left(\frac{m}{2\pi kT}\right)^{1/2} \int_{(2V\epsilon/m)^{1/2}}^{\infty} v v_0 e^{-mv_0^2/2kT} dv_0. \quad (6)$$

³ Fry, Phys. Rev. [2] 17, 441 (1921).

⁴ Langmuir, Phys. Rev. [2] 21, 419 (1923).

Changing the variable to v gives

$$\begin{aligned}\left(\frac{dV}{dx}\right)^2 &= 16\pi m N_0 \left(\frac{m}{2\pi kT}\right)^{1/2} \int_0^\infty v^2 e^{-mv^2/2kT - V\epsilon/kT} dv \\ &= 8\pi N_0 kT e^{-\epsilon V/kT}\end{aligned}\quad (7)$$

since the integral is a well known form having the value $\frac{1}{2}(8\pi k^3 T^3/m^3)^{1/2}$.

Taking the square root and performing the next step in the integration gives

$$x = \left(\frac{kT}{\pi N_0}\right)^{1/2} \frac{1}{2\epsilon} e^{\epsilon V/2kT}. \quad (8)$$

The first boundary condition requires that V and x shall approach infinity together as dV/dx approaches zero, and this is satisfied by the above equations. The second condition specifies that at the surface the number of free electrons per cubic centimeter has a fixed value, in this case N_0 . That requires that the surface of the metal shall be at x_0 given by

$$x_0 = \left(\frac{kT}{\pi N_0}\right)^{1/2} \frac{1}{2\epsilon}. \quad (9)$$

Combining Eqs. (1) and (5) and integrating at once gives Boltzmann's equation

$$N = N_0 e^{-\epsilon V/kT}. \quad (10)$$

We could, in fact, have arrived at Eq. (8) by combining (10) with Poisson's equation. But (10) is of interest now in that, combined with (8) it gives us the concentration at various distances from the surface. The quantities V , dV/dx , x , and N are so related that as soon as we have fixed one all the others may be determined from various combinations of Eqs. (7), (8), and (10). It is also seen that a different metal, with a different electron concentration at the surface, could be handled by the same equations with an appropriate value of x_0 at the surface.

EQUILIBRIUM. FERMI-DIRAC DISTRIBUTION LAW

If in Eqs. (1) and (4) we replace the classical expression for $f(v_0)$ by that obtained from Fermi-Dirac statistics, the problem becomes much more complicated.

Now

$$f(v_0) = \frac{2\pi kT G m^2}{h^3} v_0 \log(A_0 e^{-mv_0^2/2kT} + 1) \quad (11)$$

where A is a measure of the degeneracy of the electron gas. This gives us instead of (1) and (4) the following.

$$N = \frac{4\pi kT G m^2}{h^3} \int_{(2V\epsilon/m)^{1/2}}^\infty \frac{v_0}{v} \log(A_0 e^{-mv_0^2/2kT} + 1) dv_0 \quad (12)$$

and

$$\left(\frac{dV}{dx}\right)^2 = 32\pi^2 kTG \left(\frac{m}{h}\right)^3 \int_{(2V\epsilon/m)^{1/2}}^{\infty} vv_0 \log (A_0 e^{-mv_0^2/2kT} + 1) dv_0. \quad (13)$$

Making the change of variable from v_0 to v gives

$$N = \frac{4\pi kTGm^2}{h^3} \int_0^{\infty} \log (A e^{-mv^2/2kT} + 1) dv \quad (14)$$

where

$$A = A_0 e^{-\epsilon V/kT}$$

and

$$\left(\frac{dV}{dx}\right)^2 = 32\pi^2 kTG \left(\frac{m}{h}\right)^3 \int_0^{\infty} v^2 \log (A e^{-mv^2/2kT} + 1) dv. \quad (15)$$

Since the evaluation of these integrals is rather complicated, it will be convenient to make certain substitutions.

Let

$$\frac{mv^2}{2kT} = u^2.$$

Let

$$f(A) = \int_0^{\infty} \log (A e^{-u^2} + 1) du$$

and

$$g(A) = \int_0^{\infty} u^2 \log (A e^{-u^2} + 1) du.$$

Then

$$N = \frac{2\pi G(2mkT)^{3/2}}{h^3} f(A) \quad (16)$$

and

$$\left(\frac{dV}{dx}\right)^2 = \frac{16\pi^2 Gm^{3/2}(2kT)^{5/2}}{h^3} g(A). \quad (17)$$

For the case where $A < 1$ the solution is fairly simple. Expanding the $\log (A e^{-u^2} + 1)$ du we get

$$f(A) = \int_0^{\infty} [A e^{-u^2} - \frac{1}{2} A^2 e^{-2u^2} + \frac{1}{3} A^3 e^{-3u^2} \dots] du \quad (18)$$

and

$$g(A) = \int_0^{\infty} [A u^2 e^{-u^2} - \frac{1}{2} A^2 u^2 e^{-2u^2} + \frac{1}{3} A^3 u^2 e^{-3u^2} \dots] du. \quad (19)$$

The integrals involved are ordinary probability integrals. Hence

$$f(A) = \frac{1}{2}(\pi)^{1/2} [A - A^2/2^{3/2} + A^3/3^{3/2} \dots] \quad (20)$$

$$g(A) = \frac{1}{4}(\pi)^{1/2} [A - A^2/2^{5/2} + A^3/3^{5/2} \dots]. \quad (21)$$

Further, for the case where $A \ll 1$ we get the usual Boltzmann relation that $N = N_0 e^{-eV/kT}$. When the gas is not classical the Boltzmann relation becomes $A = A_0 e^{-eV/kT}$, as Waterman has found from a different point of view.

When $A > 1$ the solution becomes more difficult since the expansion used above is not valid over the total range of integration. It is necessary to divide the range of integration into two parts, for which Ae^{-u^2} is less than or greater than unity. Then

$$f(A) = \int_0^{(\log A)^{1/2}} \log [Ae^{-u^2}] du + \int_0^{(\log A)^{1/2}} \log [e^{u^2}/A + 1] du \\ + \int_{(\log A)^{1/2}}^{\infty} \log [Ae^{-u^2} + 1] du \quad (22)$$

and

$$g(A) = \int_0^{(\log A)^{1/2}} u^2 \log [Ae^{-u^2}] du + \int_0^{(\log A)^{1/2}} u^2 \log [e^{u^2}/A + 1] du \\ + \int_{(\log A)^{1/2}}^{\infty} u^2 \log [Ae^{-u^2} + 1] du. \quad (23)$$

If $A \gg 1$ (i.e., the electron gas completely degenerate) the first term is the only one of consequence.

This first term can be integrated directly to give

$$f(A) = 2/3 (\log A)^{3/2} \quad (24)$$

$$g(A) = 2/15 (\log A)^{5/2} \quad (25)$$

And finally by means of series expansion and integration by parts, involving steps of questionable rigor but justified by the result, one obtains

$$f(A) = \frac{2}{3} (\log A)^{3/2} \left[1 + \frac{\pi^2}{8 (\log A)^2} + \frac{7\pi^4}{640 (\log A)^4} + \frac{31\pi^6}{6144 (\log A)^6} \right. \\ \left. + \frac{4191\pi^8}{5 \times 2^{16} (\log A)^8} \dots \right] \quad (26)$$

$$g(A) = \frac{2}{15} (\log A)^{5/2} \left[1 + \frac{5\pi^2}{8 (\log A)^2} - \frac{7\pi^4}{384 (\log A)^4} - \frac{155\pi^6}{43008 (\log A)^6} \right. \\ \left. - \frac{381\pi^8}{2^{16} (\log A)^8} \dots \right] \quad (27)$$

where these series, though not convergent, may be used for large values of A , and have been checked by graphical integration.

In the Sommerfeld-Fermi-Dirac statistics, the number of particles per unit volume and the energy per unit volume are expressed in terms of two

Fig. 1. $N = 5.4830 \times 10^{15} T^{3/2} f(A) / \text{cm}^3$ $E = 1843.9 T^{5/4} [g(A)]^{1/2} \text{ volts/cm}$. $X = 2.1631 \times 10^{-9} \phi(A) / T^{1/4} \text{ cm}$. $V = 1.9851 \times 10^{-4} T \log_{10} A \text{ volts}$.

Fig. 2.

functions $F(A)$ and $G(A)$. It turns out that $f(A)$ as used above is equal to $\pi^{1/2}/2 \cdot F(A)$, while $g(A) = \pi^{1/2}/4 \cdot G(A)$, thus confirming the results of the questionable steps mentioned above.

We now have expressions for $f(A)$ and $g(A)$, hence for N and $(dV/dx)^2$ over four regions, completely degenerate, less degenerate, approaching classical, and completely classical. The two extremes are handled by exact expressions, the intermediate regions by series, and there is a region between for which neither series is valid. $f(A)$ and $g(A)$ have been evaluated graphically for this intermediate region. Numerical results of this graphical integration and of the series expansions are given in Figs. 1, 2 thus covering the regions between the exact expressions for completely degenerate and completely classical states.

For the degenerate state $N = 4\pi G(2mkT)^{3/2}/3h^3 \cdot (\log A)^{3/2}$ and for the classical state $N = G(2\pi mkT)^{3/2}/h^3 \cdot A$. For intermediate states $N = 2\pi G(2mkT)^{3/2}/h^3 \cdot f(A)$ where $f(A)$ for any value of A may be found from the figures.

Further for the degenerate state

$$\left(\frac{dV}{dx}\right)^2 = 32\pi^2 G m^{3/2} (2kT)^{5/2} / 15h^3 \cdot [\log(A_0 e^{-eV/kT})]^{5/2}.$$

Taking the square root of both sides and integrating directly gives

$$x = \frac{15^{1/2} h^{3/2}}{2^{7/4} \pi G^{1/2} m^{3/4} (kT)^{1/4} e} \log A^{-1/4}. \quad (28)$$

For the classical state

$$\left(\frac{dV}{dx}\right)^2 = \frac{4Gm^{3/2}(2\pi kT)^{5/2}}{h^3} A_0 e^{-eV/kT}.$$

This also may be integrated directly to give

$$x = \frac{h^{3/2}}{2^{5/4} G^{1/2} m^{3/4} \pi^{5/4} (kT)^{1/4} e} \cdot A^{-1/2}. \quad (29)$$

For the intermediate region graphical integration is required, since there is no exact solution. It is seen that

$$\frac{dV}{dx} = \text{const } (g(A))^{1/2} = \text{const } (g(A_0 e^{-eV/kT}))^{1/2}.$$

Since values for the expression under the radical have been tabulated as a function of A , easily convertible to a function of V , it is possible to perform a graphical integration. To simplify the arithmetical work this has been done to give a new function $\phi(A)$ proportional to x , values for which are given in Figs. 1 and 2.

$f(A)$, $g(A)$, and $\phi(A)$ are perfectly general functions, independent of temperature and of the nature of the electron emitter. The coefficients of these functions in the various equations take care of the effect of temperature. The curves in Fig. 1 show these functions plotted against A . The origin at $\log A = 0$ is purely arbitrary. In effect there is no origin, or better, perhaps, each particular problem provides its own origin, fixed by the conditions of the sur-

face. In practice it is convenient to consider distances and potential differences from x_1 , V_1 corresponding to A_1 , to x_2 , V_2 , corresponding to A_2 . The formulae below together with the tables cover the entire range of an electron gas.

$$V(\text{volts}) = 300kT/\epsilon \cdot \log A = 690.8kT/\epsilon \cdot \log_{10} A$$

$$= 1.9851 \times 10^{-4} T \log_{10} A \quad (30)$$

$$N = 2\pi G(2mkT)^{3/2}/h^3 \cdot f(A) = 5.4830 \times 10^{15} T^{3/2} f(A) \quad (31)$$

$$A \gg 1 \quad N = 4\pi G(2mkT)^{3/2}/3h^3 \cdot (\log A)^{3/2} = 1.2772 \times 10^{16} T^{3/2} (\log_{10} A)^{3/2} \quad (32)$$

$$A \ll 1 \quad N = G(2\pi mkT)^{3/2}/h^3 \cdot A = 4.8591 \times 10^{15} T^{3/2} A \quad (33)$$

$$E = 2^{13/4} \pi G^{1/2} m^{3/4} (kT)^{5/4} / h^{3/2} \cdot [g(A)]^{1/2} \text{E.S.U/cm}$$

$$= 1843.9 T^{5/4} [g(A)]^{1/2} \text{volts/cm} \quad (34)$$

$$A \gg 1 \quad E = 2^{15/4} \pi G^{1/2} m^{3/4} (kT)^{5/4} / 15^{1/2} h^{3/2} \cdot (\log A)^{5/4}$$

$$= 1909.8 T^{5/4} (\log_{10} A)^{5/4} \text{volts/cm} \quad (35)$$

$$A \ll 1 \quad E = 2^{9/4} \pi^{5/4} G^{1/2} m^{3/4} (kT)^{5/4} / h^{3/2} \cdot A^{1/2} = 1227.4 T^{5/4} A^{1/2} \text{volts/cm} \quad (36)$$

$$x = h^{3/2} \times 0.046052 / 2^{13/4} \pi G^{1/2} m^{3/4} (kT)^{1/4} \epsilon \cdot \phi(A) \text{ cm}$$

$$= 2.1631 \times 10^{-9} \phi(A) / T^{1/4} \text{ cm} \quad (37)$$

$$A \gg 1 \quad x = 15^{1/2} h^{3/2} / 2^{7/4} \pi G^{1/2} m^{3/4} (kT)^{1/4} \epsilon \cdot (\log A)^{-1/4}$$

$$= 4.1770 \times 10^{-7} / T^{1/4} \cdot (\log_{10} A)^{-1/4} \text{ cm} \quad (38)$$

$$A \ll 1 \quad x = h^{3/2} / 2^{5/4} G^{1/2} m^{3/4} \pi^{5/4} (kT)^{1/4} \epsilon \cdot A^{-1/2}$$

$$= 1.4112 \times 10^{-7} / T^{1/4} \cdot A^{-1/2} \text{ cm.} \quad (39)$$

A small additive correction is necessary to join different regions. This may easily be calculated, but has been omitted here to avoid further complications.

Fig. 3. Height of potential barrier at different distances from the surfaces.

If then N is known for any point, A , V , x , and E may be found from these formulae used in conjunction with the figures. And as soon as one of these is fixed for another point, all the others may be found. The separation of the points in space and in potential is found by subtracting the V 's and x 's for the two points. Figs. 3, 4 give some characteristic results for various conditions.

Fig. 4. Distances between electrons at different distances from the surface.

CURRENT TO THE ANODE

The analysis just given applies to the case of no current, effectively an equilibrium case, though it was considered from the point of view of emerging and returning streams. Fortunately it is possible to take advantage of earlier work by Fry and Langmuir in going over to the case where a current is flowing from the hot cathode. In Langmuir's paper two variables are defined

$$\xi = 4(\pi/2kT)^{3/4}m^{1/4}(\epsilon i)^{1/2}(x - x_m) \quad (40)$$

$$\eta = \epsilon(V - V_m)/kT. \quad (41)$$

It is easily seen that $\eta = \log A - \log A_m$ in our notation. Now the current passing a potential barrier V is given by

$$i = 2\pi\epsilon kT G m^2 / h^3 \cdot \int_{(2V\epsilon/m)^{1/2}}^{\infty} u \log (A_0 e^{-mu/2kT} + 1) du \quad (42)$$

$$i = 2\pi G m \epsilon (kT)^2 / h^3 \cdot A_0 e^{-\epsilon V/kT} = 2\pi G m \epsilon (kT)^2 / h^3 \cdot A \quad (43)$$

provided $A_0 e^{-\epsilon V/kT} < 1$.

If this value of i is put into the expression for ξ above we get

$$\xi = 2^{9/4} \pi^{5/4} (kT)^{1/4} m^{3/4} \epsilon A_0^{1/2} e^{-\epsilon V/kT} (x - x_m) / h^{3/2} \quad (44)$$

from which it appears that $\xi = 0.046052 \pi^{1/4} / 2^{3/4} \cdot \phi(A) \cdot A^{1/2}$ with similar relations beyond the range of $\phi(A)$. Thus it is possible to apply the Langmuir Fry analysis to this case if a little care is exercised, using the relation $\xi = \xi_1 A_0^{1/2} e^{-\epsilon V/2kT} = \xi_1 A^{1/2}$.

The Langmuir-Fry analysis assumes electrons streaming out from the electrode with velocities according to Maxwell's distribution law. Of these the highest velocity electrons escape completely, so that the returning stream consists of only a part of the Maxwellian distribution. Now in thermionic emission the currents are generally so small that the loss of electrons to the returning stream is of no consequence close to the electrode where the distribution is no longer classical. In the region where the loss of electrons is of consequence, the distribution is classical or so nearly so that the Langmuir-Fry analysis can be joined to mine as indicated without serious error.

ILLUSTRATION OF THE METHOD OF CALCULATION

Let us take the case of an emitter at 3000°K .

$N_0 = 6.2 \times 10^{22}$ (tungsten)

Parallel plane electrodes 1 cm apart.

From the figures $\log A_s = 9.534$

$A_s = A$ at surface

Arbitrarily $\log A_m = -3.0000$

$A_m = A$ at potential minimum

A simple calculation gives i corresponding to A_m as 3.612×10^{-4} amps/cm²

From the figures $\phi(A_s) = 126.59$

$\phi(A_m) = 2002.06$

Using equation (45) $\xi_{1m} = 43.399$

$\xi_{1s} = -2.744$

$\xi_1 = 46.143$

Multiplying by $A^{1/2}$ gives $\xi = 1.4592$

To this we add 1.1397 to fit classical to Fermi,

giving ξ_1' (from surface to potential minimum) = 2.5989

From 40 or 44 $\xi' = 43.041$

so that ξ_2' (from potential minimum to collecting electrode) = 40.442

From tables of Langmuir, extended to cover some cases dealt with here,
 $\eta_2 = 87.49$ (from potential minimum to collecting electrode.)

$\eta(\text{total}) = 74.96$ $V = 19.387$ from equation 41

Repetition of this process for a series of values of A_m leads to the results given in Fig. 5.

Fig. 5. Current from emitter at 3000° to parallel electrode 1 cm distant for different accelerating potentials.

DISCUSSION OF RESULTS

Fig. 3, showing the height of the potential barrier at various distances from the surface, for tungsten, $N_0 = 6.2 \times 10^{22}/\text{cm}^3$ is interesting in that it shows a value for the work function much larger than that conventionally accepted, this larger value being necessary to nullify the effect of the zero-point energy of a highly concentrated electron gas.

Fig. 4 shows in effect the average distance between electrons as a function of distance from the surface. The distance between electrons is comparable with the distance from the surface at a point so close that the image force is meaningless, and slightly further out it is seen that an electron is further from the surface than its nearest neighbor, showing that space charge is certainly important.

When considering the calculations shown in Fig. 5, it should be remembered that the calculations were carried out for plane parallel electrodes, whereas experiments have almost invariably used coaxial cylinders. The rapid change of space charge outward radially from a fine wire would naturally lead to different results. In order to test this question, an attempt is now being made to reproduce experimentally the conditions here treated theoretically.

There are two more questions of importance that must be recognized here. In the first place, the calculated electric field at the surface is so large that a great reduction of electron concentration within the surface should result from the very large surface charge. Just what effect this might have on the case of a current cannot be predicted. The calculations for the equilibrium case are still valid, if one chooses a proper electron concentration at the surface. A second question, of course, is that of the validity of Poisson's equation. It seems to the author that probably this calculation is reasonably close to the truth in regions where the concentrations of electrons is large. But at considerable distances from the surface, where the concentration is low, the approximation to the truth cannot be as good. It is for this reason that for the calculation of emission currents the electrodes were chosen so close together. Also for this reason results are not given for currents at lower temperatures. This particular problem will be investigated further.

In conclusion the author wishes to thank Professor A. T. Waterman for many helpful discussions of the problem.

THE ANGULAR DISTRIBUTION OF ELECTRONS SCATTERED BY MERCURY VAPOR

By J. M. PEARSON AND W. N. ARNQUIST

NORMAN BRIDGE LABORATORY, CALIFORNIA INSTITUTE OF TECHNOLOGY

(Received February 27, 1931)

ABSTRACT

Instead of using pressures of the order of 10^{-2} mm the apparatus described is designed for pressures in the range 10^{-3} to 10^{-4} mm. Heavy primary current densities are used to afford measurable scattered currents, and high angle scattering is found to be more easily measurable. It is found that the angular distribution curves for electrons scattered by mercury are not monotonic functions of the angle of scattering. For a given energy of incident electrons the curve passes through a minimum, the angular position of which depends upon the energy.

I. SCHEME OF EXPERIMENT

Fig. 1. Diagram of tube.

THE principles of design of this type of apparatus are well enough known so that it will be necessary here to point out only the salient features.

The tube is constructed of brass. It is 15 cm in diameter, and shaped as in Fig. 1. Electrons are accelerated from the tungsten filament F (supplied at the center-tap), through the grid A , and retarded between the grid A and the first of the collimating slits S_1 .

The circuits are so arranged that the entire enclosure is maintained at ground potential. The electron beam passes diametrically across the chamber to the slits S_2 , and through these to the Faraday cage C_2 .

The axis of the main beam is oriented to be parallel to the horizontal com-

ponent of the earth's field, which is carefully neutralized by one set of large Helmholtz coils. A magnetic pendulum was used to determine the necessary current.

Slits S_1 and S_2 are optically aligned, and by means of another pair of large Helmholtz coils the vertical component of the magnetic field in the apparatus is adjusted until the main beam is received on C_2 . By changing the current in the latter coils the beam can be moved back and forth across the slits S_2 . This affords a means of measurement of the divergence of the beam.

Electrons scattered from the main beam are collected principally by the walls of the chamber, which are made more absorbing by the use of the copper gauze as shown.

A portion of the electrons scattered at an angle θ in the center of the apparatus, pass through the slits S_3 and reach C_3 . The axis of collimation of slits S_3 passes always through the center of the apparatus as θ is varied. See Fig. 2 for a vertical section.

Fig. 2. Vertical section of tube.

Slits S_3 and cage C_3 are mounted in the lid on a movable, central, stem with a tapered joint as shown. A pointer P reads the angle θ , on a scale engraved on the lid.

Slits S_1 and S_2 are 10 mm long. Slits S_3 are 8 mm long. The spacings and widths are so adjusted that, with length considered, 90 percent of the electrons passing any pair of slits is contained within an angle of $\pm 1.5^\circ$ of the central axis of that pair.

Other details such as accessibility of the filament or of the chamber, are explained by the figures.

The electric circuits are shown in Fig. 3.

II. THEORY OF APPARATUS

Let ΔV be the volume of the intersection of the paths of collimation of S_1 and S_3 . Let p be the gas pressure in mm Hg; α the coefficient of scattering in the expression,

$$I = I_0 \exp(-\alpha p x).$$

Let I be the current in amperes, at the point " x " measured along the main beam from ΔV ; I_0 the main beam current entering ΔV ; l_2 the distance from C_2 to ΔV ; l_3 the distance from C_3 to ΔV (constant). Let $f(\theta)d\theta$ be the probability under given conditions that a scattered electron will be deflected between the angles θ and $\theta+d\theta$.

At any point x in the beam passing ΔV we have the current

$$I = I_0 \exp(-\alpha p x). \quad (1)$$

So in the distance dx

$$dI = -\alpha p I_0 \exp(-\alpha p x) dx. \quad (2)$$

$-dI$, is therefore the scattered current in the distance dx .

Let us consider now the current we can hope to receive on C_3 at the angle θ . Let I_s be the current scattered in ΔV ; w_3 the width of slits S_3 . Then

$$I_s = -dI = \alpha p I_0 \exp(-\alpha p x) dx = \alpha p I_0 w_3 / \sin \theta.$$

since $x=0$ at ΔV and $dx = w_3 / \sin \theta$. Hence the fraction of I_s that is scattered between θ and $\theta+d\theta$ is given by

$$I_s f(\theta) d\theta = \frac{\alpha p I_0 w_3 f(\theta)}{\sin \theta} d\theta. \quad (3)$$

Of this current only a fraction, K_3 , will reach C_3 because of slits S_3 . The current is also attenuated by scattering along the path of length l_3 from ΔV to C_3 . So the current, I_e , received on C_3 is

$$I_e = \frac{\alpha p I_0 w_3 f(\theta) K_3}{\sin \theta} d\theta \exp(-\alpha p l_3). \quad (4)$$

Consider next the current received on C_2 : because of the slits S_2 only a fraction, K_2 , of the incident main beam will reach C_2 . The beam is also attenuated by scattering along the path of length l_2 . Hence the current, I_o , received on C_2 is

$$I_o = I_0 K_2 \exp(-\alpha p l_2). \quad (5)$$

If we divide (4) by (5) we eliminate I_0 :

$$\frac{I_e}{I_o} = \frac{\alpha p K_3}{K_2} w_3 \frac{f(\theta)}{\sin \theta} d\theta \exp(\alpha p [l_2 - l_3]).$$

so that

$$f(\theta) = \frac{K_2 \exp(-\alpha p [l_2 - l_3])}{K_3 \alpha p d\theta w_3} \frac{I_e}{I_o} \sin \theta.$$

$$f(\theta) = K \frac{I_e}{I_o} \sin \theta \quad (6)$$

where

$$K = \frac{K_2 \exp(-\alpha p [l_2 - l_3])}{K_3 \alpha p d\theta w_3}.$$

The value of K is constant so long as one set of conditions is constant, since $d\theta$, K_2 , K_3 , l_2 , and l_3 , are all functions of a fixed geometry. The K 's seem to depend upon the electron speed, and upon the condition of equilibrium of the apparatus. This is probably because the condition of the slit surfaces depends upon the bombardment they receive. During a given run, if the apparatus has previously been brought to equilibrium, K will remain quite constant. However, when the apparatus has been out of equilibrium between runs, K will vary by as much as a factor of 5.

It follows that by measuring I_e , I_g , and θ , the value of $f(\theta)/K$ can be calculated as a function of θ .

It is noted that the current I_e received by C_3 ,

$$I_e = \frac{\alpha p I_0 w_3 K_3 f(\theta) d\theta}{\sin \theta} \exp(-\alpha p l_3)$$

goes to zero for high pressures because of the exponent, and to zero for low pressures because of the factor p . However it goes to zero much more slowly

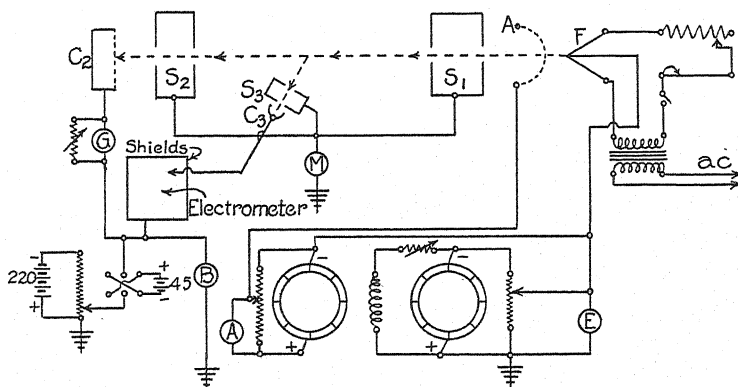

Fig. 3. Diagram of electrical arrangement.

on the low pressure than on the high pressure side of its maximum. This is fortunate since the maximum lies at such a high pressure that the condition of "single" scattering is not satisfied in an apparatus of practical dimensions.

In using lower pressures if the product pI_0 is kept constant, I_e can be maintained at a readable value.

I_e was measured by a "null" circuit using a modified Dolezalek electrometer.¹

From the experimental values of α , and the dimensions of this apparatus, the mean free path of an electron is about the diameter of the apparatus at $p = 10^{-3}$ mm Hg. Thus at the pressure used ($1.8 \cdot 10^{-4}$ mm) the condition for single collision scattering is well satisfied.

¹ J. M. Pearson, Journ. Op. Soc. 19, 6, p. 371.

In order to obtain the intensities of main beam desired some concessions had to be made in the voltage distribution of the electrons. Coated, equipotential, low temperature cathodes were tried, but were short lived owing to the heavy positive ion bombardment. Heavy tungsten was finally used, with a center-tap through which to supply the space current.

Studies were made of the voltage distribution of the electrons received on the Faraday cages. Two things were discovered, namely: (1) that the electrons were distributed over a range of 3 volts at E ; and (2) that the cages were inefficient electron collectors. This was made evident by the fact that the electron current was cut off by a bias as much as 20 volts less than E , in vacuum, when the bias was applied to the cage. If however, the bias was applied to a grid somewhat ahead of C_2 (not shown), the cut-off bias was the same as E . This indicated that a deeper cage was necessary, or at least that an assisting gradient towards the cage was necessary.

Because of this low resolving power both at the collectors and at the filament, inelastic electrons were not resolved from the elastic electrons.

The currents received on C_2 are of the order of microamperes, and are measured by a suitably shunted wall galvanometer "G" (Fig. 3).

III. MANIPULATION

The apparatus is manipulated as follows:

(1). After several hours of pumping the filament is lit and the slits are bombarded. Liquid air is maintained on both traps. (see Fig. 4.) From two to five hours generally suffices to reach a state of equilibrium.

Fig. 4. Scattering chamber and connecting traps.

(2). When equilibrium is reached, an ice bath, vigorously agitated, is substituted for the liquid air on trap No. 1. Liquid air is maintained on trap No. 2, on the other side, connected to the chamber through a long tube. Thus after another lapse of hours the mercury vapor pressure inside the chamber becomes stable at very close to $1.8 \cdot 10^{-4}$ mm Hg.

(3). With the magnetic field neutralized and the values of the accelerating and retarding potentials adjusted, two sets of simultaneous readings of I_e and I_o are made at each setting of θ . When these pairs of readings check to ± 5 percent at each point, the run is accepted. Otherwise the apparatus is considered to be out of equilibrium.

In order to eliminate the effects of the positive ions that are collected due to the negative bias on the cages, readings are first taken with a low bias and

then with a high bias so that the difference of the readings gives the electron current. The positives are usually of the order of one-tenth the strength of the electrons. The biases used are marked on the curves.

IV. RESULTS

The curves of Figs. 5 to 9 give a graphic summary of the results obtained. Of special interest is the fact that the curves are not monotonic, but behave as though the scattering were negligible at a certain angle for each electron energy. That these phenomena are associated with the mercury is attested by the fact that other gases (air, for instance, in this case) gave monotonic scattering curves. In a vacuum (as in (1), manipulations,) no scattering is found at all.

Fig. 5. Scattering curves. Energy, 100 volts. *A*, 95 volts; *E*, 100 volts; *M*, 0.007 amp.; *B*, -75, -102 volts. Curve 1, positive angles; Curve 2, negative angles taken several hours later; Curve 3, negative angles taken several days later.

Fig. 6. Scattering curves, Energy 125 volts. *A*, 165 volts; *E*, 125 volts; *M*, 0.0058 amp.; *B*, -100, -126 volts. Curve 1, positive angles; Curve 2, positive angles taken later; Curve 3, negative angles taken next day; Curve 4, negative angles taken two hours later.

An interesting relationship is presented by the last curve, where the co-tangents of the positions of the minima are plotted with the energies. However, lacking a theoretical interpretation this relation may be fortuitous.

For energies less than 100 electron-volts the main beam currents become unmanageably small, while above 200 electron-volts the minima are concealed in the steep part of the curve.

That these minima have not been reported before is perhaps due to the high angles at which they occur. In this case the use of high primary currents makes measurements at the higher angles comparatively easy.

The apparatus can also be used to check the scattering at low angles, and the results fit Langmuir's² empirical equation very well:

$$f(\theta) = f(\theta)_{\theta=0} \exp(-\theta^2/\theta_0^2).$$

The experimental points found fit best when $\theta_0 = 12.7^\circ$ at 150 electron-volts energy.

Langmuir finds that for Arnot's³ curve for 82 volt electrons, $\theta_0 = 11.3^\circ$ is the best value.

Fig. 7. Scattering curves. Energy 150 volts. *A*, 190 volts; *E*, 150 volts; *M*, 0.006 amp.; *B*, -120, -150 volts. Positive and negative angles read in succession. The solid dots are check points taken later.

Fig. 8. Scattering curves. Energy 175 volts. *A*, 210 volts; *E*, 175 volts; *M*, 0.007 amp.; *B*, -140, -180 volts. Curve 1, negative angles; Curve 2 positive angles taken later. The triangles are check points on negative angles taken two days later.

Some objections to measurements made at small angles can be offered in that the resolving power is somewhat diminished at small angles because of the slit length. Further investigations may justify a correction for this effect.

It is the authors' intention to present these data as being more of a preliminary than of a final nature. Improvements and simplifications which will follow from further work with this type of apparatus, will undoubtedly make for greater precision. At present, the loci of the minima are probably not determined better than $\pm 1.5^\circ$.

ELECTRONIC VELOCITIES IN THE POSITIVE COLUMN
OF HIGH FREQUENCY DISCHARGES

BY EGON HIEDEMANN
PHYSIKALISCHES INSTITUT
UNIVERSITÄT KÖLN
(Received March 9, 1931)

ABSTRACT

Theoretical discussion of the mechanics of individual electrons in the positive column of high frequency discharges with special consideration of the effect of elastic impacts proves that small mean values of the electric force do not prohibit the production of electrons of sufficient velocity to excite or even ionize gas molecules.

IN A recent paper Charles J. Brasefield¹ has published measurements of the potential drop at the electrodes and the electric force in the positive column of high frequency discharges in mercury, helium, and neon for different gas pressures and frequencies of oscillation. The procedure of measuring the electric force in the positive column was the same as that used by the author.² and others in earlier work on high frequency discharges. It consisted in measuring the total voltage between the electrodes for various distances of the electrodes and a given current. The mean electric force of the positive column can then be calculated in the known manner, if one assumes that the drop in potential at the electrodes is, for a given current, independent of the separation of the electrodes.

Discussing his interesting results Brasefield concluded that "these results showed that in general, the magnitude of the electric force was too small to produce electrons whose velocity would be sufficient to ionize or excite the gas." This statement would be of the greatest importance for the theory of the positive column in high frequency discharges if it were the only reasonable inference to be drawn from the experimental results. But an explanation, and a very plausible one, may be obtained by calculations similar to those given by the author for a similar problem in an earlier paper.³

In order to look clearly into this matter it is necessary to give the experimental results, the calculations and the proposed solution of the problem in essential detail.

Brasefield, as others, observed that for a given current and a given frequency there exists an optimum pressure at which the conductivity is a maximum. The electric force at this gas pressure and at gas pressures near to it is very small. He then calculates the electric force necessary to give an electron the ionizing velocity in an electric field alternating with high fre-

quency. His calculation gives values for the necessary minimum electric force, which is much higher than the electric forces measured at or near the maximum of conductivity.

It may be pointed out at first that this calculation is based on the assumption that the electric force in the positive column of the high frequency discharge is the same at any point of the column, which supposition is by no means proved or even probable. But supposing that the above-mentioned procedure of measurement really gives the electric force in the positive column, not merely the mean value of it, a more comprehensive calculation gives a result, which differs slightly but not unimportantly from the result of Brasefield.

If E_0 is the amplitude of the electric force and f the frequency of oscillation, then the following equation is valid:

$$m\ddot{x} = eE_0 \sin 2\pi ft. \quad (1)$$

Integration of Equation (1) gives

$$\dot{x} = -\frac{e}{m} \frac{E_0}{2\pi f} \cos 2\pi ft + C. \quad (2)$$

If at the time zero, the electron has the velocity v_0 in the initial direction of the electric field⁴ then

$$C = v_0 + \frac{e}{m} \frac{E_0}{2\pi f}.$$

The velocity of the electron in the direction of the field is then given by Equation (3):⁵

$$\dot{x} = \frac{e}{m} \frac{E_0}{2\pi f} (1 - \cos 2\pi ft) + v_0. \quad (3)$$

The maximum velocity in the direction of the field will be obtained when $t = 1/2f$ and is given by

$$v_{\max} = \frac{e}{m} \frac{E_0}{\pi f} + v_0. \quad (4)$$

⁴ By the direction of the electric field that direction is meant, in which the e.m.f. accelerates an electron.

⁵ Brasefield gives the equation:

$$\dot{x} = \frac{e}{m} \frac{E_0}{2\pi f} [\cos \delta - \cos (2\pi ft + \delta)]$$

where δ is a phase constant depending on the value of E at the instant the velocity of the electrons is zero. Brasefield's equation includes therefore only those electrons which, at the time zero, have no velocity or a velocity contrary to the initial direction of the acceleration and smaller than the maximum velocity obtainable in half a cycle by the acceleration produced by the electric field. Equation (3) on the contrary includes electrons of all directions and velocities.

The total maximum velocity of the electron is the velocity in the resulting direction of the electron. If this direction forms an angle θ with the direction of the electric force, then the total maximum velocity V_{\max} will be given by

$$V_{\max} = \frac{1}{\cos \theta} \left(\frac{e}{m} \frac{E_0}{\pi f} + v_0 \right). \quad (4a)$$

The real velocity V of the electron at any moment is the essential element in all processes of exciting or ionizing gas molecules. For the following discussion, however, it will be sufficient to regard only the velocities in, or contrary to, the direction of the electric field. To simplify matters, Eq. (4) instead of (4a) will therefore be used from now on.

The essential difference between the result of this calculation and that given by Brasefield is that, to the velocity an electron may obtain in half a cycle the velocity of the electron at the beginning of the half cycle must be added, with the right sign of course. To calculate the electric force necessary to give to an electron the ionizing velocity v_i , we must use

$$E_0 = \frac{v_i - v_0}{e} m \pi f. \quad (5)$$

Now the electric forces measured by Brasefield demand—near the maximum of conductivity at least—velocities v_0 which are not small compared with v_i . That means that electrons of nearly sufficient velocity must be present at the beginning of half a cycle. How can such electrons be produced? This can easily be seen, if one remembers that an electron will make elastic impacts with gas molecules before it has obtained the excitation energy.⁶ By these elastic impacts it will lose insignificant amounts of energy only, but the direction of its motion will be changed. To simplify the discussion only those impacts will be regarded, for which an electron will after the impact have a component of velocity v' in the direction contrary to that before the impact.

Let us consider now an electron which, at the time zero, has the velocity zero. After half a cycle it will have obtained the velocity v_{\max} . Now this electron may have an elastic impact and may immediately after the impact have the velocity v' in the direction contrary to its direction before the impact. As v' is a part of its former velocity, we may define v' by

$$v' = v_{\max}/n. \quad (6)$$

The next half cycle will give to this electron the velocity v''

$$v'' = V_{\max} + v' = V_{\max}(1 + 1/n). \quad (7)$$

⁶ Here purposely no correct discrimination is made between the possibility for an electron to get excitation and that to get ionization energy because the difference of these energies is small compared with the difference between one of these energies and the maximum energy obtainable by the e.m.f. in half a cycle. The excitation energy is of primary importance too; especially in those cases in which metastable states are produced and ionization effected by successive impacts.

As this may happen several times and the various n must not be large compared with unity, one easily sees that, as a result of elastic impacts, an electron may obtain a multiple of the maximum velocity obtainable in half a cycle.

This effect of the elastic impacts on the electronic velocities will be efficient especially at gas pressures for which the path of an electron during half a cycle is comparable with the mean free path of the electron. The path of an electron with the velocity v_0 at the time zero between $t=0$ and $t=1/2f$ has been calculated⁷ by integration of Equation (3) to be

$$x = \frac{v_0}{2f} + \frac{e}{m} \frac{E_0}{4\pi f^2}. \quad (8)$$

The gas pressures at which x will be comparable with the mean free path of an electron can thus easily be calculated. The result gives pressures of the same order of magnitude as the optimum pressures measured.⁷

From Eq. (8) one sees that Equation (7) is not quite correct, because if an electron of the velocity zero at the time zero has made an impact with a gas molecule after $t=1/2f$ then the electron will after the impact meet a gas molecule before the second half cycle is finished. The velocity of the electron immediately before the second impact will therefore be smaller than $v' + v_{\max}$. A correct equation can be obtained without difficulty, but even without doing so it can easily be seen that matters are much too complicated to allow more than a very rough calculation of the critical order of magnitudes.

In determining the conductivity not only the electrons with excitation or ionization energy are of importance, but the positive ions and the slower electrons too. In an earlier work A. v. Hippel⁸ has shown that the energy which positive ions may periodically acquire in the alternating electric field of a high frequency discharge, is to be neglected compared with the ionizing energy. He has also directed attention to the fact that positive ions oscillate with only very small amplitudes, which at the optimum pressures measured by Brasefield may be neglected in comparison with the mean free path. This means that, if positive ions have once been produced, the chance of their getting lost from the discharge is relatively small when no static electric field is present. A small loss of ions on the other hand means a high degree of ionization and a high conductivity. The degree of ionization is limited by recombination and molecular diffusion to the glass walls and to a large extent probably by the static field due to the potential of the glass walls. By elastic impacts electrons will not only get a component of velocity parallel to the direction of the alternating electric force but also normal to it. As this velocity will not be altered by the electric force and as the mobility of the electrons is large a steady current of electrons should be directed to the glass walls and produce there a negative charge. A short time after the beginning of the discharge a stationary state will be reached and a static electric force will be produced.

⁷ See also Charles J. Brasefield, *Phys. Rev.* **35**, 1073 (1930).

⁸ A. v. Hippel, *Ann. d. Phys.* (4) **87**, 1035 (1928).

This static field will enlarge the loss of positive ions and produce a deformation of the electric field of the alternating e.m.f. Hence the supposition that the electric force in the positive column is the same at any point of the column cannot be right and any calculation based on this assumption will not give correct, but at the best only approximate results. This is another reason that the small measured mean values of the electric force in the positive column do not call for the conclusion that electrons of excitation energy cannot be produced in the high frequency discharge at the maximum of conductivity.

Another important factor in the conductivity is introduced by the oscillation of the slower electrons in the alternating electric field. Their importance for the mechanism of the high frequency discharge at low pressures was pointed out first by F. Kirchner.⁹ The motion of these oscillating electrons is given by⁵

$$m\ddot{x} = eE_0 \cos 2\pi ft \quad (9)$$

and the path in a quarter of a cycle; i.e., the amplitude of oscillation; is given by

$$x' = \frac{e}{m} \frac{E_0}{4\pi^2 f^2} \quad (10)$$

By comparison of Eq. (10) with Eq. (8) it can be seen that the optimum pressure for the oscillating electrons has not quite the same value as for the non-oscillating electrons, but that it is of the same order of magnitude. The importance of the oscillating electrons for the conductivity of the discharge lies, as is known, in the fact, pointed out by Kirchner, that by oscillating in the field these electrons will remain in the discharge.

Those electrons which at the time zero have no velocity or a velocity in the direction of their acceleration in the initial half cycle, will not oscillate in the discharge, but go in one direction only (of course without taking account of the effect of impacts). During half a cycle, they will be accelerated, during the next half they will be retarded by the alternating e.m.f. but they will always go forward. At very low pressures, where the mean free path of the electrons cannot be neglected compared with the separation of the electrodes, such non-oscillating electrons produced near the electrodes may thus reach the positive column and their part in the excitation or ionizing processes in the positive column may perhaps not be neglected.

In conclusion it may be said, that the surprisingly small mean values of the electric force measured in the positive column of high frequency discharges near the maximum of conductivity do not at all force one to assume that electrons of excitation energy cannot be produced in the positive column of these discharges.

THE ELECTRICAL STATE OF THE SUN

BY ROSS GUNN

NAVAL RESEARCH LABORATORY, WASHINGTON, D.C.

(Received March 13, 1931)

ABSTRACT

The magnetic field due to the rotation of our galaxy is calculated, and it is shown (a) that electricity cannot be annihilated in the sun or stars; (b) that the net electrical charge on the sun or a typical star cannot exceed 1 coulomb. The electric fields, space charge and potentials of the solar atmosphere are calculated from data relating to the solar anomalous rotation and numerical values given. The negative surface charge on the sun is calculated to be of the order of 10^9 e.m.u. The problem of the maintenance of the solar electric field is touched upon.

SYSTEMATIC observation of the solar surface by Mount Wilson astronomers and others has shown that many solar phenomena are of such a nature that they can be attributed to electrical and magnetic effects. The magnitude and distribution of the solar magnetic field has been determined by a laborious analysis of Zeeman spectra¹ and sufficient data accumulated to show that the solar magnetic field is not unlike that of the earth, save for its radial limitation. In 1915 an attempt was also made by Hale and Babcock² to determine the electric fields by measurements of the Stark effect but they could not detect fields smaller than 100 volts per centimeter and were only able to set an upper limit to the suspected electric field. Investigators have generally stated that the electrical fields in the emitting layers of the sun were negligibly small due to the high electrical conductivity and important effects arising from such electric fields were therefore absent. In the following discussion we shall endeavor to indicate the importance of the electric field and give numerical values for the electrical constants of the sun, insofar as they apply to obvious solar problems.

SEPARATION OF CHARGE INSIDE THE SUN

In an important paper A. Pannekoek³ noted that in any highly ionized gaseous region acted on by gravitational forces and in thermal equilibrium, the lighter ions diffused upward until their separation produced an electric field which opposed further separation. It is readily shown that the volume charge ρ_0 expressed in e.m.u., resulting from the separation, is given by

$$\rho_0 = \gamma d \mu / c^2 e \quad (1)$$

where γ is the gravitational constant, d is the density of the ionized matter,

μ the mean mass of the molecules, c the velocity of light, and e the electronic charge expressed in *e.m.u.* Using data appropriate to the sun and Eq. (1) we find that the total positive volume charge inside the sun amounts to 33 *e.m.u.* or 330 coulombs. In another place we shall show that a negative charge of equal magnitude probably resides on the solar surface.

When the temperature is non-uniform the more mobile ions in a conductor diffuse toward cooler regions and in the equilibrium state, an electrical field is set up which prevents further diffusion. The space charge ρ_i existing when equilibrium has been attained is given (in the one dimensional case) by

$$\rho_i = - \frac{k}{8\pi c^2 e} \frac{d^2 T}{dr^2} \quad (2)$$

where k is the Boltzmann constant, r the space coordinate and T the absolute temperature. Application to the interior of the sun at the present time will not be attempted for little is known about the internal solar temperature. If we follow the star models considered by Eddington⁴ the temperatures are so related to gravitational forces that the space charge due to non-uniform temperatures will be of the same order of magnitude as the space charge due to gravitational forces. If, on the other hand, we should adopt Milne's⁵ star model which suggests central temperatures of the order of 10^{11} degrees, it is evident that the interior space charge is likely to be large.

ANNIHILATION OF ELECTRICITY

Attempts to account for the earth's atmospheric electric current have led several writers to assume that electricity is annihilated at some definite but slow rate. Simpson⁶ suggested that electricity might be generated spontaneously while Swann⁷ assumed that positive electricity died constantly inside the earth but neither writer suggested where the required energy for the transformation might originate. Anderson⁸ supplied the theoretical deficiency and assumed that the loss of the protonic mass supplied the necessary energy to annihilate the protonic charge. Thus he postulated a subatomic transformation in which the mass of one proton vanished for each protonic charge annihilated. Evidently if the energy corresponding to a given transformation is known then the lost mass and electrical charge can be immediately calculated. Anderson's calculations indicated that the sun was throwing off negative electricity at a rate of 4×10^{16} *e.m.u.* per second. This tremendous negative charge was assumed to dissipate itself through all space and finally be lost. In many respects Anderson's hypothesis is interesting in spite of the objections which will occur to the atomic physicist. We proceed to show, however, that in stars the annihilation of electricity is not probable unless the released ions leave our universe in a highly specialized and improbable manner.

⁸ W. Anderson, *Zeits. f. Physik* **42**, 475 (1927).

The system of stars embraced by the Milky Way stretches far out into space and forms our galactic system. The motions of the stars in this system, their masses, radiation, numbers and distribution are known and if electrical charges are constantly given off by each member of the galactic system, observable magnetic effects should be measured on the earth. We will assume that when ions are thrown off by a star the ion preserves its angular momentum about the gravitational center of the galaxy as it finds its way to outer space. Thus the systematic motion of the stars about the center of the galactic system is shared by the electricity which has been thrown off by them.

The systematic motion constitutes an electrical convention current and will produce a magnetic field. In the present connection we need only the order of magnitude of the effect and a rough calculation which directs attention to the physics of the problem will readily serve. Let us suppose that the entire negative charge in the space outside the stars but inside the galaxy, is compressed into a ring of radius equal to the mean radius of the system. Then the magnetic field H at the center of the system is

$$H = 2\pi Q\omega \quad (3)$$

where Q is the total free charge and ω is the mean angular velocity about the center of the system. The earth is not at the center of the system but it is difficult to see how its position and motion could change the value of the magnetic field at the earth by more than an order of magnitude.

The angular motion of our galaxy is known from astronomical data and Q is determined by calculating from the total radiation of the galactic system, the rate of release of negative electricity. We must note further that the time the released electricity remains in the system proper must be at least as great as the time it would take light to traverse the path. Thus

$$Q \geq Ir/c \quad (4)$$

where I is the total current thrown off by all stars of the galaxy as calculated by Anderson's hypothesis, r is the mean radius of the galactic system and c the velocity of light. The mean star of the galaxy has a mass 1.6 that of the sun and there are roughly 10^{10} of them,⁹ so that we may assume that the total current I of the system is 10^{10} that of the sun or 10^{26} e.m.u.¹⁰ Taking $r = 10^3$ parsecs, $\omega = 10^{-13}$ rad/sec and combining Eq. (4) with Eq. (3) we find that the magnetic field at the center of the galaxy is of the order of 10^{25} gauss.

Such a large magnetic field seems absurd and we conclude that observation demands either that the charges which leave a star, leave in a very special manner, or else that annihilation of positive charge in stars does not occur. The evidence is such that we believe Anderson's and other similar hypotheses must be abandoned.

NET SOLAR CHARGE

An upper limit may be set for the net charge which the sun may carry if we are willing to assume that the sun is a star typical of the average star of

⁹ Russell, Dugan and Stewart, *Astronomy* (1927).

¹⁰ R. Gunn, *Phys. Rev.* 32, 133 (1928).

our galaxy. Magneticians have been collecting precise data on the variations of terrestrial magnetism for a great many years but there is no evidence of which we are aware that suggests that there may be an extra-terrestrial magnetic field which would be observed to have a period of a sidereal day. Certainly such a field would have been found if it was as great as 10^{-3} gauss and probably a field much smaller would be noticed. We may then assume that if a galactic magnetic field exists its value H is probably less than 10^{-3} gauss.

If the stars of our galaxy (of which the sun is typical) carry free electrical charges, then certainly their ordered motion in our galaxy will give rise to a magnetic field. In Eq. (3) we substitute for Q the product of the total number of stars n , by q the mean charge on each, and write the inequality

$$q \leq H/2\pi\omega n. \quad (5)$$

Substituting the appropriate numerical values in Eq. (5) we find that the mean charge on each star of our galaxy cannot be greater than 0.1 e.m.u. or one coulomb. In the present case there is no question regarding the motion of the charges for they are attached to the stars. When we reflect that the total surface charge of the earth is of the order 10^5 coulombs we see that stars are neutral to a high degree of approximation. We note in passing that measurements show the earth is probably neutral as a whole. These considerations lead us to assume that the sun as a whole is electrically neutral.

SOLAR ATMOSPHERIC ELECTRICITY

The highly ionized regions of the solar surface which can be observed are known to be regions of low pressure and the ion free paths are therefore very long. An early paper¹¹ showed that when ions execute long free paths in crossed electric and magnetic fields, ions of both kinds were swept in a direction perpendicular to both the electric and magnetic fields with a velocity which depended only on the relative magnitude of the crossed fields. This effect is of the nature of a mass motion and is of great importance because it connects directly the easily observable mechanical motions of an ionized region with the magnitudes of the impressed electric and magnetic fields. In a series of papers¹¹ the above electromechanical effect was shown to account quantitatively for the observed anomalous solar rotation, if the sun possessed an atmospheric electric field which was strikingly similar to the field observed on the earth.

The superposed drift velocity u of an ionized atmosphere is given by

$$u = \frac{E \times B}{B^2[1 + (R/\lambda)^2]} \quad (6)$$

where E and B are the electric and magnetic fields respectively, R the radius of the spiral generated by an ion as it is constrained to move about the impressed magnetic fields and λ is the mean free path. We calculate R from

¹¹ R. Gunn, Phys. Rev. 35, 635 (1930); 36, 1251 (1930); 37, 283 (1931).

$$R = \frac{mv^1}{Be} = \frac{(2mkT)^{1/2}}{Be} \quad (7)$$

where m is the mass of the ion, v^1 the component of its velocity perpendicular to the magnetic field B , and e the ionic charge in e.m.u. In the atmospheric levels of the sun which we can see, λ is large compared to R and if we agree for simplicity to consider only the motions at the solar equator, Eq. (6) takes the simpler scalar form.

$$E = Bu \quad (8)$$

where E is now the radially inward electric field, B the northward magnetic field and u the eastward atmospheric ion drift measured with reference to the surface of the sun proper. The eastward superposed drift u is readily determined from

$$u = u_0 - a\omega \sin \phi \quad (9)$$

where u_0 is the measured velocity of the observed point whose colatitude is ϕ , a is the solar radius and ω is the angular velocity calculated from the rotation of the sun's magnetic pole. The magnetic field B can be measured directly by the Zeeman effect, so that E can always be calculated for all observed levels. The drift velocity u is known to change with altitude, solar activity and to be subject to large local fluctuations. As we have seen elsewhere¹¹ the fluctuations are probably due to variations in E rather than B .

In a typical region of the reversing layer the magnetic field is observed to be 25 gauss and the difference of velocity of the surface proper and that actually measured or u is 5×10^4 cm/sec. By aid of Eq. (8) we find the electric field in this region is 0.013 volts/cm. Similarly where the magnetic field is 55 gauss the electric field is 0.027 volts/cm. Now the difference in altitude between these two points is roughly 8×10^6 cm, according to Mt. Wilson data, and we can estimate the volume charge by a one dimensional Poisson's equation. Thus

$$\rho_a = - \frac{u}{4\pi c^2} \frac{dB}{dr} \quad (10)$$

where ρ_a is the atmospheric volume charge in e.m.u. and the other quantities are those defined before. From Eq. (10) and the foregoing observational data we find that over a small interval the space charge in the solar reversing layer is $+1.66 \times 10^{-23}$ e.m.u./cm³ or on the average there is one singly charged free positive ion per liter.

The space charge increases rapidly as we go deeper and deeper into the sun and if the magnetic field and drift velocity were known at all levels the surface charge and total atmospheric charge could be determined. The solar astronomical data giving the intensity of the magnetic field as a function of the altitude are not very reliable on account of the difficulties of measurement and there is even sharp disagreement as to the scale of altitudes in the reversing layer. In an earlier paper¹¹ a semi-empirical relation was employed to

represent the magnetic field as a function of altitude and the constants so chosen as to fit observation over a limited range. Precise analysis requires appeal to direct observational data for it is unlikely that the radial distribution of the magnetic field is as simple as our assumed formula indicates. We will assume that the magnetic field at any level in the solar atmosphere is given¹¹ approximately by

$$B = B_0 \exp \left[-\frac{zHg(r-a)}{2kT} \right] \quad (11)$$

where B_0 is the magnetic field of the sun at the "surface proper," z the mean atomic weight of the atmospheric ions, g the acceleration due to gravity, H the mass of the hydrogen atom and $(r-a)$ the altitude above the sun. Relation (10) becomes by aid of Eq. (11)

$$\rho_a = \frac{uzHgB}{8\pi c^2 kT} \quad (12)$$

so that the total atmospheric volume charge in a prism 1 cm² in cross-section is given by

$$\int_a^\infty \rho_a dr = uB_0/4\pi c^2 \quad (13)$$

and since on the whole the sun is neutral and there is no external electric field it follows that the surface charge on the sun proper is equal and opposite to the positive space charge. Following earlier work¹² we use 12,000 gauss for B_0 and calculate the total positive charge in a prism 1 cm² extending from the sun outward and get $+5.3 \times 10^{-14}$ e.m.u. The surface charge is equal and opposite. The total negative surface charge of the sun is therefore 3×10^9 e.m.u.

We can use Eq. (11) to determine the potential difference between the surface proper and free space if we combine it with Eq. (8) and integrate.¹¹ Let ϕ_1 be the potential difference, then

$$-\phi_1 = \int_a^\infty E dr = u \int_a^\infty B dr \quad (14)$$

which by aid of Eq. (10) becomes

$$\phi_1 = \frac{2uB_1kT}{zHg} \quad (15)$$

where B_1 corresponds to a level where the atmospheric electrical conductivity begins to drop off rapidly due to the solar magnetic field^{11,12} and it amounts to about 280 gauss.¹¹ Substitution of the approximate values in Eq. (15) shows that the sun proper is negative with respect to free space by 1.5×10^6 volts. The foregoing values, calculated by aid of semi-empirical formula cannot be expected to be precise for we have made the assumption that the equatorial

¹² R. Gunn, Phys. Rev. 33, 614 (1929); 34, 1621 (1929).

drift velocity was the same constant at all altitudes. In the region of the reversing layer where the constants were made to fit the known points the equations are more reliable.

MAINTENANCE OF THE SOLAR ELECTRIC FIELD

The electrical conductivity of the solar atmosphere is high even in the reversing layer where the magnetic field greatly reduces the mobility of the ions.¹⁰ It is readily shown that the solar atmosphere would discharge itself in 10^{-10} seconds if no mechanism was provided to maintain the current. We are therefore faced with precisely the same problem that has puzzled physicists for years in connection with the earth's electric charge. As in the case of the earth we may now assert that the sun is neutral to a high degree of approximation and we may further maintain that electricity does not continuously leave the sun. These restrictions narrow down the investigation to fairly definite problems and several have been examined keeping always in mind that the mechanism of replenishment should also be capable of modification to fit the earth. Even though the mechanism in the sun must be quite simple compared to that on the earth, no definite conclusion has been reached. The extreme variability of the electric field as indicated by the atmospheric motions suggest that local conditions may affect the field greatly somewhat in the manner that an electrical storm disturbs the earth's local electrical state. Young¹³ had the idea long ago that the solar atmosphere "rained" condensed metallic particles and brought charges down with them. While the idea is tempting because of present ideas regarding the maintenance of the earth's charge it has several weak points and cannot be made quantitative. It has been shown¹¹ that the electrical energy dissipated in the solar atmosphere is an appreciable fraction of the total radiated energy and any mechanism which will account for the field must be a moderately efficient one.

CONCLUSION

Our study has shown that the rather artificial postulate of the annihilation of charge is inconsistent with observation and that to a high degree of approximation the sun is electrically neutral. Our calculations show that the separation of charge in the solar atmosphere is considerable and that the resulting distribution of electric field is remarkably similar to that observed on the earth. In a typical equatorial region of the reversing layer the electric field is radially inward and amounts to 0.015 volts/cm, a value far too small to be detected by measurements of the Stark effect. In the present paper the fields have been calculated from data derived from the observed solar atmospheric motions. In a forthcoming paper the electric fields will be calculated from certain spectroscopic data and the values obtained shown to be consistent with the present estimates.

SURFACE TENSION OF MERCURY

BY MARIE KERNAGHAN, R.S.C.J.

DEPARTMENT OF PHYSICS, THE SAINT LOUIS UNIVERSITY

(Received March 9, 1931)

ABSTRACT

Consistent values for the surface tension of mercury in a high vacuum (air pressure less than 1.2×10^{-5} mm Hg throughout the period of experimentation), ranging from 438.4 ± 0.3 dynes per cm at 12.5°C to 423.9 ± 0.6 dynes per cm at 67°C , have been found by a modified flat-drop method. In evaluating them Worthington's equation

$$\sigma = \frac{(K-k)^2 \rho}{2} \cdot \frac{1.641 L}{1.641 L + (K-k)}$$

was used. The temperature gradient, determined from the best mean straight line through the experimental points, is 0.3015 dyne per cm per degree. Hence the average value of k , in the Eötvös relation, was found to be 1.82. Reproduction of concordant results at intervals during a period of four months affords ample evidence of the thorough outgassing of the apparatus and is attributed to the great care used in securing relative perfection of details.

INTRODUCTION

WITHIN the last decade many publications (between one and two on an annual average) have been concerned with the surface tension of mercury¹⁻²¹ and the greater number have dealt with its measurement in a vacuum. Hogness⁹ and later Bircumshaw² have given excellent summaries of

the work done in that line since 1898. Hence another summary just now is unnecessary. Suffice it to say that in spite of the great variety of methods painstakingly tried by eminent experimenters, the final results continue to be discordant even in single experiments, the values obtained ranging from "340 to 575 dynes per cm."²¹ The true value of the surface tension of mercury cannot be as erratic as the above quoted discordant values would make it. Since the modified flat-drop method, used in finding the surface tension of sodium in a vacuum,²² gave perfectly consistent results, it was decided to try it out on mercury. Some of its marked advantages are: a high degree of accuracy, perfect control of temperature conditions, facility in the production of fresh and uncontaminated surfaces, possibility of maintaining a high vacuum during a long interval of time, and independence of the contact angle.

APPARATUS

The apparatus (Fig. 1) though similar in general outline to that used in the experiment on sodium,²² differed in several details. The chief difference lay in the shape and size of the surface tension chamber *C* (Fig. 1). It was

Fig. 1. Diagram of apparatus.

arranged in a horizontal position and though shorter it was wider and more roomy than the first. The plane circular glass window *W* (made to order by the Corning Glass Company) was fused into the end of the tube in preference to the side, in such a way as to render the entire disk optically available. The shallow cup *D* in which the flat drop of mercury was formed was ground with fine emery until all clip scars had disappeared. While similar in general appearance to the cup used for sodium it was wider (average outer diameter 6.04 cm) and deeper (maximum depth 1.2 cm). The difference existing between the various diameters was not more than 0.02 cm. As in the case of sodium, the mercury was introduced into the cup by means of a thick-walled capillary tube *F* which served to prevent too rapid introduction and consequent surging back and forth of the liquid. The tube *J* necessary for outgassing purposes prevented an accumulation of pressure behind the cup. To

²² F. E. Poindexter and M. Kernaghan, *Phys. Rev.* **33**, 837-843 (1929).

procure a fine levelling adjustment at any time during the course of the experiment the cup chamber was tightly clamped and exteriorly cemented to a levelling stand *S*; and coiled tubes *G* one on either side of *C* were inserted into the apparatus. The presence of the flask *M* was merely an added precaution against contamination resulting from any possible overflow of mercury from the McLeod gauge. The entire piece of apparatus, including the McLeod gauge, was constructed of Pyrex glass, having only glass seals throughout.

Redistilled mercury was well shaken with chromic acid solution and then thoroughly rinsed with distilled water. It was next distilled in a current of air, then in a vacuum. This whole process was gone through twice before admitting it into the flask *A*. After sealing off *E* and thoroughly outgassing the apparatus the mercury was carefully distilled in a vacuum with a hand burner into the reservoir *B* from which it was distilled into the cup *D* as needed. The surface tension chamber was sufficiently roomy to allow the cup to be emptied and refilled without disturbing the apparatus.

The heater of the sodium experiment,²² adjusted to suit the modification of the cup chamber, was used, hence the temperature conditions were those of the former experiment and hence within one degree of correct values. A frosted glass window arranged in the back panel of the heater made it possible to illuminate the drop from without and thereby get a sharp focus along the meniscus. Once this arrangement was perfected there was no difficulty in determining the exact top of the drop.

The combination of travelling microscope and dividing engine, used as a measuring device in the sodium experiment, was again employed. But instead of locating a number of points on the meniscus of the drop and then graphing the curve, it was decided to use a small carbon filament lamp for locating the top of the meniscus. It was mounted in a manner similar to that described by Richards and Boyer²⁰ and used by Iredale,¹² Cook,⁵ and others. The small lighted lamp, attached to the telescope some distance behind it and on a level with it, was reflected from a spot on the maximum horizontal diameter as a tiny star which could be brought easily to a focus on the cross hairs. The vertical distance from the maximum horizontal diameter to the top of the drop ($K-k$ in Table I) could then be found by direct measurement. The diameter of the drop was measured directly by means of the dividing engine.

DATA AND RESULTS

A summary of the results obtained from readings taken at intervals during a period of more than four months is given in Table I. The temperatures below 41° (second column) were room temperature in degrees centigrade. The number of separate readings of K (the top of the drop) and of k (the location of the star), from which $K-k$ was in each case determined, may be found in the third column. The values for the density quoted in column 4 have been taken from the Smithsonian Physical Tables.²³ For each set of

readings two values for the surface tension are given. That under uncorrected value (seventh column) was found by means of Quincke's simple formula²⁴

$$\sigma = \frac{1}{2} h^2 \rho \cdot 980 \quad (1)$$

(where σ and ρ are surface tension and density respectively; 980 cm per sec² is the value of the acceleration of gravity in Saint Louis.) The corrected values of σ (eighth column) were determined according to Worthington's equation²⁵

$$\sigma = \frac{(K - k)^2 \rho}{2} + 2\sigma(K - k) \left\{ \frac{1}{b} - \frac{1}{3.282L} \right\} \quad (2)$$

²⁴ G. Quincke, Ann. d. Physik, 105, 1-48 (1858); 139, 1-89 (1870); 160, 337-374 (1877).

²⁵ A. M. Worthington, Phil. Mag. 20, 51-66 (1885).

(where $(K - k) = h$ = distance from vertex to maximum horizontal diameter; b = radius of curvature at the vertex and L = maximum horizontal radius).

According to Worthington²⁵ for values of L greater than 2 cm the term $1/b$ is negligible. Therefore since in this experiment the minimum value of L was 2.84 cm it was at all times sufficiently large to justify the omission of $1/b$ from the equation, which consequently reduces to the form

$$\sigma = \frac{(K - k)^2 p}{2} \cdot \frac{1.641L}{1.641L + (K - k)} \times 980. \quad (3)$$

Fig. 2. Surface tension of mercury as function of temperature.

Hence to correct values computed from equation (1) we have only to multiply the result obtained by the correction factor

$$\left(1 + \frac{K - k}{1.641L}\right)^{-1}$$

Since there was scarcely any appreciable variation in the size of the drops used, the correction factor reduced to either $1/1.055$ or $1/1.056$.

From the two surface-tension, temperature graphs (Figs. 2 and 3) it is evident that temperature variations gradually decrease as temperature increases. However, for values of T lower than 65°C the deviation of experimental points from a straight line is slight. Hence from the best mean straight line through the experimental points (Fig. 3) σ at 0° and at 63° was

judged to be 442 and 423 dynes per cm, respectively. Hence the temperature gradient is 0.3015 dyne per cm per degree.

Upon differentiating with respect to temperature, the Eötvös relation $\sigma v^{2/3} = k(T_c - T)$ we get,

$$v^{2/3} \left(\frac{d\sigma}{dT} \right)_v + \frac{2}{3} \sigma v^{-1/3} \left(\frac{dv}{dT} \right)_\sigma = -k \quad (4)$$

(σ , v , T represent surface tension, volume of a gram atom, temperature respectively. T_c and k are constants.)

The Eötvös constant, k , was found at 20°C by substituting in Eq. (4) for $(d\sigma/dT)_v$ and for σ experimental values, and for v and $(dv/dT)_\sigma$ values

Fig. 3. Surface tension of mercury as function of temperature.

calculated from data given in the Smithsonian Physical Tables, as quoted in the thirteenth edition of Handbook of Chemistry and Physics.²³ The value found is 1.82.

DISCUSSION

Every possible precaution was taken to procure absolute cleanliness. Boiling hot chromic acid solution was used to cleanse not only the entire glass apparatus (including the still used for distilling the mercury in a current of air), but also the beakers and the bottles into which the mercury was poured at any stage of experimentation. Several consecutive days were devoted to a thorough outgassing of the apparatus. During periods of four or

five hours each, while the pump was running, the entire apparatus was kept at a high temperature by means of the heater and a hand burner. The thoroughness of the process was proven by the fact that the McLeod gauge registered stiction (a gas pressure less than 1.2×10^{-5} mm Hg) except when filtered air was purposely admitted into the apparatus. Occasionally over night the pressure rose to 4.6×10^{-5} mm Hg, but then the apparatus was again outgassed. No readings were recorded except when the McLeod gauge registered stiction.

The main purpose of this experiment was to get consistent values for the surface tension of mercury in a vacuum hence no perfection of detail that might lead to a higher order of accuracy was overlooked. To eliminate vibration of the mercury drop a special wall table was constructed. The difficulty experienced by Cook⁵ in determining the exact position of K (the top of the drop) was obviated by keeping the drop enclosed in the heater, even when working at room temperature, and by illuminating it from without. As previously mentioned, for all readings recorded the top showed as a sharp dark line. The small lamp used for determining the point of vertical tangency was set at the same level as the center of the objective of the travelling microscope, by means of a reading telescope. The utmost care was used to keep it in that exact position for it was noticed that the least deviation from it caused a considerable difference in the readings of K and k . The same is true of the level position of the travelling microscope and the dividing engine.

A tenths thermometer, calibrated by comparison with a standard thermometer was throughout immersed in the heater to the same depth and at the same angle of inclination. Stem correction was, however, found to be negligible for temperatures lower than 70°C , i.e., for temperatures used in this experiment.

No set of readings was recorded until all details were brought to relative perfection. On the other hand no set of readings was discarded after that point had been reached, except in cases of fluctuating temperature.

On two different occasions a set of readings was taken in a vacuum (15 and 16; 19 and 20, Table I) the dish was partially emptied by violent shaking, filtered air was admitted and the apparatus was allowed to stand for a while. When again pumped to stiction the change in surface tension was merely that to be expected from variation in temperature.

Popesco^{17,18,19} Iredale¹² and Cook⁵ have determined the surface tension of mercury in a vacuum by the flat-drop method. However, the experiments of the first two differed from this experiment in some important details—to mention only a few: the method of forming the drops was essentially different; both used wax seals. Iredale was himself conscious that “the experimental conditions would be very much improved if such adhesives could be done away with.” (reference 12, page 607) Both worked on drops too small (Popesco’s was about 3.6 cm in diameter; and Iredale’s ranged from 1.2 cm to 1.5 cm in diameter) to be considered perfectly flat. The values obtained by Iredale from eleven consecutive drops, at a temperature of 19.5°C , vary from 430 to 472 dynes per cm. Cook’s flat-drop method is essentially the same as

the one used in this experiment. But he has quoted only one value found for the surface tension of mercury in a vacuum; and that value seems abnormally high even though in the author's words "the measurements were very carefully checked." (reference 5, page 517). The apparatus of this experiment was as completely outgassed as his, but not once was a value any where near as high as his obtained. His readings of K and k were taken with a cathetometer the vernier of which "reads directly to 0.02 mm and under the microscope can be estimated to 0.01 mm" (reference 5, page 516). The travelling microscope used in this experiment records to 0.002 mm.

The dates given in the last column of Table I show how well conditions were reproduced. In turn the consistent values obtained seem to point to the fact that, more than a new theory, we need a high vacuum, uncontaminated surface and utmost care in manipulation.

This work was suggested by and carried on under the guidance of Doctor F. E. Poindexter in the laboratories of Maryville, Corporate College of Saint Louis University. I wish to thank him for his generous cooperation. I wish to thank both him and Rev. Professor James I. Shannon for their many helpful and encouraging suggestions. Thanks are also due to Brother A. Zeller for his kindness in rearranging the heater to fit the remodelled apparatus.

CORRECTED VALUES FOR THE COEFFICIENT OF RE-COMBINATION OF GASEOUS IONS

BY OVERTON LUHR AND NORRIS E. BRADBURY
PHYSICAL LABORATORY, UNIVERSITY OF CALIFORNIA

(Received March 9, 1931)

ABSTRACT

Previously published values of the coefficient of recombination are found to be twelve percent too high because of the distortion of the field between the plates of the ionization chamber. Corrected values which may be used for the purpose of calculation are given as follows: Air, $(1.23 \pm 0.1) \times 10^{-6}$; O₂, $(1.32 \pm 0.1) \times 10^{-6}$; N₂ and A, $(1.06 \pm 0.1) \times 10^{-6}$; H₂, $(0.28 \pm 0.05) \times 10^{-6}$.

RECENTLY one of the writers^{1,2} has published results of research on the recombination of ions produced by x-rays in a number of gases. It was found that the coefficient of recombination given by $\alpha = (1/t)(1/n - 1/n_0)$, the integrated form of the equation $dn/dt = -\alpha n^2$ is not a constant, but varies with the age of the ions. It was assumed that the high initial values of α and rapid drop at short time intervals (up to 0.05 to 0.1 seconds after the formation of the ions) is due to non-random distribution, and that the later more gradual drop is due to the loading up of the ion with impurities and subsequent selective recombination, producing abnormally low values of α at long time intervals up to one or two seconds. On the assumption that normal conditions were most closely approximated between the ages of 0.05 and 0.1 seconds, so-called "absolute values" were set which would be useful for purposes of calculation. Hydrogen is the only gas which did not exhibit any change in the value of α with time.

In all the results heretofore published it was assumed that the volume of ionization swept out by the electric field was the total geometrical volume contained between the plates of the ionization chamber. In planning for further work with the same apparatus, it has been found that, despite the guard ring surrounding the upper plate, there is an error of about twelve percent in this assumption. Owing to the proximity of the grounded walls of the chamber, the field is not uniform between the plates, the lines of force curving slightly towards the walls. (See Fig. 1.) The magnitude of the error was obtained by plotting the equipotential lines for a cross-section model of the chamber, making use of a telephone buzzer and probe points in a conducting solution. On drawing the lines of force, which are perpendicular to the equipotential lines, it was found that the volume swept out by the field was about twelve percent smaller than the assumed geometrical volume. In this connection it is interesting to note that under conditions where grounded

¹ O. Luhr, Phys. Rev. 35, 1394 (1930).

² O. Luhr, Phys. Rev. 36, 24 (1930).

walls are within a few centimeters of the plates of the ionization chamber, the guard ring would have to be approximately equal in width to the distance between the plates to obtain a uniform field.

In calculating the coefficient of recombination, n , the number of ions of either sign per cm^3 is found by dividing the total number of ions swept to the upper plate by the volume. Hence the equation is of the form $\alpha = (V/t)(1/N - 1/N_0)$. As the volume was actually twelve percent smaller than that assumed in the previous results, all values of α should be reduced by a cor-

Fig. 1. Cross section of the ionization chamber drawn to scale showing equipotential lines and lines of force when a potential is applied to the lower plate. $ABCD$ is the geometrical volume, while $ABC'D'$ shows the actual volume of ionization swept to the upper plate by the field.

responding amount. This error is not as serious as it might seem offhand since the curves will retain their same form, which after all is the most important result of the experiments as apparently there is no absolute value for the coefficient. The so-called "absolute values" which may be useful for purpose of calculation are now set as given in Table I.

TABLE I. Corrected values of the coefficient of recombination.

Gas	Coefficient of Recombination
O_2	$(1.32 \pm 0.1) \times 10^{-6}$
N_2	$(1.06 \pm 0.1) \times 10^{-6}$
A	$(1.06 \pm 0.1) \times 10^{-6}$
H_2	$(0.28 \pm 0.05) \times 10^{-6}$
Air	$(1.23 \pm 0.1) \times 10^{-6}$

It must be understood that the possible error of plus or minus one-tenth indicated in these results is not an experimental error, but represents a portion of the curves between ages of 0.05 and 0.1 seconds. The experimental error is probably not more than two or three percent for all of the gases except hydrogen. The writers take pleasure in expressing their gratitude to Professor R. B. Brode whose critical suggestion led to the present revision of the values of α , and once more to Professor Leonard B. Loeb under whose able direction the whole research has been accomplished.

LETTERS TO THE EDITOR

Prompt publication of brief reports of important discoveries in physics may be secured by addressing them to this department. Closing dates for this department are, for the first issue of the month, the twenty-eighth of the preceding month; for the second issue, the thirteenth of the month. The Board of Editors does not hold itself responsible for the opinions expressed by the correspondents.

An Attempt to Measure the Energy of the Cosmic Electrons by Magnetic Deflection

An attempt has been made to measure the energy of the cosmic electrons with an apparatus based on Bothe and Kolhörster's¹ coincidence principle making use of Geiger-Müller tube-counters. A description of the method has previously been given.²

Fig. 1.

The arrangement is schematically shown in Fig. 1. *A* and *B* represent two tube-counters, viewed end-on, which serve to define a beam of the particles, *M* is a closed-core "magnet" which furnishes the deflecting magnetic field

(produced directly in the iron), and *C* is a third counter which serves to analyse the beam which has passed through the magnet. An electrical vacuum tube system records on an impulse counter only triply coincident discharges of the three counters, events which are assumed to indicate the passage of an electron through the apparatus.

The principal experiment consisted in making counts of the triple coincidences for various displacements (*d*) of the analysing counter with the magnet unmagnetized and with it successively magnetized to a magnetic induction of 17,000 in either direction. The results are shown in the curve of Fig. 2. The values are believed to be reliable to about 8 percent (the statistical error is about 4 percent) with the exception of the points at the central position and those at 4 cm north which were studied more carefully and should not be in error by more than about 4 percent. The shape of the curve is about what is expected from the geometry of the arrangement, assuming rectilinear passage of the ionizing particle, and the count at the 10 cm displacement represents that due to chance coincidences. It is seen that within the present limits of error no deflection exists. This result is of interest because if the assumptions on which the operation of this apparatus is based are correct the energy of the particles is very high. On making what appears to be the correct assumption that the force on an electron in the iron is given by $(e/c)[v \times B]$

¹W. Bothe and W. Kolhörster, *Zeits. f. Physik* 56, 751 (1929).

²*Phys. Rev.* 35, 1125 (1930). Experiments with the present method have been independently made by Rossi, *Rend. Acc. dei Lincei* 2, 478 (1930).

where B is the magnetic induction, a deflection of 2.2 cm measured at the analyser is expected for electrons of energy 10^9 e-volts. It is seen from the curve that an easily observable change in count should be produced by such a deflection, particularly at the most favorable displacement of about 4 cm. Accordingly, with the reservation mentioned above, it appears that the energy of the majority of the cosmic electrons is greater than about 2×10^9 e-volts. The possibility that these particles may be protons or heavier nuclei should also be considered. This seems unlikely on various grounds, but even if the particles were protons we can conclude that the energy must be greater than about 10^9 e-volts.

ficient for the cosmic radiation, that a considerable fraction of the electrons should have energies ranging from zero to a few hundred million e-volts (about 30 percent between zero and 2×10^8 e-volts). Were this the case, an effect of the magnetic field should have been observed. Consequently, if we wish to interpret this experiment to mean that the energy of the bulk of the electrons is as great as indicated above it is necessary to find a method of absorption for very penetrating electrons which gives considerably greater absorption than that expected on the ordinary theory. A possibility in this direction which should be investigated is a consideration of nuclear effects which are negligible when treating the

Fig. 2.

There is, however, a difficulty with the assumption of electrons of such high energies, which comes from a consideration of the process by which they are absorbed. From the usual theory of multiple scattering it is found that the path of such a particle should be nearly rectilinear until it has lost a large fraction of its energy, so that absorption must be principally due to a gradual loss of energy by the production of ions along the path. Accordingly, since the cosmic radiation (assumed electronic) is known to follow an exponential absorption law, we should expect to find at any point electrons with a definite distribution of velocities ranging from zero to some maximum. In fact, if the Thomson absorption law is still valid for these high energies, it is found, by using the known absorption coef-

absorption of electrons of low energy but which might be expected to become important when dealing with electrons of such large penetrating power.

It should be mentioned that absorption measurements have been made with this apparatus by taking counts with the magnet in position and with it withdrawn from the beam. In agreement with the result of Bothe and Kolhörster, the observed absorption is nearly the same as the value calculated for these conditions from the absorption coefficients obtained by the electroscope measurements.

It is also necessary to be sure that the coincidences are actually produced by a corpuscular radiation and not by a γ -type radiation. This question has been investigated by Bothe

and Kolhörster¹ both experimentally and theoretically, with the result that they do not find it possible to ascribe the coincidence effects to a γ -type radiation unless some new phenomenon is postulated. In view of our present result it would seem desirable to re-examine this question. On the experimental side a possibility in this direction would be to look for a definite correlation between coincidences in tube-counter and tracks in a suitably disposed cloud expansion apparatus. Such an experiment appears feasible and is in progress.

In view of the foregoing considerations and also on account of certain difficulties³ with the assumption of a corpuscular nature for

the cosmic radiation, it would seem that a definite conclusion with regard to the significance of the present experiment must await further study.

A part of this work was done at the California Institute through the kindness of the members of the administration of that institution.

Transmission of Gases from 20 to 33 μ

In a letter to this section Dickinson and West¹ reported a Raman shift for liquid sulfur dioxide of 524.3 cm⁻¹. Bailey, Cassie and An-

been determined in the spectral region 20–33 μ and the results are given in Table I. These values are for a layer of gas four inches thick

TABLE I.

Gas	Reststrahlen Wave-length:	20.75 μ	22.9 μ	27.3 μ	29.4 μ	32.8 μ
SO ₂		7	58	100	99	96
NH ₃		65	95	84	79	63
H ₂ S		96	98	93	89	82
N ₂ O		86	100	100	100	100
C ₂ H ₂		95	100	100	98	97

gus² interpret this as a combination band. I have found the transmission of a four inch layer of this gas for the 20.75 μ quartz reststrahlen to be only 7 percent. Such strong absorption would seem more likely to be associated with a fundamental band.

The transmissions of several gases have

at atmospheric pressure and are probably correct to 2 percent.

A Preliminary Report of the Application of the Photoelectric Cell to the Reading of Minima in a Magneto-Optic Method of Analysis

It has been found that chemical compounds in solution, when traversed by polarized light and subjected to particular types of transient magnetic fields, are characterized under certain conditions by the scale readings of the minima of light intensity produced, by means of which a compound may be detected when present in a concentration as low as about 1 part in 10¹¹ (Allison and Murphy, Journal

the American Chemical Society 52, 3796 (1930); Physical Review 36, 1097 (1930)). These results have been interpreted upon the hypothesis of differential time lags in the Faraday effect. Inasmuch as the results thus far reported were obtained by visual observations only, the importance of devising some objective means of reading the minima has long been recognized. We have recently suc-

ceeded in building a photoelectric cell circuit which indicates the presence of the minima by the deflection of a galvanometer. The method of current amplification is similar to that described by DuBridge (Physical Review 37, 392 (1931)), two FP-54 Photron tubes being employed together with other tubes for additional amplification. We have as yet had opportunity to take observations with the photoelectric cell upon only a few of the compounds which have been studied visually, but those selected are representative and their metallic elements contain isotopes. We used concentrations ranging from about 1 part in 10^{14} to 1 part in 10^3 . Our results, which confirm those based on visual observations, may be summarized as follows.

(a) The photoelectric cell reads minima at the exact points of the scale at which they have been observed visually.

(b) The photoelectric cell is able to detect

a compound when present in an amount as small as about 1 part in 10^{12} .

(c) The photoelectric cell, in addition to detecting minima corresponding to the number of isotopes of the metallic element of the compound, indicates by the galvanometer deflections the relative abundance of the isotopes. This indication, however, is a rough one and does not as yet yield quantitative estimates of precision.

(d) The photoelectric cell registers but very slight differences in the blackness of the minima with changes in concentrations over wide limits, a result in agreement with visual observations.

A New Source of Active Nitrogen

It has been possible for the first time to produce the afterglow of active nitrogen in an uncondensed discharge. The discharge was produced by a 25000 volt 1 KW Thordarssen transformer at pressures ranging from 0.1 mm to about 5 mm. Although a tremendous number of discharges of the same type in the same gas have been observed by the writer during the past four years, this is the first time that the afterglow associated with active nitrogen has been obtained. The afterglow was as strong as those obtained with the usual sources of active nitrogen, namely, condensed discharges and electrodeless ring discharges. The spectrum of the glow was observed with a direct vision spectroscope and also photographed and it consists of the usual sharp selection of the first positive bands of nitrogen as obtained in the ordinary afterglow. If there are any differences between this and other glows then more photographs may bring them out. The glow was obtained in two different tubes, each time however only after about two weeks running of the tubes at almost a no-discharge vacuum, i.e., at about 0.001 mm pressure. While other factors may have an effect, the long running of the tube certainly indicates that the condition of the walls is an important factor in the production of the glow.

A few very interesting points about the

glow will be mentioned, which will help to emphasize the unusual nature of the phenomenon. For example, the exciting discharge itself possesses a spectrum which could readily be taken for an afterglow spectrum. The β bands of nitric oxide and the violet cyanogen bands, both of which are usually observed in nitrogen afterglows and but seldom in electric discharges, were both present in the exciting discharge. These, and the first positive bands of nitrogen comprised most of the radiation of the exciting discharge in the visible and the first positive bands also showed a structure similar to the one observed in active nitrogen. The second positive bands of nitrogen, which are strong in almost any type of nitrogen discharge and which are unusually strong in the condensed discharge, were almost completely missing from the exciting discharge in the present experiments. Just one remark will be made regarding the significance of the nature of the exciting discharge in these experiments. The writer has at various times assigned the weak radiations of the aurora spectrum to the first positive bands of nitrogen and has explained them as arising in processes similar to those that take place in active nitrogen. This assignment always raised the embarrassing question in the writer's mind as to the nature of an electric discharge in which the spectrum is so much like that of an

afterglow or a chemiluminescence phenomenon. This question has now been answered and one can say that as far as the first positive bands of nitrogen are concerned there is added spectroscopic evidence that the auroral displays are electric discharges at low pressures. That the discharge conditions in the upper atmosphere are unusual can be seen by the consideration that the upper atmosphere is really a discharge tube without walls. In view of some recent attempts to explain the

aurora the present experiments should merit some attention. In another communication more will be said about some experiments in which other spectroscopic features of the aurora are pointed out and studied.

The Zeeman Effect and Uncoupling Phenomena in Helium Bands

Weizel¹ has calculated the energies due to the uncoupling of the electronic angular momentum from the electric axis in light molecules. He predicts that such uncoupling should, if present, be greater for large values of the total quantum number, n , for large values of the difference between the orbital angular momentum quantum number of the series electron, l , and its projection on the electric axis, λ , and for large values of the rotational quantum number, K . For the helium molecule, rigid coupling of l to the molecular axis, so that λ is a true quantum number, should correspond to Hund's case b' . For large rotational energies the coupling should be destroyed and the molecule correspond to Hund's case d' . Since this uncoupling is not expected to be abrupt, many levels should correspond to cases intermediate between b' and d' . The energy of a case b' molecule in a magnetic field of strength H is well known to be

$$\Delta E = \frac{\mu_1 H M \Lambda^2}{K(K+1)}$$

where M is the magnetic quantum number and $\Lambda = \lambda$ for the present case. The corresponding relation for case d' can be calculated in the same manner as for the above case. The relation is

$$\Delta E = \frac{\mu_1 H M [K(K+1) + L(L+1) - R(R+1)]}{2K(K+1)}$$

where R is the rotational quantum number, and K the quantized resultant of l and R . It is evident that the Zeeman effect should afford a means to determine the degree of conformity to the limiting cases and indicate the presence or absence of uncoupling phenomena. Information may be drawn from partially resolved patterns by applying the intensity relations for the components of a spectral line

given by Honl² and Kronig.³ Harvey⁴ has pointed out that unusual widths of the helium band lines in a magnetic field can be interpreted as indicative of uncoupling phenomena in certain states of this molecule. To check the above predictions quantitatively, an extensive investigation of the Zeeman effect in the ortho-helium bands has been carried out.

The spectrum has been photographed in the second and third orders of a 21-foot grating affording a dispersion of 1.31 Å per mm in the second order with field strengths up to 30,500 gauss. Measurable Zeeman patterns have been obtained for at least six lines of the bands $2p\pi^3\Pi^{(0)} - 4s\sigma^3\Sigma^{(0)}$, $2s\sigma^3\Sigma^{(0)} - 3p\pi^3\Pi^{(0)}$, $2s\sigma^3\Sigma^{(0)} - 4p\pi^3\Pi^{(0)}$, $2p\pi^3\Pi^{(0)} - 4d\delta^3\Delta^{(0)}$, $2p\pi^3\Pi^{(0)} - 3d\delta^3\Delta^{(0)}$, $2p\pi^3\Pi^{(0)} - 4d\pi^3\Pi^{(0)}$, $2p\pi^3\Pi^{(0)} - 3d\pi^3\Pi^{(0)}$, $2p\pi^3\Pi^{(0)} - 4d\sigma^3\Sigma^{(0)}$, and $2p\pi^3\Pi^{(0)} - 3d\sigma^3\Sigma^{(0)}$. In agreement with previous investigators, the first three above mentioned bands correspond rigorously to case b' predictions. Departure from case b' appears in the band $2p\pi^3\Pi^{(0)} - 4d\delta^3\Delta^{(0)}$ at values of K greater than 9. Evidence of uncoupling in the band $2p\pi^3\Pi^{(0)} - 4d\pi^3\Pi^{(0)}$ is shown by departure from case b' patterns for all values of K greater than 2 and a gradual approach to case d' predictions as K increases to 14. Similar evidence of uncoupling is found in the band $2p\pi^3\Pi^{(0)} - 4d\sigma^3\Sigma^{(0)}$ for values of K greater than one. The approach to case d' patterns is more rapid in this band than in the others mentioned above. In the last two mentioned bands the rate of uncoupling is somewhat more rapid than for

⁴ A. Harvey, *Proc. Roy Soc. A* **126**, 583 (1930).

the bands of the same electronic transition but of total quantum number 3.

It may, therefore, be stated that Zeeman patterns of the ortho-helium bands confirm the idea that the peculiarities of some of these bands, in particular those with large values of n and with l greater than λ for the series electron, can be explained by a gradual uncoupling of l from the molecular axis with in-

creasing rotation. The Zeeman patterns offer a new means of following the progress of the uncoupling.

A complete report of data and results will be presented at a later date.

The Alleged Production of Adsorbed Films on Tungsten by Active Nitrogen

Pure molecular nitrogen has no effect on the thermionic emission from tungsten. The decrease in emission that occurs if a discharge is passed through the nitrogen with voltages above about 20 has been attributed to the formation of a film of adsorbed nitrogen.¹ Kenty and Turner found that the accommodation coefficient for heat conduction from the tungsten surface by nitrogen was increased about 20 percent by this treatment.

More recent experiments in this laboratory have shown that the film produced on the tungsten by active nitrogen is an oxygen film. The active nitrogen, coming into contact with the walls of the tube and the surfaces of electrodes, decomposes adsorbed water vapor or metallic oxides which are almost always present and thus drives oxygen (probably atomic) into the gas phase, whence it reacts with the filament. With great care to avoid oxygen and with the bulb cooled in liquid air, active nitrogen does not produce any adsorbed film which

alters the electron emission or the accommodation coefficient, but instead it is able to remove any oxygen film already present.

A similar evolution of oxygen from well baked out glass surfaces occurs when neon metastable atoms strike the walls of a discharge tube.

The detailed description of these experiments will soon be submitted to the Journal of the American Chemical Society for publication.

Partial Absorption of X-Rays

Ray,¹ Majumdar,² and Bhargava and Mukerjee³ have found evidence that a quantum of x-rays may, in passing through matter, give only a part of its energy to a bound electron and continue in its original direction with diminished frequency. These authors do not give detailed information regarding their experiments, but Ray reproduces spectrograms which clearly show the lines which he ascribes to partially absorbed x-rays. Ray estimates the intensity of these lines to be between 1/400 and 1/500 of that of the parent line.

¹ B. B. Ray, Nature 125, 746 and 856 (1930); 126, 399 (1930); Zeits. f. Phys. 66, 261 (1930).

² R. C. Majumdar, Nature 127, 92 (1931).

³ S. Bhargava and J. B. Mukerjee, Nature 127, 273 and 305 (1931).

Cork⁴ and Lindsay⁵ have tried to produce these modified lines, but with negative results. Cork claims to have been able to detect lines, if present, of 1/1000 to 1/3000 of the intensity of the parent line. Lindsay reproduces photometric curves of the K-spectrum of copper taken through a carbon absorbing screen which show definitely the presence of the $K\alpha_{3,4}$ satellite of copper, known to have about 1/400 the intensity of the α_1 line, but no trace of a modified line.

We have tried to find lines corresponding to the partial absorption of the $K\alpha$ doublet of molybdenum by aluminum, but without success. We used the spectrometer and calcite

⁴ J. M. Cork, Comptes Rendus 192, 153 (1931).

⁵ G. A. Lindsay, Nature 127, 305 (1931).

crystal recently described by us.⁶ The source of x-rays was a water-cooled Coolidge tube with molybdenum target, operated at about 60 KV peak potential and 12–13 ma current. The first slit was about 16.8 cm from the crystal and 0.04 mm wide. The second slit was 4.5 cm from the crystal and wide enough to permit the full beam from the first slit to fall on the crystal. The photographic plate was placed normal to the direct beam at such a distance from the crystal that the $K\alpha_1$ line of molybdenum was in focus. The absorbing screen consisted of powdered "alumina" (obtained from the General Electric Co. of Schenectady) pressed between two sheets of "celophane" about 0.02 mm thick and was placed close to the second slit, between it and the tube. In some cases the screen was about 1 mm thick and in others about half that thickness. During exposures the crystal was rotated back and forth through an angle of about 52.5' around a position at which it should reflect the modified lines due to absorption in aluminum. The rotation was produced by means of a cam designed to give the crystal approximately constant angular velocity between turning points. The mean position about which the crystal rotated was slightly different for different plates. The exposures for the modified

lines lasted for about 15 hr., and then short exposures were taken to record the central image and the $K\alpha$ and $K\beta$ lines of molybdenum on both sides of the latter.

All the plates showed a band of continuous spectrum corresponding in position and width to the range of rotation of the crystal. The band on each plate had a structure which was probably due to irregularities in the cam since the structure remained fixed with respect to the band when the position of the latter on the plate was changed. No lines were found as definite as those appearing on Ray's photographs.

Since the bands of continuous spectrum were quite dark, the modified lines may have been obscured. We are planning to eliminate the continuous spectrum as much as possible by introducing a crystal between the first slit and the x-ray tube.

The Absorption Spectrum of Bromine

In the absorption spectrum of bromine vapor at room temperature with columns of vapor long enough (two to four meters) to bring out the progressions of the visible band system arising from the fifth and sixth vibrational states of the normal level a number of new bands appear in the region 6400Å to 7500Å. These can be classified into five rapidly converging progressions of which three can be followed nearly to the point of convergence. Assigning $v''=1$ to the lowest observed progression the G'' differences agree well with those for the "main" system, and the point of convergence agrees with the assumption that these bands constitute a new system the upper level of which leads to dissociation into two atoms in the $^2P_{1/2}$ state. This level may thus be a member of the case $c^2\Pi$ multiplet predicted by Mulliken.¹ The dispersion employed (first order of a 3 m. concave grat-

ing giving 5.4Å/mm) was not sufficient to determine the character of the bands, which should consist of Q branches only, if the new level is Mulliken's 0_u^- level.

The vibrational isotope effect has not been definitely located so that the v' numbering, on which calculations of the constants given in the accompanying table are based, is arbitrary. This table shows also the constants resulting from a re-examination of the main system in which the isotope effect has been observed for a number of bands in the $v''=0, 1$, and 2 progressions. These measurements indicate that Kuhn's v' numbering should be increased by four. This is in addition to a further correction of +5 to be made for v' greater than Kuhn's 11, which resulted from an incorrect assignment of bands.³ The $\Delta G:v$ curves for the upper level of the main system and of the extreme red system show points of

¹ R. S. Mulliken, *Phys. Rev.* **36**, 699, 1440 (1930).

inflection⁴ at about 65 percent of the dissociation energy, and only observations at points lower than these have been used in making least squares calculations of the constants given in Table I. The ground level of the

Bands which may correspond to the extreme red system of bromine have been found in the infrared absorption spectrum of iodine (vapor pressure 1 atmosphere, in a 1 m tube at 185°C) between 8000Å and 9000Å. These

TABLE I. *Molecular constants of bromine.*

Electronic Level	ν_e cm ⁻¹	ω_e	$\omega_e x_e$	D (volts)	Dissociation products
<i>A</i>	0	323.86	1.150		
<i>B</i>	15,910.5	165.39	1.579	0.464	$^2P_{1/2} + ^2P_{1/2}$
<i>C</i>	14,841.4	115.69	3.395	0.144	$^2P_{1/2} + ^2P_{1/2}$

molecule is denoted by *A*, the upper level of the main system by *B*, and of the extreme red system by *C*.

From the measurements of Bodenstein⁵ on the dissociation equilibrium an estimate of the moment of inertia of bromine has been made by means of the Gibson-Heitler equation, the mean value of I'' from observations at the ten highest temperatures being 445×10^{-40} C.G.S. and the average deviation from the mean 5.6×10^{-40} . With this value of I the equation gives $\Delta F^\circ 298.1 = 38,600$ cal. for the reaction $\text{Br}_2(\text{g}) = 2\text{Br}_\cdot$. The heat of dissociation deduced from the equilibrium measurements is in excellent agreement with the spectroscopically determined value, 1.962 volts.

have not yet been analysed. An account of them will be given at a later time as well as detailed results for bromine. Further experiments with a view to determining the character of the new bromine bands and the isotope effect are being undertaken.

BOOK REVIEWS

Applications of Interferometry. W. EWART WILLIAMS. Pp. viii+104, diagrams 43. E. P. Dutton and Company, New York. Price \$.85.

This is as complete a treatment of the subject as could reasonably be presented in a monograph. As the author says in his preface, it is not possible to include in such a book all the applications which can be made of interferometry. Certainly the selection made is representative and interesting.

Perhaps the most prominent feature of the work is the classification of interference phenomena into two groups: first, those in which a division of wave front is accomplished as in Young's interference experiment, second, those in which there is a division of amplitude as in the Michelson interferometer. For a monograph devoted largely to technical applications it contains a considerable amount of theory, with simplifications which enable a technical man, not extensively trained in mathematical theory, to understand what is meant without too much additional reading. Particularly lucid are the description of Michelson's apparatus for the measurements of stellar diameters and the chapter on multiple beams, in which the Fabry-Perot interferometer, the Lummer plate, and similar instruments are described.

A good bibliography is given at the end of each chapter. It is unfortunate that the abbreviations of the journal references are not more consistent. For instance, on page 45, *Annales de Chimie et de Physique* is abbreviated in three different ways. The book is free from technical errors, and the diagrams are good. It should make a very substantial addition to the reference material for teachers and students of optics, and persons engaged in other divisions of scientific work.

GEORGE S. MONK

Matter and Radiation, with particular reference to the detection and uses of the infrared rays. JOHN BUCKINGHAM. Pp. 144, figs. 15. Oxford University Press, London, 1930. Price \$3.00.

This book summarizes in a semi-popular way, the many interesting discoveries concerning matter and radiation that have been made in the last century. In particular, the complete electromagnetic spectrum is discussed in connection with the recent theories of atomic structure. It is pointed out that the powerfully destructive rays one occasionally reads about in the newspapers are the result of imagination, or at least enormous exaggeration. While the text is usually accurate, there are a few blunders and inaccuracies. Occasionally, but not always, these are evidently introduced for simplicity or for effect. Thus the miracle of the shortest light path would lose some of its effectiveness if it were also pointed out that sometimes light chooses the longest path. One also finds the naïve statement that x-rays readily pass through matter because their wave-lengths are smaller than the holes between the atoms. However, while it occasionally falls short of scientific accuracy, the book makes very interesting reading.

JOSEPH VALASEK

A Treatise on Light. R. A. HOUSTOUN. Pp. 494, 6th Edition, Longmans, Green and Company, New York, 1930. Price \$4.00.

The sixth edition of this much used text book is not greatly different from the preceding editions. There seem to be no changes in the first two "parts" of the book, viz.: (I) Geometrical Optics and (II) Physical Optics. In part III, Spectroscopy and Photometry, the most important changes are the addition of three paragraphs dealing with the elements of the Bohr theory of spectral series, resonance potentials, and band spectra. It seems unfortunate that the treatment of the Zeeman effect was not changed so as to introduce the idea of the Larmor precession. In part IV, mathematical theory, the principal changes are the introduction of Einstein's proof of Planck's Law of radiation and a restatement of the status of the relativity principle. In the "Notes" on recent advances is a notice of the Raman effect. *Houstoun's Light* has the virtue of giving a little information about a great many subjects. That is also its weakness, along with the lack of any adequate number of references to sources of fuller information.

T. TOWNSEND SMITH

PROCEEDINGS
OF THE
AMERICAN PHYSICAL SOCIETY

MINUTES OF THE NEW YORK MEETING, FEBRUARY 26-28, 1931
JOINT MEETING WITH THE OPTICAL SOCIETY OF AMERICA

The 169th regular meeting of the American Physical Society was held in New York City on Thursday, Friday and Saturday, February 26-28, 1931, as a joint meeting with the Optical Society of America. The presiding officers at the sessions of the Physical Society were Dr. W. F. G. Swann, President of the Society, Dr. Paul D. Foote, Vice-president and Professor R. C. Gibbs. All sessions were held at Columbia University.

The joint session with the Optical Society of America was held on Friday afternoon at 2:30 o'clock in the McMillin Theater of Columbia University. This session was a Symposium on "Physical Problems Related to the Biological Effects of Radiant Energy." The President of the Optical Society, Dr. L. A. Jones presided. The invited papers were as follows: "Some Physiological Effects of Light," by Brian O'Brien, Institute of Optics, University of Rochester; "The Spectra and Anti-Rachitic Potency of Various 'Therapeutic' Lamps," by Harvey B. Lemon, University of Chicago; and "Methods of Measuring Radiant Energy," by Harold W. Webb, Columbia University. The attendance was between four and five hundred.

The Optical Society held its sessions at the Museum of Science and Industry Thursday morning and afternoon, occupied with papers on "Color". Their regular Friday morning and Saturday morning and afternoon sessions were held in the Physics Laboratory of Columbia University.

On Friday evening the Society joined with the Optical Society for dinner at the Hotel Commodore after which they attended the Color Exhibition at the Museum of Science and Industry. This dinner was attended by 175 guests.

Meeting of the Council. At its meeting on Thursday, February 26, 1931, Professor Albert Einstein was unanimously elected to Honorary Membership in the Society.

The Council accepted the cordial invitation of Union College and the General Electric Company to hold the summer meeting in Schenectady in September. It was decided that this meeting should be of an informal nature much like the one held last year in Ithaca. A one-half day session of this meeting is to be devoted to papers on Faraday and Henry commemorating their notable work in the field of electromagnetic induction. The Council furthermore accepted the invitations extended by Harvard University and the Massachusetts Institute of Technology to hold the meeting of the Society in February, 1932 in Cambridge.

The Treasurer reported the receipt on January 29, 1931 of a contribution of \$1,425.42 to meet the deficit of the Physical Review as of December 31, 1930 and moved that the thanks of the Council be expressed to the Chemical Foundation for this contribution.

The Council elected four persons to fellowship, one hundred and nineteen persons were transferred from membership to fellowship and twenty-five were elected to membership. *Elected to Fellowship:* G. H. Dieke, Rudolf Ladenburg, Leo J. Peters and Max von Laue.

Transferred from Membership to Fellowship: Fred Allison, Donald H. Andrews, Alice H. Armstrong, Edward J. Baldes, Russell S. Bartlett, J. W. Beams, J. A. Bearden, Ralph D. Bennett, F. Russell Bichowsky, Francis Bitter, Oswald Blackwood, Walker Bleakney, C. Boeckner, Joseph C. Boyce, Charles J. Brasefield, A. Keith Brewer, Ferdinand Brickwedde, James B. Brinsmade, W. G. Brombacher, Detlev W. Bronk, S. Leroy Brown, Andrew B. Bryan, Perry Byerly, Theodore W. Case, Andrew Christy, George L. Clark, Kenneth S. Cole, J. R. Collins, Richard T. Cox, Donald Cooksey, William H. Crew, Leo H. Dawson, David M. Dennison, Elmer Dershem, Jane M. Dewey, Leo A. DuBridge, Jesse W. M. DuMond, Theodore Dunham Jr., James M. Eglin, Frederick E. Fowle, John G. Frayne, James B. Friauf, William F. Giauque, George Glockler, Frank Gray, Grover R. Green-slade, Ross Gunn, Otto Halpern, William R. Ham, Arthur C. Hardy, L. Grant Hector, Edward L. Hill, Maurice L. Huggins, Elmer Hutchisson, Sydney B. Ingram, Lewis V. Judson, J. C. Karcher, Sebastian Karrer, E. Lee Kinsey, Dewey D. Knowles, Lewis R. Koller, Frank C. Kracek, Victor K. LaMer, R. M. Langer, Karl Lark-Horovitz, Charles C. Lauritsen, Victor F. Lenzen, H. H. Lester, Noel C. Little, Walter A. MacNair, Louis R. Maxwell, Helen A. Messenger, Louallen F. Miller, Allan C. G. Mitchell, Philip M. Morse, L. L. Nettleton, J. Rud Nielsen, Wayne B. Nottingham, Christian Nusbaum, Paul S. Olmstead, A. R. Olpin, Lars Onsager, Dimitry E. Olshevsky, John M. Ort, Frederic Palmer Jr., I. I. Rabi, Hubert H. Race, N. Rashevsky, Howard P. Robertson, Vladimir Rojansky, Duane Roller, Edward O. Salant, William Schriever, Nadiashda Galli-Shohat, Francis G. Slack, William W. Sleator, Sinclair Smith, Ambrose H. Stang, F. W. Stevens, John B. Taylor, James D. Tear, Lewi Tonks, Alva Turner, M. A. Tuve, J. T. Tykociner, D. S. Villars, G. R. Wait, Warren Weaver, Lars A. Welo, T. Russell Wilkins, Robert C. Williamson, Thomas A. Wilson, Enos E. Witmer, Jay W. Woodrow, Winthrop R. Wright, Oliver R. Wulf, Ralph W. G. Wyckoff, Otto J. Zobel and Vladimir Zworykin.

Elected to Membership: B. C. Adkerson, R. H. Bacon, L. J. Buttolph, Jessie Y. Cann, Samuel L. Case, T. C. Chow, H. M. Evjen, Isidor Fankuchen, Louis W. Gardner, Maria Goeppert-Mayer, Harold W. Harkness, Francis E. Haworth, Nathan Howitt, Lorenz D. Huff, George B. Lamb, K. O. Lee, Charles F. Lucks, John C. Melcher, Harry B. Mulkey, Edward J. Murphy, H. V. Neher, Filmer S. C. Northrop, Robert W. Perry, William B. Plum and James G. Potter.

The titles and abstracts of papers presented before the Optical Society

of America will be found the Proceedings of that Society, published in the Journal of the Optical Society.

The regular scientific program of the American Physical Society consisted of 49 papers, numbers 5, 6, 8 and 35 were read by title. The abstracts of these papers are given in the following pages. An Author Index will be found at the end.

W. L. SEVERINGHAUS, *Secretary*

ABSTRACTS

1. Water vapor absorption spectrum in the near infrared. E. D. McALISTER, *Division of Radiation and Organisms, Smithsonian Institution*, and H. J. UNGER, *University of Oregon*.—The 1.13, 1.38 and 1.45 μ water vapor bands have been obtained with a self recording spectrograph using an effective slit width of 6A. The fine structure of the 1.13 and 1.45 μ bands has been revealed for the first time and several lines have been added to the 1.38 μ band. Forty lines appear in the 1.1 μ region and eighty-five in the 1.4 μ region. A comparison of these bands with similar ones due to atmospheric absorption in the solar spectrum identifies several superimposed solar lines. Regularities in frequency and intensity are lacking, due to the fact that a 6A slit is much too coarse to reveal the true structure of these bands.

2. Transmission of radiation through fog. S. HERBERT ANDERSON, *Signal Corps Laboratories*.—A laboratory method for the production of fog was developed in which the processes of formation of natural fogs were closely simulated. Transmission of radiation through this laboratory-made fog was measured for a range of wave-lengths from 3000A to 26,000A. A wide range of fog densities was used corresponding to natural fogs in which the visibility varies from 5 meters to 500 meters. A minimum transmission was found in the visible spectrum, the position of the minimum being a function of particle size. From λ_{\min} to $\lambda = 26,000\text{A}$ the transmission increased, likewise from λ_{\min} to $\lambda = 3000\text{A}$. The transmissions obtained have been used to test King's equation $I = I_0 e^{-(a+b\lambda^{-4})}$. This equation if found *not* to hold for transmission of radiation through fog, contrary to the conclusion reached by Granath and Hulburt (Phys. Rev. **34**, 140, 1929). The discrepancy is probably due, (1) to the difference in particle size, (2) the width of the bands in the infra-red used by Granath and Hulburt, (3) to the absorption of water vapor, the effect of which was eliminated in this work but not in Granath and Hulburt's.

3. The absorption spectrum of blood and its relation to rickets. R. C. GIBBS, J. R. JOHNSON AND C. V. SHAPIRO, *Cornell University*.—The ultraviolet absorption spectra of solutions, obtained by haemolyzing the red blood cells of healthy and rachitic rats, have been found to be identical. This result is contrary to that reported by Suhrmann and his co-workers, Phys. Zeits. **30**, 959 (1929), whose curves for the two sets of animals show a difference in intensity, which increases in the direction of shorter wave-lengths. Calculations based on Rayleigh's law of light scattering indicate that this difference can be attributed to the presence of an excess of a disperse phase in the solution whose absorption is the more intense. Experimental verification of this hypothesis has been obtained by measuring the absorption of one of our solutions after it had been centrifuged to remove most of the suspended matter. The new curve so obtained is less intense than the original and the difference increases toward shorter wave-lengths, in close accordance with the Rayleigh law. This evidence points to a physical cause for the variation reported by Suhrmann and renders unnecessary his improbable assumption of a chemical change in the haemoglobin. The discrepancy between his results and ours may be accounted for by assuming either that there are two types of rickets, possibly brought on by different diets, or else that the variation reported by him, especially in view of its physical origin, is due to some cause, not necessarily associated with rickets.

4. Energy distribution in the lunar ultraviolet spectrum. BRIAN O'BRIEN AND E. DICKERMAN O'BRIEN, *Institute Optics, University of Rochester, N. Y.*.—The energy distribution in the ultraviolet spectrum of sunlight reflected from the full moon has been measured from 4400A to

$\lambda 3020\text{\AA}$, by the method previously applied to direct sunlight. (Phys. Rev. **36**, 381 (1930)). Uniformity of slit illumination was secured by an astigmatic telephoto combination of quartz provided with rectangular stops, the measured spectral energy distribution being an average across a lunar diameter. Transmission coefficients and ozone content of the earth's atmosphere were obtained directly. The amount of ozone at night has been found to differ only slightly from the day values obtained on succeeding days in agreement with Chalonge and Götz (Gerl. Beit. z. Geophys. **24**, 20) (1929)). By comparison with direct sunlight the reflection coefficients for the moon's surface have been calculated throughout the above spectral region. No pronounced maxima or minima of reflecting power have been found within this range of wave-lengths. A test of some delicacy is thus provided, with negative results, for very small amounts of ozone (and hence oxygen) surrounding the moon.

5. Raman spectra of some organic halides. CLAUD EDWIN CLEETON AND R. T. DUFFORD, *The University of Missouri*.—Raman spectra obtained by helium excitation from nineteen organic compounds, several of which have not been studied previously, are reported and discussed. It has been found by one of the writers (C. E. C.) that in the cases of many simple organic halides the observed frequencies can be expressed as harmonics or combinations of four fundamentals (five in the cyclic compounds), two of which are not found in the Raman spectra, and are lower than predicted by any theory available, and hence may prove to be illusory; but the scheme does serve to point out certain regularities in these spectra. The bearing of such theory as is available is discussed.

6. Raman spectra and a slight asymmetry of the carbon and nitrogen atoms. R. T. DUFFORD, *The University of Missouri*.—The interpretation of the Raman spectra of the simpler organic halides and other related compounds is discussed; it is shown that most of the observed frequencies can be associated with vibrations of pairs or groups of atoms as predicted by theory, except that, in order to explain the multiplicity of certain lines, it seems necessary to assume a slight dissymmetry—i.e., a lack of equality of the valance bonds—of the carbon atom. Similar but less extensive evidence seems to indicate that the three valences of nitrogen are also not quite equally strong.

7. Vibrational quantum analysis of the ultraviolet SO_2 and CS_2 absorption bands. WILLIAM W. WATSON AND ALLAN E. PARKER, *Yale University*.—Analysis of spectrograms taken with a Hilger E-1 spectrograph shows that the SO_2 bands may be represented by the formula

$$\nu = 30586 + \left\{ \left[381.1(v_1' + \frac{1}{2}) + 6.22(v_1' + \frac{1}{2})^2 - 0.223(v_1' + \frac{1}{2})^3 \right] - \left[1381(v_1'' + \frac{1}{2}) - 20(v_1'' + \frac{1}{2})^2 \right] \right\} \\ + \left\{ \left[436.7(v_2' + \frac{1}{2}) + 2.94(v_2' + \frac{1}{2})^2 - 0.199(v_2' + \frac{1}{2})^3 \right] - \left[1157(v_2'' + \frac{1}{2}) - 12.5(v_2'' + \frac{1}{2})^2 \right] \right\}$$

Noteworthy points are: positive quadratic term of the upper state levels, agreement with two of the fundamental frequencies determined by Raman and infrared analysis, no evidence for the 606 cm^{-1} deformation frequency, and the existence of various addition series as given by the double formula. Apparently a triplet electronic level is involved. High dispersion plates do not resolve the rotational fine structure. Most of the bands of the CS_2 system are given by

$$\nu = 28880 + 215(v_1' + \frac{1}{2}) - 802(v_1'' + \frac{1}{2}) + 270(v_2' + \frac{1}{2}) - 1466(v_2'' + \frac{1}{2})$$

the anharmonic coefficients being nearly negligible. There is slight evidence for a deformation frequency of 208 cm^{-1} in the ground state. Series of addition bands are found as for SO_2 . The Raman frequency 655 cm^{-1} is the difference between the 1466 cm^{-1} and 802 cm^{-1} fundamental frequencies.

8. Paschen-Back effect and hyperfine structure in the spectrum of bismuth III. J. B. GREEN, *Ohio State University*.—A study of the spectrum of Bi in a field of 34000 gauss yields interesting data with respect to the hyperfine structure of Bi III. In particular, the line 4561, classified by McLennan as $^2P_{1/2}^2S_{1/2}$ gives 2.52 cm^{-1} for the 2S separation, and 0.53 cm^{-1} for the $^2P_{1/2}$ separation. Several "forbidden" components appear on the plates. The line 3695, classified as $^2P_{3/2}^2S_{1/2}$ seems to indicate that the $^2P_{3/2}$ separation is much smaller.

9. Hyperfine structure in Bi II and Bi III. R. A. FISHER AND S. GOUDSMIT, *University of Michigan*.—The hyperfine structure of several lines in Bi II and III has been determined. The

results form a partial confirmation of the classification given by McLennan, McLay and Crawford (Proc. Roy. Soc. A129, 579 (1930)). It is possible to derive the hyperfine splitting for a number of levels. Together with the data on Bi I they form useful material for theoretical investigation. Bismuth is at present the only element for which hyperfine structure depending upon other than a single s electron is known for several levels.

10. Difficulties in the theory of hyperfine structure. S. GOUDSMIT, *University of Michigan*.—Sum rules and formulae for the hyperfine separations of the levels are derived for complicated configurations. The observed hyperfine structure of neutral and ionized bismuth, shows large deviations from the theoretical expressions. The nature of the discrepancies suggests that the present theory of the interaction between a single electron and nuclear spin is incomplete.

11. The theory of complex spectra II. E. U. CONDON AND G. H. SHORTLEY, *Princeton University*.—Formulas for the relations between the energies of multiplets arising from the same electron configuration for all two-electron configurations up to ff and several cases of three-electron configurations have been worked out following Slater's method. A systematic comparison of the known data with this first-order perturbation theory shows only rough agreement in most cases although in a few there is excellent agreement. The theory predicts the observed alternation in the relative position of singlet and triplet through S, P, D, F , etc. in the pd and pf triads and the dd and df pentads. For the d^2 configuration it was found that good fits are obtained except for the 1S which theory indicates is much higher than the 1S which spectroscopists assign to this configuration. The same is probably true for 2S in d^2s .

12. The determination of heats of dissociation from predissociation spectra. LOUIS A. TURNER, *Princeton University*.—Two distinct types of predissociation spectra are known. In one the broadening of the lines begins suddenly at a definite wave-length, in the other it sets in gradually. Consideration of various possible relationships of potential energy curves suggests that the one or the other type occurs according to whether the curves for the two states concerned intersect below or above the energy of dissociation in the perturbing state, respectively. Accurate values of heats of dissociation can be obtained only from predissociation spectra of the first type. The others give merely upper limits. A predissociation of each kind is observed in the spectrum of NO_2 and the numerical relationships are in accord with the theory.

13. The inverse-cube central force field in quantum mechanics. G. H. SHORTLEY, *Princeton University*.—The problem of the motion of a particle in an inverse-cube central force field is fully treated by quantum mechanics and the results compared with the classical theory. Taking the effective radial potential energy as $(M^2/2\mu - S)/r^2$, one gets good correspondences between the quantum mechanical and classical solutions except for S between $l(l+1)h^2/8\pi^2\mu$ and $(l+\frac{1}{2})^2h^2/8\pi^2\mu$, where one gets a peculiar absence of oscillations in the ψ -function near the origin and somewhat poor agreements in regard to the radial probability functions. This is interesting in view of the uncertainty as to which value to compare with the classical angular momentum. However, the correspondence in allowed energies is complete only if the value $l(l+1)$ is taken. Solutions are found corresponding to the six classical types of orbits, with no quantization whatever. The solutions involve Bessel functions of both real and imaginary order with both real and imaginary arguments.

14. van der Waals' forces of helium and the stability of a small energy helium molecule. HENRY MARGENAU, *Yale University*.—Hopfield (Astrophys. J. LXXII, 133 (1930)) has recently postulated the existence of a He molecule of very low energy of binding. Theoretical evidence for the existence of such a molecule will here be given. The work consists of two parts. (1) A general method is outlined by which van der Waals' forces can be calculated without the knowledge of wave functions. Main features are: The expression for the interaction energy of 2 atoms in their lowest state is written in terms of the dispersion f -values, which are shown to be derivable with good approximation, by the aid of the "Summensatz" of Thomas and Kuhn, from the relative intensities of the resonance lines and the polarizability. The method is applicable to atoms (and molecules) more complex than He. Results for He:

$$\Delta E = 11.58/R^6 \times 10^{-61} \text{ ergs, } R > R_0.$$

(2) From the potential energy curve given by this expression and $\Delta_2 E = +\infty$ for $R < R_0$, R_0 being taken as 2.33×10^{-8} cm, the vibrational states for the resulting molecule are computed. Results: Minimum of potential energy = -10^{-14} ergs; the molecule has but one vibrational state of energy about 3.3×10^{-16} ergs = 0.2 millivolts, which is in qualitative agreement with Hopfield's predictions

15. Group theory and the electric circuit. NATHAN HOWITT, *Naval Research Laboratory Bellevue, D. C.* (Introduced by Elias Klein).—The paper shows that electrical networks consisting of inductances, resistances, and capacitances form a group with the impedance function as an absolute invariant. That is, to a given impedance function there corresponds an infinite number of networks, any one of which can be obtained from any other by a special linear transformation of the instantaneous mesh currents and charges of the network. In this manner one may arrive at the complete infinite set of networks equivalent to a given network of any number of meshes. This is done by writing down the three fundamental quadratic forms of the network. Then a linear affine transformation of the instantaneous mesh currents and charges of the network results in the formation of new quadratic forms, the matrices of the coefficients of which represent a member of the group, i.e., an equivalent network. Instead of performing the substitutions, the three matrix multiplications $C'AC$ are used, one for each quadratic form, where A represents the original matrix, C the transformation matrix, and C' its conjugate. It may be possible to extend this theory to include continuous systems where the quadratic forms become integrals or infinite series and one deals with infinite matrices and infinite transformations.

16. Magnetic lag at low flux densities. L. W. MCKEEHAN, *Yale University*.—Energy losses in alternating magnetization are often compared by assuming that H and B vary sinusoidally, B lagging by an angle ϵ . At low flux densities ϵ is not fully accounted for by calculated eddy current and hysteresis terms if each branch of the hysteresis loop is assumed parabolic with least slope equal to that at the origin of the normal magnetization curve. The residue, ϵ_n , is a true magnetic lag. No explanation for it has hitherto been offered. It is now pointed out that Barkhausen discontinuities involve a magnetic lag which may suffice to explain the existence of ϵ_n . For example, 600 equal discontinuities per half cycle would suffice if $\epsilon_n = 10^{-3}$. The necessary mean magnitude of these discontinuities is improbably great unless it is principally strained regions which are affected by weak applied fields. If Jordan, *Zeits. f. techn. Physik* **11**, 2-8 (1930), is right in supposing that ϵ_n is independent of H_{\max} over the small range in which it can be measured with any precision, the average magnitude of the discontinuities would have to vary directly with H_{\max} throughout this range. This is not inconsistent with the parabolic form of (smoothed) magnetization curves at low flux densities.

17. Ferromagnetism of dilute solid solutions. FRANCIS BITTER, *Westinghouse Elec. & Mfg. Co., East Pittsburgh*.—Since the atoms of the solvent are known to move about in the solute it is possible to consider annealed and aged solutions as systems in thermodynamic equilibrium. It is shown that the strains set up by the atoms of solvent in the solute do not produce long range forces. There are, then, no long range repulsive forces tending to produce a microscopically uniform distribution. Under these circumstances the fluctuations in density of the solute will be at least as large as those in a perfect gas, and may become much larger (as large as those giving rise to opalescence, for instance). Local concentrations or rarifications of impurities may play an important part in determining magnetic properties through the inhomogeneities and strains they set up. For instance, in the iron-carbon diagram, the observed magnetic transformation of Austenite at 770°C would necessitate a drastic revision of ideas about ferromagnetisms if it were granted that Austenite is a solid solution of carbon in γ -iron. If, however, it is assumed that Austenite contains small inclusions of α -iron where there are local rarifications of carbon concentration, the difficulty disappears. Whether Austenite contains α -iron at 770°C should be determined by x-ray investigations. It is further suggested that the magnetic properties of dilute solutions of ferromagnetic substances in other metals are largely determined by local concentrations of ferromagnetic atoms.

18. Capillary rise in sands of uniform spherical grains. W. O. SMITH, PAUL D. FOOTE, AND P. F. BUSANG, *Gulf Research Laboratory, Pittsburgh*.—Uniform spheres packed in regular

array form a non-cylindrical cyclic capillary, characterized by a maximum and minimum capillary rise with intermediate positions of possible equilibrium. In practice spheres may be packed to a variety of porosities P thus requiring a mixture of regular and irregular piling arranged in a very distorted pattern. However the meniscus is also distorted to conform in a general way with the distortions of the lattice. Accordingly positions of maximum and minimum rise may be expected. The meniscus for maximum rise tends to pass through the plane of centers of neighboring spheres. Slight deviations from this condition due to the rise at sphere contacts are shown to be of minor importance. Any piling may be treated statistically as a hexagonal array with a spacing $2r+d$ where d is computed to give the observed porosity. In such a system three types of cell occur with a definite frequency, and these cell types are assumed present in the meniscus with the same frequency distribution. Hence it is possible to evaluate $pr/a = \rho ghr/\sigma$ where p =perimeter, r =grain radius, a =area of pore opening, g =acceleration of gravity, σ =surface tension, ρ =density and h =capillary rise. The final formula so derived reduces to

$$\frac{pr}{a} = \frac{\rho ghr}{\sigma} = \frac{2}{\frac{0.9590}{(1-P)^{2/3}} - 1}$$

This agreed with experiments made with several sizes of grains, porosities, and liquids. The minimum rises were also determined but a satisfactory interpretation in terms of a model has not been effected.

19. The variation of the thermal boundary layer of a miniature airfoil. MERIT SCOTT, *Guggenheim Research Physicist, Cornell University*.—By mounting thin, narrow conducting strips parallel to the span of an airfoil, and flush with its surface, it is possible, experimentally, to measure a thermal dissipation coefficient, p_e , associated with a particular location on the lifting surface, as well as its variation with velocity and angle of attack, α . Such measurements have been accomplished with a velocity range of 12 to 24 m/sec and for angles of attack varying from -40° to $+35^\circ$. It is found that p_e , independent of position on the surface, is a linear function of the velocity at the strip. Curves, showing its variation with angle of attack, present definite maxima and minima, characteristics which bear no direct correspondence to the velocity at the strip. It was to be expected that the variation of p_e , at a given location, with angle of attack would be of the same character as its variation with position along the chord. This is experimentally verified. Theoretical considerations suggest converting this coefficient to boundary layer thickness, B , and interpreting this thickness as identical with the viscous boundary layer. The measurements have been extended over the wide range of angle of attack so that the relation of these quantities to the useful range of the airfoil might be studied.

20. The variation of C_p of oxygen and nitrogen with pressure at 26° and 60°C . E. J. WORKMAN, *National Research Fellow, Bartol Research Foundation*.—By the use of improved apparatus of the type previously described by the author (Phys. Rev. **36**, 1083 (1930)) the ratio of C_p at a pressure p to C_p for the same gas at a pressure of one atmosphere is determined. Oxygen and nitrogen gas have been studied at 20 and 60°C in the pressure range 10 to 130 Kg per cm^2 . Values of the ratio as measured may be inferred from smooth curves drawn through the points plotted from the data in the table below, where the pressure is given in Kg/cm^2 .

Oxygen, 26°C		Oxygen, 60°C		Nitrogen, 26°C		Nitrogen, 60°C	
Pressure Kg/cm^2	Ratio C_p/s	Pressure Kg/cm^2	Ratio C_p/s	Pressure Kg/cm^2	Ratio C_p/s	Pressure Kg/cm^2	Ratio C_p/s

21. Some Physiological Effects of Light. BRIAN O'BRIEN, *Institute of Applied Optics, University of Rochester*. Invited paper

22. The Spectra and Anti-Rachitic Potency of Various "Therapeutic" Lamps. HARVEY B. LEMON, *University of Chicago*. Invited paper.

23. Methods of Measuring Radiant Energy. HAROLD W. WEBB, *Columbia University*. Invited paper.

24. X-ray measurements of the elastic deformation of metals. WILLIAM P. JESSE, *The General Electric Company*.—The metal wire to be tested lies along the axis of a precision x-ray camera. A series of photographs is taken with various loads on the wire. On the photograph only the lines are measured where the resolving power is a maximum, i.e., where the incident angle θ is almost 90° . As the load on the wire increases, these high order lines shift in the direction indicating smaller grating spaces. This shift measures the contraction of the crystal lattice in a direction perpendicular to the direction of stress. For duralumin wire this contraction is in approximate agreement with the value calculated from the macroscopic Young's modulus and Poisson's ratio for the material. Similar results have been obtained with steel piano wire.

25. A new x-ray tube based on the "transparent target" principle. DIMITRY E. OLSHEVSKY, *Yale University*.—A new "transparent target" x-ray tube is described in which the portion of x-rays transmitted through the target is utilized. It is found that by using a properly designed, thick, double layer target in contradistinction to the thin single layer targets used by Owen and by Coolidge satisfactory heat dissipation may be secured at comparatively little sacrifice due to absorption. The new tube has a target made of a thick layer of low atomic number metal, backing a thin layer of high atomic number metal, in thermal contact with the former. A simplified theory of heat dissipation from the cathode spot is developed and a table is given, showing merits of various target materials as functions of wave-length. Important advantages of the tube over the conventional Campbell-Swinton arrangement are: proximity of the cathode spot to the outer surface of the tube and the possibility of utilizing x-rays in the direction of the initial electron beam. As applied to crystallographic purposes, vertical beam models were built in which the first slit of the spectrograph is defined by a hole drilled in the body of the tube immediately behind the target. This arrangement permits higher intensities at the second slit on account of a shorter slit distance from the cathode spot. Both slits are made integral with the tube, the whole arrangement possessing complete symmetry around the vertical axis. This vertical design, with the beam directed upwards, complete shielding of the tube proper and high tension leads concealed in a grounded table, contributes to the safety and comfort of work and is valuable for x-ray studies involving the liquid state. Special tubes based upon the new principle may prove of value for medical purposes.

26. New K series x-ray lines. WILLIAM DUANE, *Harvard University*.— K series x-rays have been examined by means of a Bragg spectrometer, the Moseley photographic method being employed. The incident ray and that reflected by the crystal to the photographic plate through distances of 4725 mm passed through long metal tubes, exhausted of air in order to reduce the absorption. The K_β doublet lines of molybdenum ($\Delta\lambda = 0.00056\text{\AA}$), examined by photometric curves, appear separated 0.88 mm. No third line lies in the immediate neighborhood of the β doublet. Between the γ line and the short wave-length limit of the series appears a marked blackening that represents several lines close together. They are not in the position of a line reported by Leide. The new lines may be due to 0 electrons falling into the K level, but a better explanation is, perhaps, that the lines are produced by falls into the K level of conductivity electrons which may from time to time lie in outer atomic energy levels. Several photographs produced by long exposures show a fainter single line, roughly halfway between the β_2 and the γ lines. It does not correspond to a known x-ray line of any chemical element reflected in the first or second order.

27. Electron diffraction by a silver crystal. H. E. FARNSWORTH, *Brown University*.—A previous investigation of electron diffraction by a copper crystal, for normal incidence on a (100) face (Phys. Rev. 35, 1131 (1930)) revealed a series of weak beams requiring unit refractive

index, in addition to the more intense beams requiring refractive indexes greater than unity. These weak beams are in most cases so close in voltage to the main beams that they appear as components or satellites of them. A similar series of measurements for two silver crystals shows, in general, the same to be true for silver, although certain beams have more complex structures containing additional components. In many cases the different components are extraordinarily sharp and intense. These results for low-velocity electrons suggest a complex variation of the inner potential near the surface of the metal.

28. Radiation from low speed electron bombardment of metals. F. L. MOHLER AND C. BOECKNER, *Bureau of Standards*.—A small probe surface at a positive potential in a discharge may draw a current of many amperes per cm^2 with the potential gradient limited to a thin sheath over the surface. Under such conditions a continuous spectrum is emitted by metal surfaces in caesium, potassium, and helium discharges. With a copper probe at 7 volts in caesium vapor, the intensity J remains of the same magnitude between 6200Å and 2400Å with a minimum at 5800 and a maximum at 3800. Below 4 volts the spectrum has a high frequency limit in this range (3000Å for copper at 2.15 volts). On the assumption that this is analogous to a continuous x-ray spectrum, observed limits indicate work functions of 1.95 for Cu, 2.1 for Ag, 1.45 for W (all in caesium vapor). The absolute intensity (except for Ag) agrees within a factor of 2 with values computed from the theoretical equation for intensity of the continuous x-ray spectrum. Efficiency for Cu at 7 volts is estimated as 3×10^{-7} . Comparison with published data on photoelectric effect of radiation from electron bombardment of metals indicates that the magnitude of effects below 10 volts can be explained by this continuous spectrum.

29. The distribution of electricity near the surface of contact of two conductors. A. T. WATERMAN, *Yale University*.—Two dissimilar metals are postulated in contact along an infinite plane, and the equilibrium distribution of electricity is sought in a direction perpendicular to this plane on the basis of Sommerfeld's electron theory using Poisson's equation and the Boltzmann principle. The problem is solved under the assumptions that the potential and the electric intensity are continuous across the boundary, and that the P.D. between points in the two metals far from the boundary is equal to the contact P.D. In general, if the normal concentration of conducting electrons is assumed to be one per atom the electrons in both metals remain in the degenerate state, though their concentration may vary from normal by 30 to 50 percent at the boundary. In this case the distribution is unaffected by temperature. In this special case of a pair of metals with high contact P.D., such as Cs and W, the electrons near the boundary in the more electropositive metal are reduced to the classical state and the distribution is a function of temperature. The possible bearing of these results upon the properties of thin metallic films is discussed.

30. An estimation of patch sizes on a thoriated tungsten filament. LEON B. LINFORD, *National Research Fellow, Princeton University*.—It is well known that coated filaments fail to follow Schottky's equation for thermionic emission in strong accelerating fields. Becker and Mueller (Phys. Rev. 31, 341 (1928)) showed that the emission from thoriated tungsten is what would be expected if the surface fields were much larger than image fields at distances greater than 10^{-5} cm from the surface. These fields were confirmed by the author using the photoelectric method (Phys. Rev. 36, 1100 (1930)). One explanation assumes that these large fields are due to a non-uniform surface distribution of positive ions. If these patches are assumed to be square and of dimension b , arranged checkerboard fashion with a contact potential difference V_0 between adjacent patches, the field above the center of a more positive area can be calculated. Using two values of the observed ion field the size of the patches was found to be about 2×10^{-4} cm, with about 0.5 volts contact potential difference V_0 . The sum of the field produced by such a charge distribution and the image field was within experimental error of the observed field. From the surface field, and the threshold at a known accelerating field, the work function at zero field was found to be 2.7 volts or 1.8 volts less than that of pure tungsten.

31. Some thermionic properties of barium films absorbed on tungsten. HERBERT NELSON, *RCA Radiotron Company, Harrison, New Jersey (Introduced by G. R. Shaw)*.—The activity and the change in contact potential difference have been studied as a function of the thickness of

the barium film. The velocity distribution of the electrons, the effect of non-uniformities in the film, and the effect of field intensity on the activity have also been studied. The experimental tube was constructed such that the measurements could be made on a small area of the filament in order that errors due to lead losses, non-uniformities, and voltage drop along the filament might be minimized. A vacuum tube electrometer was used in measuring the electron currents. The experimental results obtained by Eglin were confirmed, i.e., the activity of the composite surface was found to increase with the thickness of the barium film until an optimum thickness was reached after which further deposit caused the activity to decrease. A relation such as derived by Richardson was found to exist between the thermionic constants and the contact potential difference. The distribution of velocities of the emitted electrons were found to be Maxwellian for all thicknesses of the barium film. The presence of non-uniformities in the emitting surface had the effect of decreasing the slope of the Maxwellian distribution curve.

32. Time changes in oxide-coated filaments. E. F. LOWRY AND W. T. MILLIS, *Westinghouse Electric and Mfg. Co., East Pittsburgh*.—The oscillograph is made use of in studying time changes in the electron emission of oxide-coated filaments. The decay of emission with time while drawing current is compared with rate of recovery when instantaneous measurements are made. It is found that similar phenomena, though of much less magnitude, occur when thoriated tungsten or bariated filaments are used. It has also been found that this fading effect is not a universal characteristic of oxide filaments though it is present in greater or less amount in the majority of instances. Oscillograph methods have also been employed in studying oxide emission at normal operating temperature.

33. Grid current required by hot-cathode, grid controlled mercury arcs before discharge. W. B. NOTTINGHAM, *Bartol Research Foundation*.—The hot-cathode, grid-controlled mercury arc or "thyatron" has been described by A. W. Hull, (*G. E. Rev.* 32, 213 and 390 (1929)). Although the thyatron has been called "an electrostatically controlled arc rectifier," a definite grid current is required in the grid or control circuit. With a d.c. plate potential, this grid current, before the discharge begins may have any value from 6×10^{-3} amp. to 10^{-7} amp. depending on the type of thyatron, the plate potential and the mercury condensation temperature. In certain cases, the temperature enters so drastically that a change in ambient temperature of only a few degrees can cause the thyatron to fail to operate. With 60 cycle a.c. plate and grid potentials, experiment seems to show that 0.001 second is required to set up conduction in the thyatron. A time lag of this amount was unexpected. A comparison of the "phase shift" and "critical potential" methods of controlling a thyatron with photoelectric currents showed that for extremely small light intensities, the critical potential method is the more sensitive, although for greater light intensities the phase-shift method is perhaps more reliable. Satisfactory operation using either method of control was obtained with 10^{-8} amp. photoelectric current (approx. 3×10^{-4} lumen). The measurements were made on General Electric FG-17; FG-27 and FG-67 thyatrons.

34. A further study of galvanoluminescence. ROY RICHARD SULLIVAN WITH R. T. DUFFORD, *Bell Telephone Laboratories and The University of Missouri*.—Previous work by one of the writers has been checked and extended in several directions. The glow surrounding aluminum anodes was studied in several new solutions, as well as those already described. Several-fold larger efficiencies have been obtained by using water-cooled electrodes. Study of the glow seems to be against the theory of a gas film covering the electrode; the spectrum of the glow is a typical luminescence spectrum, and the brightness and efficiency lie in the same range as for other luminescent reactions under study in this laboratory. In many cases, the law of increase of brightness with voltage seems to have closely the same form as for a tungsten filament. The spectrum of the sparkles which appear at higher voltages is, however, a bright-line spectrum; the two strongest lines coincide with the strongest lines in the spark spectrum of aluminum. The glow surrounding various metals in ether solutions of Grignard reagents and of $\text{MgBr}_2 \cdot 2(\text{C}_2\text{H}_5)_2\text{O}$ has been studied, giving the highest efficiencies so far found in this type of luminescence. Systematic differences between chemical groups of metals are found. The work was done at the University of Missouri.

35. Intensities of the magnetic and electric illumination components in the electrodeless discharge. CHAS. T. KNIPP, *University of Illinois*.—Recent theory (J. T. Tykociner and J. Kunz, Chicago Meeting, American Physical Society, November 1930, paper No. 5) indicates that a considerable portion, perhaps even 80 or 90 percent of the illumination in the electrodeless discharge is due to the electrostatic field. A discharge vessel was constructed experimentally to test this point. Obstructions were set in it with the idea that each type of discharge would cast its own shadow. With the most favorable conditions for a discharge passing due wholly to the magnetic field, shadows were obtained in the plane of the exciting coil which extended one-third way around the tube, while there were no indications of shadows at right angles, i.e., in the direction of the electrostatic field. By placing a band conductor to the right and to the left of the medial line, and removing the energizing coil entirely, a powerful electrostatic field was produced and shadows in this direction were now readily obtained, but the characteristic ring discharge was gone. Hence it appears, when conditions are favorable for the formation of *ring discharges*, that the intensity of the attending illumination is in part, if not entirely, due to carriers moving in the plane of the energizing coil. This result seems to support the calculations of Sir J. J. Thomson.

36. High frequency behavior of a plasma. LEWIS TONKS, *General Electric Company, Schenectady, N. Y.*—Earlier work on spontaneous short-wave oscillations in a low-pressure mercury arc plasma (Phys. Rev. 33, 195 (1929)) has been extended to forced oscillations by experiments similar to those of H. Gutton (Ann. de Physique 13, 62 (1930)). Theory gives $K = 1 - \nu_e^2/\nu^2$, where ν is the impressed, $\nu_e (=8980 (N_e)^{1/2})$ the plasma-electron frequency, for the specific inductive capacity of a plasma. The unit cube thus behaves like a tuned shunt circuit $C = 1/4\pi$, $L = m_e/N_e e^2$. This disagrees with Gutton's conclusion. A modified Mossotti theory requires that a cylindrical plasma between plane condenser plates show shunt resonance when $\nu_e = (2)^{1/2}\nu$. With a constant impressed frequency, the positive column of a Hg arc always resonated at two values of arc current (ionization density) and sometimes at three, due possibly, to the non-uniformity of the plasma cross-section. The two main resonance densities were roughly in the ratio 2 to 5 and lay above and below the theoretical value. The variation with frequency was $\nu_e \propto \nu^{1.1}$ cf. $\nu^{1.0}$ theoretically. Above resonance ($\nu_e > (2)^{1/2}\nu$) the variation of K with ν_e as given above was confirmed.

37. Oscillations and travelling striations in an argon discharge tube. T. C. CHOW, *Princeton University*. (Introduced by H. D. SMYTH).—Oscillations of audible frequencies in an argon discharge tube with a long positive column were observed in a pressure range 0.06 to 4.2 mm Hg. The amplitude of the fluctuation of voltage across discharge tube is of the order of magnitude of 10 volts. Only in a certain portion of that pressure range distinct travelling striations were observed. The flash frequency, defined as the number of striations passing across a certain cross-section per second was approximately equal to the frequency heard in a telephone receiver attached to the circuit. It was found to depend on conditions in the circuit, such as current, external resistance, inductance, capacity, and filament current. The space potentials in the tube were also found to fluctuate. Tonks and Langmuir have described a kind of electric sound waves, possible if a certain condition involving electron temperature and concentration and the wave-length of the sound waves is satisfied. This condition was satisfied in our experiment. From their expression for the velocity of electric sound waves and the experimentally determined flash frequencies a set of wave-lengths were calculated most of which are integral or half-integral multiples of the length of the discharge tube.

38. The fall of potential in condensed discharges. J. C. STREET, *University of Virginia*.—The fall of potential in the initial stages of discharges has been studied by utilizing the well-known fact that an electric pulse on a wire when reflected from an open end of the wire has its maximum potential doubled at reflection, provided the length of the pulse is not greater than twice that of the wire. Transient electric pulses produced by the condensed discharge under investigation traveled along two parallel, symmetrical, straight wires to their open ends where they were reflected. The maximum potential across the open ends was measured as a function of the length of wire from the spark gap by two independent methods and was found to de-

crease when the lead wires became a few meters in length. From this curve the rate of potential fall can be obtained directly by electric circuit theory. In the case of static sparks at atmospheric pressure, where the potential was slowly applied, a comparatively slow fall of potential (6% in 2×10^{-8} sec.) was obtained at the beginning, but a very rapid (94% to $1/e$ of value in 2×10^{-8} sec.) fall later. This result is in fair agreement with the results obtained by Rogowski and Klemperer (Archiv. f. Electrot. **24**, 127 (1930)) using a different method. When the pressure in the spark gap was decreased the rate of fall of potential in the initial stages was decreased. The method gives an easy way of studying the fall of potential in various kinds of discharges and is free from certain objections inherent in other methods. Such measurements, aside from giving information concerning the electrical breakdown itself, are desirable for a complete understanding of the operation of Kerr cells and cathode-ray oscillographs.

39. The Kerr electro-optical effect in gases. E. C. STEVENSON AND J. W. BEAMS, *University of Virginia*.—The electric double refraction or Kerr electrooptical effect in CO_2 has been studied as a function of the density and the temperature. The method previously reported (Phys. Rev. **35**, 1440 (1930) and O.S.A. program Oct. 31, 1930) has been refined so that the temperature of the Kerr cell can be set and maintained to 0.05°C . The average deviation of the Kerr constant per molecule was found to be less than 2 percent throughout the density range from 0.08 to 0.18 grams per cubic centimeter when the temperature, electric field, and wave-length band (4700Å to 4300Å) were kept constant. Holding the density, electric field and wave-length fixed the Kerr constant per molecule was observed to increase with decreasing temperature. Our preliminary results show that this increase was approximately 10 percent for a temperature change from 45°C to 20°C which is in rough agreement with what might be expected from theory.

40. On the correlation of radio reception with the position of the Moon in the observer's sky. HARLAN T. STETSON, *Ohio Wesleyan University*.—Observations of the intensities of radio reception at the Perkins Observatory and elsewhere have been utilized for a study of correlation of signal strengths with cosmic phenomena. Papers already published by the writer and by Greenleaf W. Pickard call attention to apparent change in the altitude of the Kennelly-Heaviside layer with the change in solar activity. The same data have now been utilized in an investigation of the possible relation between the intensity of signal strength and the position of the moon with respect to the observer, on the assumption that the moon is at a different electrical potential from that of the earth. The result of the observations indicates that the height of the Kennelly-Heaviside layer is substantially decreased by the presence of the moon above the horizon, and elevated as the moon passes underneath the observer. A plausible explanation follows on the assumption that the moon is negatively charged with respect to the earth. The form of the curve showing correlation between the moon's altitude and the intensity of radio reception suggests an electronic tide which follows a hypothetical equipotential surface in the electrostatic field of the earth-moon system.

41. Optical dispersion of helium. HENRY MARGENAU, *Yale University*.—The numbers of dispersion electrons (f -values) for helium calculated from Hopfield's intensity data by the semi-empirical method outlined in the author's first paper in this bulletin are used to construct an optical dispersion formula. Attention is to be called to the fact that transition matrices, computed from intensities of emission lines, are subject to considerable error. Nevertheless, the dispersion formula thus obtained, in which none of the constants are adjusted in the usual fashion, shows satisfactory agreement with the experimental data on the refractive index.—The theory of molecular forces is extended to a calculation of dissociation potentials and vibrational levels of the molecules Hg-rare gas, observed by Oldenberg.

42. Intensities in the ultraviolet spectrum of mercury. E. D. McALISTER, *Division of Radiation and Organisms, Smithsonian Institution*.—The intensities of the major spectral lines in the region 2000 to 4000Å from a mercury vacuum arc have been measured. A quartz double monochromator and vacuum thermocouple were employed. The effective slit width was 2Å

at 2100A increasing to 12A at 4000A. The 2537 line gave a deflection of 50 mm with a 4A slit width. The intensities of the first four "sharp" triplets are quite close to the theoretical 1-3-5 rule.

43. Application of spinor analysis to the Maxwell and Dirac equations. OTTO LAPORTE AND GEORGE E. UHLENBECK, *University of Michigan*. With the spinor analysis developed by B. Van der Waerden (Gött. Nach. 1929, p. 100), which comprises all representations of the Lorentz group, even those not contained in ordinary tensor calculus, one is able to write all derivations and equations in an *automatically covariant form*. For the convenient translation into spinor language of Maxwell equations, it becomes important to introduce three self dual tensors, one representing the electromagnetic field, one corresponding to the Hertzian vector, and one representing a kind of current potential. These correspond to symmetric spinors of the 2nd rank. Many spinor equations thus become simpler than the corresponding tensorial equations, especially the expression for the stress energy tensor. From the 1st order Dirac equations in spinor form, as given by v.d. Waerden, we derived the 2nd order equations, which agree with the Gordon-Klein form but for a correction term which again contains the self dual field tensor. Further the expression for the current was obtained, and its decomposition into conduction and polarization currents, and finally both Maxwell and Dirac equations were derived from a spinorial variation principle, analogous to the results of Gordon and Darwin.

44. Stereoscopic three dimensional models showing the electron's motion in the Stark effect. R. W. WOOD, *Johns Hopkins University*. By means of multiple exposures with a stereoscopic camera of a rotating wire frame representing the curved quadrangle formed by the intersection of the parabolic coordinates of the Epstein-Schwarzschild treatment of the Stark effect, within which quadrangle the electron is progressively advanced along a properly curved wire, the orbital motion within the anchor-ring is very clearly brought out. The pictures when viewed with a stereoscope show the anchor-ring as a wire cage within which the precessing orbit appears as a white dotted line. The change in orientation and eccentricity of the orbit, with the constancy of the distance of the electric center from the YZ plane (field parallel to X) are easily seen. Photographs are shown illustrating various assignments of the quantum numbers n_1 and n_2 .

45. Improved technique for Raman effect. R. W. WOOD, *Johns Hopkins University*.—For excitation by the mercury arc I find that the highest efficiency is obtained with a Hanovia quartz arc (220 volts) in a metal housing with a narrow rectangular aperture just over the horizontal burner. After much experimenting with filters, I have found that two only are needed, except in special cases. A solution is made of about 1.5 grams of sulphate of quinine in 500 cc of water, acidulated with a little sulphuric acid. This is contained in a glass tube 2 inches in diameter and 12 inches in length which acts as a cylindrical lens, when mounted just above the burner. Photochemical change can be nearly prevented by a thin sheet of Corning noviol glass, transparent to 4046A and opaque to 3650A. The yellowing of the quinine is due almost entirely to the 3650 group of lines. A space of about 1 cm is left between the noviol plate and the aperture in the lamp housing for a stray draught of air from a fan. A concave reflector of polished aluminum is placed over the tube containing the liquid under investigation, which is mounted above and in contact with the filter tube. This arrangement is two or three times as efficient as any arrangement for absorbing 4046 by glass filters. The Zeiss filter, if heavy enough to reduce 4046 to one percent of its value, reduces 4358 to one third of its value. Quinine is perfectly transparent to 4358. For excitation by 4046, the 4358 line is removed by a solution of iodine in carbon tetrachloride. A saturated solution diluted to about 1:15 with CCl_4 will practically suppress 4358, when contained in a tube 1.75 inches in diameter. A 1:30 dilution will suppress all modified lines due to 4358, but the unmodified group comes out fairly strong. A 1:10 or even a 1:5 dilution can be used but with the latter concentration 4046 is considerably weakened. The iodine tube is used with the noviol glass plate below it. The cooling can be increased by mounting a flat plate in such a position as to concentrate the air draught into the gap between the top of the lamp and the noviol glass plate.

46. The masses of O^{17} . HAROLD C. UREY, *Columbia University*.—Blackett (Proc. Roy Soc. 107A, 359) and Harkins and his co-workers (Zeits. f Physik 50, 97; Phys. Rev. 35, 809 (1930)) have given the velocities of the nuclei involved in the transmutation reaction $N^{14} + He^4 \rightarrow O^{17} + H^1$ and these together with the rest masses of N^{14} , He^4 and H^1 of Aston permit a calculation of the rest mass of the O^{17} atom by assuming the conservation of mass and energy. The atomic weight of O^{17} calculated from 8 sets of data available varies from 17.00133 to 17.00502 ($O^{16} = 16$). The absolute value is not certain to this number of significant figures since Aston's values are not so certain but the uncertainty due to the probable errors in the rest masses of N^{14} , He^4 and H^1 is the same for all 8 cases and the differences must be accounted for in some other way. The discrepancies are far greater than the probable errors in Blackett's measurements. The most probable reason for them appears to be that O^{17} atoms with different masses and energies are produced and that the different values are due to different energy levels of the O^{17} nucleus. Then, the gram atomic rest mass of the O^{17} atom in the normal nuclear state is equal to or less than $17.00133 \pm \sim 0.0028$, i.e. the smallest value observed.

47. Regularities in an emission spectrum of CO_2 . H. D. SMYTH AND T. C. CHOW, *Princeton University*.—About a year ago Smyth and Arnott did some work on the excitation of the band spectrum of nitrogen by an electron beam. The method used seemed to offer two advantages for the study of the spectra of polyatomic gases, namely small chance for dissociation and a somewhat simplified spectrum. The method has been applied to CO_2 and spectra obtained showing hardly a trace of CO bands. The spectrum obtained is nearly identical with that measured by Fox, Duffendack and Barker. With their data, supplemented by preliminary measurements of our own plates, we have found a divergent set of 14 vibration terms given by $\nu = 1101.7n + 1.7n^2$ taking the lowest as zero. These combine with three higher doublet terms which are probably part of another vibration set and appear to converge strongly. Referred to the lowest of the first set as zero they are, taking the lower of each pair, 31,953.1, 34,833.0 and 37,455.1 wave-number units. The upper member is 167 wave-numbers higher in each case. Though it is impossible to be certain which is the higher and which the lower of these two sets of levels, either choice gives one set of levels divergent over the range studied.

48. Absorption of iodine lines by atoms from optically dissociated molecules. LOUIS A. TURNER AND E. W. SAMSON, *Princeton University*.—Great improvement over former results (Phys. Rev. 31, 983 (1928)) has been obtained by use of (1) a vacuum spectrograph, (2) argon at 5 cm pressure in the absorption cell, to retard diffusion of atoms to the walls, (3) a source giving fine unreversed lines (pressure 0.003 mm, excitation by short wave oscillator, outside electrodes). The absorption cell contained I_2 at a pressure of 0.03 mm and was illuminated by full light from a 13 ampere carbon arc. The only three lines in the region investigated ($\lambda > 1630$) which result from combination with the $^2P_{1/2}$ ground term, viz. 1830, 1782, and 1642 are all strongly absorbed upon illumination of the absorption cell. Six others from combination with $^2P_{3/2}$ are not absorbed.

49. Hyperfine structure in the copper spectrum. A. G. SHENSTONE, *Princeton University*.—As a result of recent observations of hyperfine structure in the copper spectrum, it can be stated that the nuclear moment is almost certainly $1\frac{1}{2}$. Several lines for which the upper state is d^9s , $s^4D_{3/2}$ have four rather widely spaced components and all other lines from that level are wide, though unresolved by the apparatus available. The term d^9s , $s^4D_{1/2}$ has two components. Lines due to the other two members of this term do not appear in the source at all. This is probably due to the Auger effect; and, if so, it is the first observation of that effect in an atomic spectrum. Back's observation of the resonance lines and Wali-Mohammad's observation of the $d^9s^2\ ^2D_{1/2}$ lines can be reconciled with the nuclear moment $1\frac{1}{2}$. Silver shows no hyperfine structure.

THE PHYSICAL REVIEW

THE THEORY OF COMPLEX SPECTRA II*

By E. U. CONDON AND G. H. SHORTLEY

PALMER PHYSICAL LABORATORY, PRINCETON UNIVERSITY

(Received March 20, 1931)

ABSTRACT

Formulas for the relations between the energies of multiplets arising from the same electron configuration for all two-electron configurations up to ff and several cases of three-electron configurations are worked out following Slater's method; Slater's table of a 's and b 's being extended to cover f electrons. A systematic comparison of the known data with this first order perturbation theory shows poor agreement in many cases and good agreement in many. The theory predicts the observed alternation in the relative positions of singlet and triplet through S, P, D, F , etc. in the pp , pd , and pf triads, and the dd and df pentads. In general the p electron configurations fit very poorly; a uniform trend with atomic number is observed for p^3 and good fits are obtained for $4p3d$ in Ti III, V IV, and Cr V. For d electrons the theory fits very well in the first long period of the periodic table, and fairly well in the second. The 1S of d^2 and the 3D of d^3 s are predicted much higher than the levels assigned to those multiplets when such an assignment is made. d^3 fits well except for 2P . An energy level table of La II is given as recently analysed by Meggers and Russell. Here we have complete $5d4f$ and $4f^3$ configurations which fit the theory very well, these calculations having assisted in the assignment of some of the singlets and resulted in a rearrangement of singlet lines.

§1. INTRODUCTION

THIS paper is a sequel to one¹ published last fall in which the first steps were taken toward working out the second approximation for atomic spectra with Russell-Saunders coupling. Before going on with that work it was thought desirable to make a careful study of the application of the first approximation formulas, given by Slater's method,² to all of the known data. That is the subject of this paper.

It will be recalled that the first-order calculation gives formulas for the energy of each of the multiplets arising from a given electron configuration in terms of certain integrals taken over the radial factor of the wave function for an electron in the central force field that lies at the basis of the calculations. These integrals represent the perturbation energy due to the electro-

* This paper was presented at the New York Meeting of the American Physical Society, February 27, 1931.

¹ Condon, Phys. Rev. 36, 1121 (1930).

² Slater, Phys. Rev. 34, 1293 (1929).

static repulsion of the electrons. It is inconvenient to work out these integrals for they involve the unknown wave functions of the screened average force field in which the electrons move. Instead these integrals are treated as adjustable (except for restrictions such as that certain of them are essentially positive, etc.) in order to see how well the data can be represented. If a good fit is obtained that is, therefore, only a partial confirmation of the theory, for the question still remains open whether the relative magnitudes assumed for the several integrals are really compatible with their definition as integrals.

Since Meggers and Russell³ have recently obtained for the first time, in La II, complete sets of multiplets involving the two-electron configurations pf , df , f^2 we have thought it worthwhile to extend Slater's tables of a 's and b 's to provide the necessary coefficients for applying the method to configurations involving f electrons. These results are presented in §2. In §3 and §4 the explicit formulas are given for the first-order energies in a number of important configurations and in §5, §6, and §7 comparison of the formulas with the data is made.

§2. SLATER'S COEFFICIENTS FOR f ELECTRON CONFIGURATIONS

In Slater's paper² there are a few details connected with normalization that need to be straightened out. Slater, in his manuscript, had normalized his wave functions in an unusual way: namely, so that the normalizing integral over the spherical harmonic factor was set equal to 4π instead of 1. This requires the normalizing integral over the radial coordinate to be set equal to $1/4\pi$. When his paper went through the Physical Review office one of us (E.U.C.) thought that a mistake had been made in the normalizing factor and inserted a $(2\pi)^{-1}$ to normalize the $\Phi(m_l/\phi)$ on page 1308 in the usual way. As Slater was in Europe at the time he did not have an opportunity to set the matter straight again. Therefore this factor should be removed from the $\Phi(m_l/\phi)$ on page 1308 and then it should be borne in mind, what Slater does not mention, that the radial wave-function is to be normalized to $1/4\pi$ instead of 1. The usual normalization of each factor to 1, is the one we prefer. To have this one needs to leave the Φ factor as printed on page 1308, to insert 2^{-1} on the right side of the equation defining $\Theta(lm_l/\theta)$ on that page, to remove the factor 4π in the equation for $I(nl)$ on page 1310 and the factor $(4\pi)^2$ in the equations for $F^k(nl; n'l')$ and $G^k(nl; n'l')$ on page 1311.

We have also found it convenient to treat the a 's and b 's of page 1311 as integers by associating the denominator of the a 's and b 's as they occur in the tables of page 1312 with the corresponding F . Therefore we write

$$F_k(nl; n'l') = \frac{1}{D_k} F^k(nl; n'l')$$

where F^k is Slater's F and D_k is the denominator of the fractional value for $a^k(l, m_l; l' m_l')$ as given on page 1312. The corresponding definition of G_k is also made.

³ See §7 of this paper.

Having detected an error in Slater's table of b 's by reaching an inconsistency in deriving the energy levels for the pd configuration it was thought worthwhile to check these tables by a complete recalculation using Gaunt's formulas⁴ for the integrals. These formulas were also used to extend the tables to the pairs, sf , pf , df , ff . This straightforward but laborious computation makes us now feel confident that there are no errors in Slater's table of page 1312 except the one originally detected. The value

$$b^3(1, \pm 1; 2, \mp 2) = 45/245$$

is correct, instead of $9/245$ as printed.

The extension to f electron values is covered in Tables I and II.

Note: In cases with two \pm signs, the two can be combined in any of the four possible ways.

§3. THE ENERGY LEVELS IN TWO-ELECTRON CONFIGURATIONS

Slater has treated in detail the method whereby the energy levels of the several multiplets are to be found in terms of the F and G perturbation integrals and has given some examples. He has shown that the electrons in

⁴ Gaunt, Phil. Trans. Roy. Soc. A228, 151 (1929).

closed shells are without direct effect on the perturbation theory, although of course, they have the indirect effect of determining the nature of the best

Note: In cases where there are two \pm signs, the two upper or the two lower signs must be taken together.

central field on which to base the approximation. Therefore, we do not need to give the details of the calculations but merely summarize the results.

Slater's F^k integrals are necessarily positive and decreasing with increas-

ing k , from their definition. Therefore, since the denominator D in the definition of our F_k increases rapidly, F_k necessarily decreases very rapidly with increasing k . Since the G 's are not essentially positive by definition, no definite statement can be made concerning their relative magnitudes; however, in every instance we have found, the G_k 's have been positive and rapidly decreasing with k . Although not consistent with its definition as an integral, it is convenient to measure F_0 , which occurs in the formula for each multiplet, from an arbitrary low level of the spectrum. (Slater's theory provides an integral I , dependent only on the configuration, to locate the height of the whole multiplet.)

If one electron is in an s state the result is simply a singlet and triplet whose L is the l of the other electron outside closed shells, as Slater shows on page 1315, duplicating by this method a result of Heisenberg.

For pp , non-equivalent p electrons, Slater gives the triplet intervals. The complete formulas are, if 3P is written for "relative energy of the center of gravity of the 3P terms,"

$$\begin{aligned}
 {}^1S &= F_0 + 10F_2 + G_0 + 10G_2 \\
 {}^3S &= F_0 + 10F_2 - G_0 - 10G_2 \\
 {}^1P &= F_0 - 5F_2 - G_0 + 5G_2 \\
 {}^3P &= F_0 - 5F_2 + G_0 - 5G_2 \\
 {}^1D &= F_0 + F_2 + G_0 + G_2 \\
 {}^3D &= F_0 + F_2 - G_0 - G_2
 \end{aligned}
 \tag{pp}$$

We note that the arithmetic mean of the corresponding singlet and triplet energies is independent of the G 's while corresponding singlet-triplet intervals are independent of F 's. Also since $G_2 \ll G_0$ usually we have ${}^1S > {}^3S$ and ${}^1P < {}^3P$ and ${}^1D > {}^3D$; an alternation which is quite a general prediction of the theory.

For p^2 , equivalent p electrons, the 3S , 1P and 3D are ruled out by the exclusion principle and the formulas for what is left are the same as those for the arithmetic means of singlet and triplet in pp , namely

$$\begin{aligned}
 {}^1S &= F_0 + 10F_2 \\
 {}^3P &= F_0 - 5F_2 \\
 {}^1D &= F_0 + F_2.
 \end{aligned}
 \tag{p^2}$$

The formulas for dd and d^2 , also ff and f^2 , show similar relationships. For dd we have

$$\begin{aligned}
 {}^1S, {}^3S &= F_0 + 14F_2 + 126F_4 \pm (G_0 + 14G_2 + 126G_4) \\
 {}^1P, {}^3P &= F_0 + 7F_2 - 84F_4 \mp (G_0 + 7G_2 - 84G_4) \\
 {}^1D, {}^3D &= F_0 - 3F_2 + 36F_4 \pm (G_0 - 3G_2 + 36G_4) \\
 {}^1F, {}^3F &= F_0 - 8F_2 - 9F_4 \mp (G_0 - 8G_2 - 9G_4) \\
 {}^1G, {}^3G &= F_0 + 4F_2 + F_4 \pm (G_0 + 4G_2 + G_4)
 \end{aligned}
 \tag{dd}$$

where the upper sign is for the singlet and the lower for the triplet. For d^2 the multiplets are $^1S, ^3P, ^1D, ^3F, ^1G$ and their energies are given by the same formulas upon omitting the terms involving G integrals.

For pd the formulas are

$$\begin{aligned} ^1P, ^3P &= F_0 + 7F_2 \pm (G_1 + 63G_3) \\ ^1D, ^3D &= F_0 - 7F_2 \mp (3G_1 - 21G_3) \\ ^1F, ^3F &= F_0 + 2F_2 \pm (6G_1 + 3G_3). \end{aligned} \quad (pd)$$

This shows the same alternation in sign of the leading G integral but differs from the preceding ones in that the F and G parts are not similar.

The formulas for pf are

$$\begin{aligned} ^1D, ^3D &= F_0 + 12F_2 \pm (3G_2 + 36G_4) \\ ^1F, ^3F &= F_0 - 15F_2 \mp (15G_2 - 9G_4) \\ ^1G, ^3G &= F_0 + 5F_2 \pm (45G_2 + G_4). \end{aligned} \quad (pf)$$

The formulas for df are

$$\begin{aligned} ^1P, ^3P &= F_0 + 24F_2 + 66F_4 \pm (G_1 + 24G_3 + 330G_5) \\ ^1D, ^3D &= F_0 + 6F_2 - 99F_4 \mp (3G_1 + 42G_3 - 165G_5) \\ ^1F, ^3F &= F_0 - 11F_2 + 66F_4 \pm (6G_1 + 19G_3 + 55G_5) \\ ^1G, ^3G &= F_0 - 15F_2 - 22F_4 \mp (10G_1 - 35G_3 - 11G_5) \\ ^1H, ^3H &= F_0 + 10F_2 + 3F_4 \pm (15G_1 + 10G_3 + G_5). \end{aligned} \quad (df)$$

Finally the formulas for two non-equivalent f electrons are

$$\begin{aligned} ^1S, ^3S &= F_0 + 60F_2 + 198F_4 + 1716F_6 \pm (G_0 + 60G_2 + 198G_4 + 1716G_6) \\ ^1P, ^3P &= F_0 + 45F_2 + 33F_4 - 1287F_6 \mp (G_0 + 45G_2 + 33G_4 - 1287G_6) \\ ^1D, ^3D &= F_0 + 19F_2 - 99F_4 + 715F_6 \pm (G_0 + 19G_2 - 99G_4 + 715G_6) \\ ^1F, ^3F &= F_0 - 10F_2 - 33F_4 - 286F_6 \mp (G_0 - 10G_2 - 33G_4 - 286G_6) \\ ^1G, ^3G &= F_0 - 30F_2 + 97F_4 + 78F_6 \pm (G_0 - 30G_2 + 97G_4 + 78G_6) \\ ^1H, ^3H &= F_0 - 25F_2 - 51F_4 - 13F_6 \mp (G_0 - 25G_2 - 51G_4 - 13G_6) \\ ^1I, ^3I &= F_0 + 25F_2 + 9F_4 + F_6 \pm (G_0 + 25G_2 + 9G_4 + G_6), \end{aligned} \quad (ff)$$

from which the values for f^2 can be obtained by ignoring the part involving G integrals and remembering that the allowed terms are $^1S, ^3P, ^1D, ^3F, ^1G, ^3H$ and 1I .

The most striking thing about these results perhaps is the uniform way in which an alternation of the relative height of singlet and triplet is predicted, since in most cases the G of lowest index will be enough larger than the others to dominate the whole expression in the G 's. Russell and Meggers⁵ called attention to this alternation in 1927 and "commended it to the attention of theoretical investigators." Its explanation by the quantum mechanics must be counted as an important success for the theory.

⁵ Russell and Meggers, *Sci. Papers Bur. Stand.* **22**, 364 (1927).

§4. THREE-ELECTRON CONFIGURATIONS

It would be a waste of time to work out all possible three-electron configurations at present, therefore we confine ourselves to cases for which we have been able to find experimental data with which to check the results. The addition of an s electron to p^2 , d^2 or pd gives three important cases.

According to the vector coupling viewpoint the addition of an s electron to p^2 gives the results $^1S \rightarrow ^2S$, $^3P \rightarrow ^2P$ and 4P , and $^1D \rightarrow ^2D$. In the formulas for p^2s the F integrals are of the type $F(np^2)$ while there now appears a G integral to represent the action of the s electron, which is $G_1(np, n's)$:

$$\begin{aligned} ^2S &= F_0 + 10F_2 - G_1 \\ ^2P &= F_0 - 5F_2 + G_1 \\ ^4P &= F_0 - 5F_2 - 2G_1 \\ ^2D &= F_0 + F_2 - G_1 \end{aligned} \quad (p^2s)$$

where $F_0 = 2F_0(np, n's) + F_0(np^2)$. Thus $3G_1$ is the $^2P - ^4P$ interval and the quantities 2S , $(^2P + ^4P)/3$ (which is the center of gravity of this combination), and 2D have the same intervals as 1S , 3P and 1D in p^2 .

Similar results hold for d^2s . Here too the singlets of d^2 become doublets and the triplets split into doublets and quartets:

$$\begin{aligned} ^2S &= F_0 + 14F_2 + 126F_4 - G_2 \\ ^2P &= F_0 + 7F_2 - 84F_4 + G_2 \\ ^4P &= F_0 + 7F_2 - 84F_4 - 2G_2 \\ ^2D &= F_0 - 3F_2 + 36F_4 - G_2 \\ ^2F &= F_0 - 8F_2 - 9F_4 + G_2 \\ ^4F &= F_0 - 8F_2 - 9F_4 - 2G_2 \\ ^2G &= F_0 + 4F_2 + F_4 - G_2 \end{aligned} \quad (d^2s)$$

in which

$$\begin{aligned} F_0 &= F_0(nd^2) + 2F_0(nd, n's) \\ G_2 &= G_2(nd, n's). \end{aligned}$$

The relation to d^2 is evident on comparison. Further we see that the doublet-quartet interval is the same for the P and the F multiplets, being equal to $3G_2$.

In the case of pd s we encounter the first instance in which it is impossible to get complete formulas by Slater's diagonal sum method since this configuration gives two different 2P , 2D and 2F . This comes about because pd gives $^1,^3P, D, F$ and the added s electron makes the singlets into $^2P, D, F$, and splits each triplet into $^2,^4P, D, F$. In such a case the method gives simply the arithmetic mean of the two doublets of similar L value:

$$\begin{aligned} (^2P) &= F_0 + 7F_2 \\ ^4P &= F_0 + 7F_2 - (G_1^{pd} + 63G_3^{pd}) - G_1^{sp} - G_2^{sd} \end{aligned}$$

$$({}^2D) = F_0 - 7F_2 \quad (spd)$$

$${}^4D = F_0 - 7F_2 + (3G_1{}^{pd} - 21G_3{}^{pd}) - G_1{}^{sp} - G_2{}^{sd}$$

$$({}^2F) = F_0 + 2F_2$$

$${}^4F = F_0 + 2F_2 - (6G_1{}^{pd} + 3G_3{}^{pd}) - G_1{}^{sp} - G_2{}^{sd}$$

in which $({}^2P)$ indicates the mean of the two 2P 's and

$$F_0 = F_0(ns, n'p) + F_0(ns, n''d) + F_0(n'p, n''d)$$

$$F_2 = F_2(n'p, n''d)$$

$$G_1{}^{sp} = G_1(ns, n'p) \quad G_2{}^{sd} = G_2(ns, n''d)$$

$$G_1{}^{pd} = G_1(n'p, n''d) \quad G_3{}^{pd} = G_3(n'p, n''d).$$

Slater has worked out p^3 , the result being that the energies increase in the order ${}^4S, {}^2D, {}^2P$ and the interval $({}^2P - {}^2D)$ is to $({}^2D - {}^4S)$ as 2:3.

For the configuration d^3 we find the energy levels to be,

$${}^2P = 3F_0 - 6F_2 - 12F_4$$

$${}^4P = 3F_0 - 147F_4$$

$$({}^2D) = 3F_0 + 5F_2 + 3F_4$$

$${}^2F = 3F_0 + 9F_2 - 87F_4 \quad (d^3)$$

$${}^4F = 3F_0 - 15F_2 - 72F_4$$

$${}^2G = 3F_0 - 11F_2 + 13F_4$$

$${}^2H = 3F_0 - 6F_2 - 12F_4$$

where $({}^2D)$ indicates the mean of the two 2D 's.

§5. COMPARISON WITH EXPERIMENTAL DATA, CONFIGURATIONS WITH p ELECTRONS

The simplest case for comparison with the data is p^2 , where the theory predicts that the multiplets come in the order ${}^3P, {}^1D, {}^1S$, as Slater noted. From

⁷ McLennan, McLay, and Crawford, Proc. Roy. Soc. A129, 584 (1930).

§3 we see that the ratio $(^1S-^1D)/(^1D-^3P) = 3/2$ according to theory. Slater gives the normal configuration of Si I as an example, and we find several more, as given in Table III.

From this it would appear that some influence depresses the 1S in general, and that the doubtful 1S given by Fowler and Selwyn for N II is probably wrong. Pb I and Bi II are so far from Russell-Saunders coupling that a good fit would hardly be expected.

The configurations p^3 and p^4 may be discussed here because they are similar to p^2 . For p^3 the theory says that the ratio $(^2P-^2D)/(^2D-^4S)$ equals $2/3$. Table IV gives the known instances.

TABLE IV. p^3 configurations

⁵ Rao, Proc. Roy. Soc. A125, 240 (1929).

⁶ Charola, Phys. Zeits. **31**, 458 (1930).

* No intercombinations are found between the quartet and doublet systems, and the relative term values are probably quite inaccurate.

The continued increase in this ratio as the total quantum number increases is to be noted particularly. The closeness of the ratio for N I and O II would indicate that the ratio for the unreliable F III should perhaps be closer to 0.51.

For p^4 the theory gives the same result as for p^2 . Table V gives the examples.

TABLE V. p^4 configurations

Element	Config.	$(^1S-^1D)/(^1D-^3P)$	Reference
Theory		1.50	
O I	$2p^4$	1.14	1
Se I	$4p^4$	1.71	2
Te I	$5p^4$	1.71	2

² McLennan and Crawford, Nature **124**, 874 (1929).

The new data of Frerichs show that O I is not in as good agreement with the theory as indicated in one of Slater's examples, his ratio being 1.55. Slater took his data from a remarkable energy-level diagram by McLennan, McLeod and Ruedy, Phil. Mag. **6**, 565 (1928), in which the wave number difference for $^1S-^1D$ is given as 39,500, although the main point of the paper is the identification of this transition with the auroral green line!

We have found two complete p^2s configurations, which should be similar to p^2 as indicated in §4. The ratio $(^2S-^2D)/(^2D-P)$, where $P = (2^4P + ^2P)/3$, which should be 1.50, is 0.58 in As I⁶ and 3.58 in Sb III.⁷

pp , pd , and pf give similar triads, in which the means of singlet and triplet should lie in the corresponding orders: $P D S$, $D F P$, $F G D$, lowest energy first, with the ratios $(S-D)/(D-P) = 9/6$; $(P-F)/(F-D) = 5/9$; $(D-G)/(G-F) = 7/20$, respectively.

We have found the pp complete only for C I⁸, N II⁹, and O III¹⁰, but since these all occur with the means in the wrong order we do not give the details.

This failure of C I, N II, and O III to agree with the theory appears also in the known pd configurations, the mean of the F 's being low in every case.^{8,9,10} Yt II,¹¹ La II,¹² and Ge I¹³ $4p5d$, also have the pd means in the wrong order. The means of Ge I $4p4d$, and Zr III $5p4d$ ¹⁴ come in the right order with the ratio $(P-F)/(F-D)$, which is theoretically 0.555, having the value 0.28 and 3.58, respectively. More interesting is the behavior of $4p3d$ in the isoelectronic sequence Ca I¹⁵, Sc II¹⁶, Ti III¹⁷, V IV¹⁸ and Cr V¹⁸. The first two come in the wrong order, giving $(P-F)/(F-D) = -0.15$ and -0.06 , respectively, but the last three agree satisfactorily, the ratios being $+0.45$, 0.49 , and 0.548 . Since $P-F = 10F_2(4p3d)$ and $F-D = 18F_2(4p3d)$, we can get two values of F_2 for each of these last three ions. Taking the average of these two, we have $F_2(4p3d)$ for Ti III, 427; V IV, 569; Cr V, 707 cm⁻¹. These are perfectly linear, as shown by the plot in Fig. 2, together with corresponding F 's for d^2 . We have a further check on the three singlet-triplet separations in terms of the two parameters G_1 and G_3 , which it is fruitless to apply to the cases in which the means fitted poorly, but interesting in the other three cases.

Ti III, V IV and Cr V all alternate properly, as pointed out in §3. Table VI shows the results of fitting the data to the formulas for the separations by least squares.

It is seen that, in the opposite order from the means, Ti III fits best and V IV next. The G 's are again approximately linear functions of the ionic charge. G^3 becomes greater than G^1 , which is allowed.

For pf in La II¹² the ratio $(D-G)/(G-F)$ is 1.05 instead of the theoretical 0.35.

There is one more instance of a configuration with p electrons in which one gets a determined ratio, namely pds . In this case (see §4) nothing can be pre-

Fig. 1. The configuration d^2 .

dicted concerning the quartets, 4P , 4D , 4F ; but the theory predicts a constant ratio between the means of the two 2P 's, the two 2D 's, and the two 2F 's which occur. If we designate these means by $P D F$, we have the order $D F P$ as in pd , with the same ratio $(P - F)/(F - D) = 5/9$. In Sc I^{16} these means have the wrong order, $D P F$; and in Yt I^{11} and Zr II^{19} the above ratio has the values 1.86 and 2.08, respectively, much too large.

In general the predictions of the theory have been seen to fit very poorly for configurations with p electrons, a uniform trend having been observed in p^3 , and good fits having been obtained for pd in the higher members of the CaI isoelectronic sequence.

§6. COMPARISON WITH EXPERIMENTAL DATA, d ELECTRONS

For d^2 the theory predicts (see §3) the energies of the five multiplets 1S , 3P , 1D , 3F , 1G in terms of three integrals, the 1S being predicted extremely high. In no instance, where a 1S is reported, is it anywhere nearly high enough, and so we have investigated the other four levels, making a least-squares fit of the separations of 3P , 1D , 1G from the low 3F , which three separations the theory gives in terms of the two parameters F_2 and F_4 .

In the isoelectronic sequence Sc II¹⁶, Ti III¹⁷, V IV¹⁸, and Cr V¹⁸, it was found possible to make the excellent fits plotted in Fig. 1 for $3d^2$. The predicted height of 1S in Sc II is shown, the other 1S 's being correspondingly high. Russell and Meggers reported a 1S between the 1D and 3P of Sc II, but later, in a note to their Yt paper¹¹ they ascribe this not to $3d^2$ but to $4s^2$. The $3d^2$ 1S as predicted would be in the midst of the configuration $4p3d$ with which they get their strong combinations, and so difficult to find. In Ti III, Russell

Fig. 2. Values of some integrals for the Ca I isoelectronic sequence.

and Lang report a 1S just under the 1G , but with a question mark. This undoubtedly does not belong to $3d^2$. In V IV and Cr V, White reports a 1S just above the 1G , but since these spectra were analyzed practically by extrapolation from Sc II and Ti III these levels also are probably not part of $3d^2$. The values of F^2 and F^4 as determined in this way show a striking linearity as plotted in Fig. 2. Slater's $F^2(3d^2)$ and $F^4(3d^2)$ are plotted in place of our F_2 and F_4 in order to show their relative magnitudes. Table VII gives these values ($D_2 = 49$, $D_4 = 441$):

TABLE VII.

	Sc II	Ti III	V IV	Cr V
$F^2(3d^2)$	36180	52840	69300	84330
$F^4(3d^2)$	22740	32520	47020	60880

These values are in good accord with Slater's rough estimate that F^4 is approximately half of F^2 .

Russell²⁰ has completed the $3d^2$ also in Ti I, the levels being shown in Fig. 1, together with the theoretical levels with $F_2(3d^2)=899.5$ and $F_4(3d^2)=66.15$. This is again an excellent fit except for 1S , as was pointed out by Slater. Meggers and Russell¹¹ have found all but the 1S in the $4d^2$ of Yt II, but here, see Fig. 1, not a very good fit is obtained of the rest of the levels, although the perturbations are not great. This plot is made with $F_2(4d^2)=625.2$ and $F_4(4d^2)=55.1$.

In contrast to these reasonable fits we have the Zr III $4d^2$ of Kiess and Lang,¹⁴ in which not only is the 1S much too low, but the *two* intervals between *no three* of the other levels may be fitted with possible values of the *two* parameters F_2 and F_4 ; either it is necessary to assume that one of the integrals is

Fig. 3. The configurations d^2s , dd , and d^3 . (Scale in thousands of wave numbers.)

negative or that F^4 is many times greater than F^2 . In the $5d^2$ of La II (see §7 for energy levels) we have a somewhat different situation. No 1S is reported, and of the four remaining levels there are three, and just three, which may be fitted with possible values of the parameters. These are 3P , 3F , 1G with $F_2=495$ and $F_4=35.4$. (The two parameters fit the two intervals exactly, of course.) This leaves the 1D almost 5000 cm^{-1} too high.

In d^2s we have exactly the same situation as in d^2 when we take the weighted means of 2P and 4P , and 2F and 4F , as analogous to 3P and 3F , respectively. Here again we can get good least squares fits of the F , 2D , P , 2G levels of $3d^2 4s$ of Ti II²¹ and $4d^2 5s$ of Yt I¹¹. These are plotted in Fig. 3. In Ti II a 2S is observed at about the same relative position as the 1S of Ti I, while calculated it should be much higher. Again in Yt I no 2S is observed. The values of the parameters are, for Ti II, $F_2=1014.7$, $F_4=59.2$ and for Yt I, $F_2=433.6$, $F_4=32.1$. We have $F^2=1.91F^4$ and $1.51F^4$ respectively in these

²⁰ Russell, *Astrophys. J.* **66**, 347 (1927).

²¹ Russell, *Astrophys. J.* **66**, 283 (1927).

two cases. In Zr II¹⁹, $4d^25s$, we have the first instance in which a 2S is found reasonably high. In this configuration, although we cannot get a very good fit, in contrast to the $4d^2$ of Zr III almost any three of the five levels will give reasonable values of the parameters, and we can get an approximate fit of all five by taking $F_2=905$, $F_4=55$ as indicated in Fig. 3 ($F_0-G_2=8000\text{ cm}^{-1}$ measured from Kiess and Kiess' low $^4F_{1/2}$, see §3). The fit would not be much improved by omitting any one of the multiplets from consideration so here we have probably a generally large second order perturbation. We have a further check in this configuration on the doublet-quartet separations, which should be the same for P and F terms, being equal to $3G_2$. We have for Ti II, $^2P-^4P=6620$, $^2F-^4F=4558$; and for Yt I, $^2P-^4P=3964$, $^2F-^4F=4357$. These show reasonable agreements, but Zr II is badly off, for here we have $^2P-^4P=-1877$, and $^2F-^4F=+5404$.

The dd configuration gives us a pentad, $^1,^3SPDFG$, with three F 's to fit the means and three G 's to fit the separations. The first and best instance of this configuration is the Sc II $3d4d$ of Russell and Meggers.¹⁶ Here we can fit the $PDFG$ means as shown in Fig. 3 using $F_2(3d4d)=107$, $F_4(3d4d)=6$ ($F_0=62330$). The S mean is observed some 1600 cm^{-1} too low, which could be caused by the 1S being about 3000 cm^{-1} too low. When we consider the separations (*singlet-triplet*) we find that we can obtain a fairly good fit of the $P D F G$ separations, with the observed S separation much too small, as shown by Table VIII.

TABLE VIII. ScII $3d\ 4d$ separations

	Obs.	Calc.
$^1S-^3S$	3872	6368
$^1P-^3P$	-4275	-4385
$^1D-^3D$	4384	4492
$^1F-^3F$	-3935	-3810
$^1G-^3G$	4864	4760

These are calculated using $G_0=2230$, $G_2=36.7$ and $G_4=3.5$, making $G^0(3d4d)=2230$, $G^2(3d4d)=1800$, $G^4(3d4d)=1540$. (The G^0 , unlike F^0 , carries here its full meaning as an integral.) The S separation is about 2500 cm^{-1} too small, which would indicate a 1S about that much too low. This is in good agreement with the predictions of the calculation of the means and indicates that this 1S is perhaps incorrect, the correct one being some $2500-3000\text{ cm}^{-1}$ higher. An error in the assignment of a singlet term, especially a 1S , is quite likely to occur, since the identification of such terms is very difficult. An interesting example of this sort will be discussed in §7.

The other instances of the dd configuration are not as good. Of the $4d5d$ of Yt II¹¹, no *three* of the means will fit with reasonable values of F_2 and F_4 , the D and the S in particular being very low. Since the S separation was also large and negative where the theory, by comparison with the other separations, says it should be positive, Professor Russell assigned the 61367 1S to $4d5d$, discovering that the 59615 level he had assigned was not real; but this still is perhaps not the right level, since we have now a separation of only

+167 whereas the S separation should probably be a great deal larger. The other levels do not fit well enough to say anything definite. In the $4d5d$ of Zr III¹⁴, Kiess and Lang do not find a 1G , but of the means of the $SPDF$ singlets and triplets, no three will fit with positive values of F_2 . Of the La II¹² $5d6d$ means the $PDFG$ will fit very well, with $F_2=115$, $F_4=4$ ($F_0=54430$), with the S much too low, as in the case of Sc II, but this fit is not borne out by the separations, which are entirely skew, the P separation even being -2176 when it should probably be positive.

The other d configuration which we have found almost complete is d^3 . Here we get 2PFGH , 4PF , and two 2D 's. Russell²¹ in Ti II $3d^3$, has found all but one 2D , and Kiess and Kiess have found all the multiplets of the $4d^3$ of Zr II.¹⁹ The theory predicts, surprisingly, that 2H and 2P should have the same energy. Of these, in our two instances, the 2H fits well, but the 2P is considerably separated from it. Of the two 2D 's only the mean is given by the theory, but in Zr II this comes far from fitting well. However, in both cases we can fit the other five levels, 2FGH and 4PF surprisingly well with our three

¹ The 1D_2 and 3F_2 of the $5d6d$ may possibly be interchanged. ($^3F_4=55321$, $^3F_3=54840$, $^3F_2=53885$.)

parameters, as indicated in Fig. 3. For Ti II we have $F_2(3d^2) = 845$, $F_4(3d^2) = 54$ ($3F_0 = 17750$); corresponding to $F^2 = 1.74F^4$. The mean of the 2D 's is predicted at 22140, which would throw the 2D not found at about 31000, very high indeed. For Zr II we have $F_2 = 683$, $F_4 = 36$ ($3F_0 = 16000$); corresponding to $F^2 = 2.11F^4$. The mean of the 2D 's is predicted at 19523, observed at 14214 (multiplets at 13869 and 14559).

We have seen that the theory works much better for d electrons than for p . It has been good in every instance in the first long period of the periodic table, and better in the second than the third.

§7. LA II AND THE f ELECTRON CONFIGURATIONS

W. F. Meggers and H. N. Russell have recently completed the analysis of La II, obtaining the first complete pf , df and f^2 configurations. Through their kindness in allowing us to use these data we have been able to obtain two beautiful fits of the df and f^2 configurations, and to prove the actual service of this theory to spectroscopists by helping to straighten out the analysis at two or three points.

Since these data are unpublished as yet, Meggers and Russell have kindly allowed us to publish a preliminary energy table, the levels being measured up from the low $5d^2\ ^3F_2$. We give only the centers of gravity of the multiplets in Table IX.

Of these the p^2 , pd , pf , d^2 , and dd have already been discussed, and were not found to agree particularly well with the theory. The new $5d4f$ and $4f^2$ remain to be considered, which will be done in some detail.

Fig. 4. Illustrating the method of locating poorly fitting multiplets and a method of estimating the values of the integrals.

As we received the data from Professor Russell, the $df\ ^1H$ was placed at 18169, rather close to 3H , instead of having the extremely great separation of about 10,000 units and being the highest level in the configuration. An attempt to fit the means by the method illustrated in Fig. 4 was made. This is incidentally the method used on many of the previous configurations. The formulas to which we are fitting these means are as follows:

$P = 25214 = F_0 + 24F_2 + 66F_4$	Calc. 25216
$D = 20534 = F_0 + 6F_2 - 99F_4$	20506
$F = 21467 = F_0 - 11F_2 + 66F_4$	21191
$G = 19038 = F_0 - 15F_2 - 22F_4$	19323
$H = 18502 = F_0 + 10F_2 + 3F_4$	22598

Since F_0 occurs uniformly, we plot in Fig. 4 the value of these means against the coefficients of F_2 . Then the line determining F_2 must be so drawn that its separations from these points are as closely as possible proportional to the coefficients of F_4 and in the direction shown by the arrows. It is seen at once that we can thus fit G, F, D , and P quite well, but that H is far too low. From the slope of the line we get $F_2 = 115$, from the average separations $F_4 = 16$ (and from the height at zero abscissa, $F_0 = 21400$). From the level diagram in Fig. 5 we see that changing none of these values will tend to improve the general fit, so that these are approximately as good as can be found. A more exact determination of these values, such as a least squares fit, gives an accuracy which is meaningless. The calculated means are shown in the above table. From the calculated H mean it would seem that the 1H should be about 8200 units higher.

When we consider the separations we have the following formulas to determine the G 's

	Calc.
$^1P - ^3P = -4421 = -2(G_1 + 24G_3 + 330G_5)$	- 4638
$^1D - ^3D = 3279 = 2(3G_1 + 42G_3 - 165G_5)$	3397
$^1F - ^3F = -6112 = -2(6G_1 + 19G_3 + 55G_5)$	- 5837
$^1G - ^3G = 4879 = 2(10G_1 - 35G_3 - 11G_5)$	4987
$^1H - ^3H = +666 = -2(15G_1 + 10G_3 + G_5)$	- 11330

It is inconvenient here to use such a method of fitting as described above, but such a diagram will readily show that the H separation relative to the others should be very large and negative. A least squares fit of the $P D F G$ separations gives $G_1 = 357.6$, $G_3 = 29.7$, $G_5 = 3.78$, and the calculated separations show in the table, a good fit. These values correspond to $G^1(5d4f) = 12,500$, $G^3 = 9350$, $G^5 = 5750$. This calculation shows that the 1H should be about 12,000 units higher.

In the data as received from Professor Russell, the $4f^2^1I$ was placed at 52,052 instead of the value noted in the table, and two possibilities given for 1S and 1D , as noted below. The f^2 consists of seven levels to be fitted with four parameters as follows:

$$\begin{aligned}
 ^1S &= \begin{Bmatrix} 69505 \\ 66592 \end{Bmatrix} = F_0 + 60F_2 + 198F_4 + 1716F_6 \\
 ^3P &= 63963 = F_0 + 45F_2 + 33F_4 - 1287F_6 \\
 ^1D &= \begin{Bmatrix} 59900 \\ 62026 \end{Bmatrix} = F_0 + 19F_2 - 99F_4 + 715F_6 \\
 ^3F &= 57939 = F_0 - 10F_2 - 33F_4 - 286F_6 \\
 ^1G &= 59528 = F_0 - 30F_2 + 97F_4 + 78F_6 \\
 ^3H &= 56080 = F_0 - 25F_2 - 51F_4 - 13F_6 \\
 ^1I &= 52052 = F_0 + 25F_2 + 9F_4 + F_6.
 \end{aligned}$$

Now from a diagram such as Fig. 4, it may be seen that F_6 will be extremely small, for a good fit of the high 1S , the low 1D , the 3P , 3F , 1G , and 3H may be obtained using just the parameters $F_2 = 94.0$, $F_4 = 22.1$. The 1I is definitely observed 10000 units too low. The correct 1S and 1D are at once determined, since the other possibilities will not fit under any circumstances.

Thus we have seen that the theory predicted the 1H of df and the 1I of f^2 both about 10,000 units higher, and when this was called to the attention of Professor Russell, he discovered that he could make this shift by rearranging his lines as shown in Fig. 6. Upon doing this he immediately was able to check each of these levels by faint cross-combination lines, thus definitely proving

Fig. 5. The configurations df and f^2 of La II. (Scale in thousands of wave numbers.)

Fig. 6. Russell's rearrangement of the La II singlets according to the predictions of the theory. (Scale in thousands of wave numbers.)

the correctness of this arrangement. Both of these singlets were raised 10,356 units to the places shown in Table IX. In Fig. 5, the old levels are shown broken and the corrected levels by full lines. The df diagram is merely the old diagram determined from the means of $P D F G$, with the H mean put in its proper place. The 1H – 3H separation becomes now 9690 against the calculated 11330 from the other four separations. The 1H was raised just about the average of the predictions from the means and from the separations. It is supposed that the $3d4d\ ^1S$ of Sc II would behave in about this fashion. For the f^2 the 1I is placed within 300 units of its prediction using the two coefficients above. Fig. 5, however, is a recalculation using least squares to fit the three

coefficients F_2, F_4, F_6 to the separations of all the levels from the low 3H . This gives a surprisingly good fit of the 6 intervals in terms of the 3 integrals, with the value of $F^2 = 21,000$, $F^4 = 23,500$, $F^6 = 1930$. Unfortunately F^4 comes out a little larger than F^2 whereas it must be smaller.

Thus we have obtained quite pleasing results with these two f -electron instances, the theory having stood the test of prediction and been of actual service in the analysis of the spectrum, both in the assignment of 1S and 1D , f^2 , the former of which Professor Russell says he had little possibility of assigning definitely, and in the rearrangement of the levels in both df and f^2 .

Kiess and Lang¹⁴ have completed the $4d4f$ configuration of Zr III except for the 3H , but when the other four means are plotted as in Fig. 4, it is seen that no three of them will fit in any fashion. The P , D , and F separations alternate but the G does not.

In conclusion we may say that this first approximation seems to be most accurate for those configurations with lowest total quantum numbers in comparison with the angular momentum quantum numbers, the $3d$ and $4f$ in particular giving good results.

We wish to thank Professor H. N. Russell for his helpful interest in this work, and him and Dr. Meggers for permission to publish their lanthanum data.

DENSITY AND CONDUCTIVITY OF BISMUTH SINGLE CRYSTALS GROWN IN MAGNETIC FIELDS WITH RELATION TO THEIR MOSAIC STRUCTURE

(Received March 2, 1931)

ABSTRACT

In continuation of the study of the thermoelectric effect, previously described by Goetz and Hasler, existing between the two halves of the same bismuth single crystal, of which one has been crystallized within, and the other outside of a strong magnetic field (21,000 gauss), the density and the specific resistance of different sections of these crystals, grown by the discontinuous method, have now been measured.

The change of density of "magnetic" crystals. The density of perfect crystals grown under normal conditions was found to be between 9.82 and 9.83 i.e., 0.2 percent higher than the values of other authors. Furthermore, it was found that any crystal-line imperfection such as twinning, etc., decreases the density; that, further there exists a difference of density between the "normal" and the "magnetic" half of the same crystal, the sign of which depends on the orientation with which the crystal entered the field: In case the trigonal axis is normal to the axis of the rod and normal to the lines of force, the "magnetic" half shows an increase of density, whereas the opposite is true in case the principal axis is parallel to the rod (and therefore parallel to the direction of growth and to the heat-flow). The difference of density is ca. 0.3 percent but can be several percent in imperfect crystals. The purity of the metal affects the change of the density. The results indicate that the ideally pure metal would not be affected by the magnetic treatment.

The specific resistance of "magnetic" crystals. The values of the specific resistance obtained on "normal" single crystals agree approximately with the results obtained by Bridgman and Kapitza and also with those obtained by spectroscopic analysis. The value of $\rho_{\parallel}/\rho_{\perp}$ was found to be much larger for bismuth, being sensitive to the "magnetic" treatment. There is a small change of resistance between the normal and the magnetic half, depending on the orientation of the crystal to the field: In case the orientation is such as to decrease the density the resistance increases and *vice versa*. The accuracy necessary for the satisfactory quantitative determination of the change could not yet be reached, since the change is of the magnitude of 0.5 percent.

An attempt is made to combine the phenomena of the magnetic effect thus far known. It seems probable that the influence of the magnetic field upon the formation of a crystal consists of a change within the mosaic structure of the lattice. The investigation is being continued.

INTRODUCTION

A THERMOELECTRIC effect within one and the same Bi single crystal of which one half had crystallized under normal conditions, the other within a strong transverse magnetic field has recently been described by A. Goetz and M. F. Hasler.¹ It was found that the size as well as the sign of the e.m.f. depends on the orientation of the crystal with respect to the lines of

¹ A. Goetz and M. F. Hasler, Phys. Rev. 36, 1752 (1930).

force and on the method of growth; also that the e.m.f. depends largely on traces of impurity within the crystal.

Due to the fact that this magnetic effect is altogether new, very little information as to the cause of the observed e.m.f. can be obtained from the observations themselves and accordingly additional measurements of another type have been here undertaken.

Although we realized in advance that the thermoelectric effect would be by far the most sensitive indicator, and other volume effects should be very minute if at all measurable, there seemed to be encouraging indications in the observations of previous authors concerning the density and the electric conductivity of Bi crystals.

THE DENSITY OF "MAGNETIC" BI CRYSTALS

The density of bismuth has been measured very frequently by different authors and it seems quite remarkable that there is no other common element for which the different observers differ so largely though they seem to have worked with great care. A study of the literature² shows that the measured density of Bi varies between 9.66 (Marcus, Giebe) and 10.055 (Zavaffiero), a difference of more than 5 percent. There can be no doubt that part of this variation is due to fissures and inclosures of gas within the metal which falsify the measurement of the volume. It is quite remarkable that the average value of a perfect single crystal is far below the maximum density measured on specimens consisting of compressed powder, thus indicating that the bismuth lattice is *not* the closest possible packing of Bi atoms.

For the present measurement of densities the usual hydrostatic method was improved only in that thin transformer oil was used for the immersing liquid instead of water. In the case of water, it was found that shortly after boiling (a process which is necessary to prevent the formation of gas-bubbles on the surface of the specimen) the absorption of air gradually changes the density until saturation is reached again. In case of oil dried artificially this trouble does not occur and its density can be kept constant for months if one works carefully. The density of the oil was measured in a pyknometer.

To reduce the inaccuracies to a minimum, two pieces of equal length were cut out of one crystal, one belonging to the normal, one to the magnetic side of it. It goes without saying that the crystal had to be free of imperfections—these could be tested for by the thermoanalyser¹—and also that its surface had to be etched in order to free it from any layer of oxide.

But in spite of the care taken in the measurements and in producing the crystals, the results obtained are not as uniform as expected. Furthermore, according to the thermoelectric results, only measurements on crystals of the same orientation and grown by the same method can be compared. Crystals of the P_1 and P_2 -type grown by the discontinuous method, have been investigated, since these orientations show the largest magnetic effects, whereas the P_2 -type is almost neutral. In addition to this, it was found that even in the

² Gmelin's Handbuch der Anorg. Chem. Vol. 8, page 35.

measurement of density only crystals of the same sort of bismuth² could be compared. Thus most attention had been paid to crystals of the "B" bismuth due to the large "magnetic" effect observed on it in the thermoelectric measurements.

Results. In toto, the density of 76 different specimens was measured. These belonged to 29 different crystals grown in general especially for these measurements. Of these specimens, 15 were of the orientation P_1 , 6 of P_2 , 16 of P_3 , 2 of P_{1-2} , and 2 of P_{2-3} **. Several specimens of the magnetic (M) and the normal (N) halves of the same crystal were cleaved into several pieces, each being measured separately in order to determine the influence of local irregularities and to reveal the accuracy of the method. Table I shows part of the results obtained. The section "number of measurements" in Table I indicates how many different measurements of the same crystal or of its different parts were taken, each measurement consisting of the necessary number of readings.

** The designation of the latter two orientations indicates mean intermediate orientations between P_1 and P_2 etc.

With regard to the absolute value of the density it is apparent that *the average value for single-crystals is between 9.82 and 9.83, slightly higher than the result obtained by Kapitza (9.80).*³ This result was checked by measurements made upon normal crystals in distilled water immediately after its separation from the absorbed air.

The density of Bi, generally speaking, appears to be abnormally sensitive to crystallographic imperfections, since polycrystals for instance as well as crystals with large twinned regions showed abnormally low values, this probably being due to the enclosure of gas at the intercrystalline borders, as was verified several times by the microscope. This sensitivity is also indicated by the fact that the highest values of the density on our best crystals (9.83) are still below the value to be expected from the x-ray data (9.86).

Nevertheless the values given in Table I have but relative importance (with the exception of the crystals 48/00/0, 49/00/0 and 49/00/1) since they are obtained in oil, the density of which could not be checked in the pyknometer as accurately as the values taken with the balance, though the accuracy indicated by the data given is justified for one and the same crystal because these values were obtained in immediate succession and under similar conditions.

The measurements thus obtained indicate the following connection between the normal and the "magnetic" part of the same crystal: *If the crystal has an orientation in which the principal axis is normal to the lines of force (P_1 and P_3) the density of both halves differs considerably, whereas no change can be found if the axis is parallel to the field. (P_2).*

Furthermore with relation to the first part it is evident that *the density of the "magnetic" half is larger than that of the normal, in case the trigonal axis is normal to the axis of the rod, (P_1), whereas the opposite is true if the axis is parallel to the axis of the rod (P_3).*

In intermediate orientations (P_{1-2}) where P_2 is unaffected, the resulting change is the same as it is in the case of P_1 , but one should not rely too much upon it, since there exists only the measurement of one crystal (orientation ca. 30°). Concerning the measurement of the crystal 73/00/0 which has the P_1 -orientation but consists of the kind C (i.e., the purest metal¹) it is striking that *no change of density could be observed.*

In consideration of the large experimental difficulties connected with density measurements of this kind, one should not put too much stress on the absolute value of the differences of the density between the normal and the "magnetic" parts, since an almost invisible layer of oxide or grease and small enclosures, difficult to detect, affect the results fatally by fogging the whole effect. Thus a number of observations had to be discarded among which were a few whose sign was not in agreement with the above statement. Nevertheless the discarding was done only after it was evident that the crystals were imperfect.

³ P. Kapitza, Proc. Roy. Soc. A119, 358 (1928).

THE ELECTRIC RESISTIVITY OF "MAGNETIC" CRYSTALS

As soon as it was evident that the growing of crystals in a magnetic field affects their density, it was decided to measure their electric resistivity, since it is well known that these qualities are closely related within the same metal.

There are a number of very exact investigations published concerning this subject (Bridgman,⁴ Schneider,⁵ Borelius and Lindh,⁶ Schubnikow and de Haas⁷ and Kapitza³). It is made quite certain by Bridgman that the Voigt-Thomson law holds also in case of Bi, whereas concerning the absolute values of the specific resistance, a small discrepancy still remains between the recent authors, a discrepancy which is very probably due to the fact that it is very difficult to obtain bismuth of sufficient purity, or better of equal impurity.

Fig. 1. Diagram of apparatus.

Also the measurements themselves must be performed with special precautions, so as to avoid the large thermoelectric forces due to small changes of temperature as well as any permanent or elastic distortion of the crystal, for these affect the results largely.

We used for our measurements, for the most part, the arrangement already described by Kapitza³ with certain modifications however, dictated by the much larger size of our crystals and by our special purpose of comparing the values of two different parts of the same crystal. Thus the arrangement was as shown in Fig. 1.

⁴ P. W. Bridgman, *Proc. Am. Acad.* **63**, 351 (1929).

⁵ G. W. Schneider, *Phys. Rev.* **31**, 251 (1928).

⁶ G. Borelius and A. E. Lindh, *Ann. d. Physik* **51**, 607 (1916).

⁷ A. Goetz, *Phys. Rev.* **35**, 193 (1930).

After a crystal of 13 to 15 cm in length, of the desired orientation, was grown within a graphite trough previously described,⁷ one half of which (*N*) was grown under normal conditions, the other (*M*) within a magnetic field, both ends including the transition between the seed crystal and the main crystal were carefully cleaved off so as to obtain the standard length of 12 cm. Then the crystal was etched and searched for imperfections or twin lamellae. In case it proved satisfactory two copper cups (*K*)—the current leads—were soldered to the crystal with Wood's metal. This method has the advantage of avoiding the necessity of heating the crystal long enough to produce an alloy between bismuth and Wood's metal, which makes the further use of the bismuth impossible, whereas here one has only to heat the cup filled with Wood's metal up to its melting point and then to put one end of the crystal into it, after which the liquid metal solidifies shrinking around the crystal. Thus a reliable contact for comparatively large currents is made.

The potential leads consisted of 0.1 mm silver wire which was spark-welded on to the crystal at 4 different points as shown in Fig. 1 to allow the measurement of the specific resistance separately across the normal and the magnetic parts of the crystal. In order to keep the temperature constant the whole arrangement was immersed in a bath of oil within a container of paraffin (*P*).

The current was measured by means of a standard ohm (St. O) and a precision potentiometer *V*, whereas the voltage across one pair of silver wires was measured directly with the potentiometer. There were furthermore the usual precautions for balancing the thermoelectric effects etc.

The largest difficulty consisted in the exact determination of the cross section of the crystal, since it could not be taken from direct measurement because of the peculiar shape of the trough. Thus it was necessary to calculate the specific resistance from the length (*L*), the weight (*G*) and the density (*D*) by means of the relation:

$$\rho = \frac{E \cdot G}{J \cdot D \cdot L^2}$$

where *J* and *E* are current and voltage and ρ the specific resistance. Since it was impossible to obtain any better accuracy by this method than 1—2 percent the variation of density between *N* and *M*, as described before, was not considered. For *D* the value of 9.82 was taken.

The reason for the inaccuracy of this method is found in the assumption that the cross section over the length used is constant. This becomes less true the larger this length is chosen. This distance between the potential leads on the other hand has to be large enough to avoid the influence of the unequal current distribution in the neighborhood of the leads and the uncertainty of the distance due to the cross section of the welding spot, which was in the present case at least 0.5 mm. The distance used was in general between 30 and 40 mm so as to decrease the uncertainty of ρ to about 3 percent.

Results. It is well known that the specific resistance parallel to the trig-

onal axis of a Bi crystal is larger than normal to it, furthermore, that the ratio between these two values increases with the increasing amount of impurity, since in this case, the resistance along the trigonal axis increases faster than perpendicular to it. The minimum values of $\rho_{\parallel}/\rho_{\perp}$ are 1.27 (Bridgman⁴) and 1.30 (Kapitza³), whereas Schneider⁵ finds 1.62 using a metal with 0.04 percent silver. Table II gives the results which seem the most reliable ones. No reliable values for bismuth D^1 could be obtained, since this kind is very hard to obtain in single-crystalline form without inclosed air-bubbles.

The values for $\rho_{\parallel}/\rho_{\perp}$ in Table II are taken at temperature of 25°C which is slightly higher than the temperatures used by Bridgman and Kapitza (20°). This difference makes it necessary to decrease our values about 2 percent to compare them with the values of these authors.

The main reason why our values are not as consistent as Kapitza's and Bridgman's is probably the indeterminacy of the cross section of the crystals. Nevertheless these observations (which are not considered to be final) indicate the following facts.

The variation of the specific resistance of the different kinds of bismuth used is in agreement with the spectroscopic analysis published previously¹ showing that C is the purest metal with a resistance $\rho_{\perp} = 1.09 \times 10^{-4}$ and ρ_{\parallel} 1.36(?) to 1.43×10^{-4} . The latter value is slightly larger than Bridgman's (1.38×10^{-4}) but can be easily explained by the lack of longitudinal compression in which case Kapitza obtained values up to 1.5×10^{-4} . Bismuth A can be easily recognized as impure and B is still worse, agreeing with the measurements of Borelius and Lindh. Fig. 2 shows the results for the three different kinds of Bi used; the hatched line below C shows Bridgman's best

values,* the dotted line crossing *B* gives the conductivity for *B* crystals grown in the magnetic field in the corresponding orientation, the abscissa is given in the usual terms of \cos^2 of the angle of orientation.

The most important fact suggested by the results consists in the influence

Fig. 2. Results for the three different kinds of Bi used. The hacked line below *C* shows Bridgman's best values. The dotted line crossing *B* gives the conductivity for *B* crystals grown in the magnetic field in the corresponding orientation.

* There is one discrepancy worth mentioning in the fact that Bridgman used Kahlbaum metal which is the same as our *D*. Kapitza's remark about this metal as well as our analysis shows that it contains a considerable amount of impurity which is different from the con-

the magnetic treatment of the crystal has on the resistance. This runs as follows: *if the crystal has an orientation in which its trigonal axis is normal to the lines of force and normal to the direction of the current the specific resistance of the magnetic half is smaller than the normal one; if the trigonal axis is normal to the lines of force and parallel to the direction of the current the specific resistance of the magnetic half is larger than the normal.*

As to the qualities of the P_2 orientation no exact measurements were yet performed because the thermoanalysis did not show any "magnetic" effect.

DISCUSSION

The results obtained as to the influence of the magnetic field upon the density and the conductivity of Bi single crystals, have a close relation. This is not altogether unexpected. The increase in density is associated with a decrease of specific resistance (P_1) and *vice versa* (P_3). Furthermore, the crystallization within a magnetic field seems to affect the density and conductivity of a metal with small impurities to a much larger extent than a pure one.

Considering the nature of the change within the "magnetic" crystal it is very difficult to say anything that is more than a mere suggestion. Both the thermoelectric effect and the change of conductivity could be explained by a change at the moment of crystallization in the orientation of the crystal when entering a magnetic field. As has been already stated in a previous paper⁷ no change in orientation could be detected, furthermore this explanation would account neither for the large influence of impurities nor for the change in density.

Another suggestion would be an allotropic change of the lattice, indicated by the change in density. Hence an x-ray investigation was started after the first indications of a change of density were found. This consisted of Bragg diagrams taken simultaneously from the (111) plane of the normal and the magnetic half of the same crystal, but, as was stated already briefly by Goetz and Hergenrother,⁸ not the slightest displacement of corresponding lines was found, thus indicating that *the atomic distance along the trigonal axis does not differ between both parts of the crystal.*

Hence there are obviously only two conclusions left, of which one assumes that the magnetic half undergoes an pseudo-allotropic change of the same type as the $\alpha \rightarrow \beta$ -transformation of iron and zinc which cannot be found by x-ray analysis though indicated by electric volume effects. In general one assumes that the transformation of the first metal is only due to an interatomic change of the distribution of electrons and it would be plausible that such an effect occurs more easily if the internal symmetry of the lattice is disturbed by impurities. Nevertheless this suggestion loses probability as it does not account for the change in density in case of Bi.

tamination of A and B but much more than C. This fact is also indicated by the size of the "magnetic" effect. We were not able to obtain reliable measurements of the specific resistance of this metal whereas Bridgman got the best results yet published.

⁸ A. Goetz, R. C. Hergenrother and A. B. Focke, Phys. Rev. 34, 546 (1929).

Thus there is apparently no mode of explanation left save that which has been suggested in a previous paper as the only way to account for the large effect of minute impurities in a crystal.¹ This way seems indeed to account for the whole phenomenology of these effects, including the change of density and electric conductivity of magnetic Bi crystals. The assumption is of a change in the secondary structure of the crystal as described first by Zwicky.^{9,10}

The experimental evidence for the existence of this structure in Bi crystals has already been given by one of the authors.¹¹ He showed that this structure, superimposed upon the Laue-Bragg lattice, consists of blocks of a definite size which is within the range of microscopic visibility. Our present suggestion is that the arrangement of these blocks is changed under the influence of the magnetic field so as to produce a closer or less close packing. This would not influence the x-ray diagram, since this depends only on the primary structure of the lattice whereas the density of the crystal as a whole would be affected by a change in the mosaic arrangements of the blocks.

This mosaic arrangement of the blocks is thus assumed to be changed by the influence of a field during the formation of the crystal. Such a change, which we have to think of as a systematic distortion, must depend on the crystallographic orientation of the crystal within the field and must disappear if this orientation causes the smallest possible content of free energy upon the crystal as is the case in the P_2 orientation where the direction of the smallest susceptibility is parallel to the lines of force as follows from the measurements of Focke.¹²

This assumption makes it plausible also that the electric conductivity changes with the density, since both depend on the compactness of the crystal.

The hypothesis as a whole implies a less compact form due to the mosaic structure for the average perfect crystal than for an ideal one.** Although it is perhaps possible to think of accidental fissures within the crystal as the cause of the difference between the theoretical and the actual density (0.3 percent), the fact that one can approach the theoretical density by the crystallization in a magnetic field under the same thermal and mechanical conditions of growth seems to be a strong argument against the presence of such fissures dependent upon imperfect growing conditions. Also the consistency of the density values obtained speaks against such an explanation.

Considering the magnitude of the change of density and conductivity in

⁹ F. Zwicky, Proc. Nat. Acad. 15, 253, 816 (1929).

¹⁰ F. Zwicky, Hel. Phys. Acta. 3, 269 (1930).

¹¹ A. Goetz, Proc. Nat. Acad. 16, 99 (1930).

¹² A. B. Focke, Phys. Rev. 36, 319 (1930).

** This conclusion does not contradict Zwicky's assumption¹³ for ionic lattices of Na Cl type, where the actual density of a crystal should be larger than the density calculated from the x-ray diagrams due to the contracted II-planes sandwiched between normally spaced regions. (Hel. acta, page 288.)

magnetic crystals (0.5 percent) one must call these second-order effects in comparison with the magnitude of the thermoelectric changes.¹ This fact also seems to support the suggested hypothesis, since it is well known that thermoelectric effects in general are much more structure-sensitive than density and conductivity known as structure-insensitive.

There are two more arguments in favor of the above explanation: if there is a possibility of a distortion within the mosaic structure, i.e., among the blocks, this can only be possible if during the genesis of the crystal these units possess a larger mobility among themselves than do the molecules of the primary lattice. This is necessary for the following reason: an orienting influence upon the crystal exerted by the magnetic field presupposes the existence of an anisotropic susceptibility. Besides the fact that liquid Bi is almost neutral magnetically and the further fact that the large diamagnetic properties of Bi arise only at the moment* the lattice forms, make it obvious that the magnetic anisotropy cannot exist either before the primary lattice is formed. Hence the orienting influence of the field can only occur if a lattice already exists. As the forces exerted upon the crystal by the fields used are far too small to deform the lattice permanently the only explanation left seems to be the distortion of the secondary structure. This explanation presupposes that the primary structure exists before complete solidification, a fact which former work by one of the authors made highly probable in the case of Bi.¹¹ The second support of the above hypothesis is found in the observation that a possibility of an orienting influence upon the crystal "*in statu nascendi*" exists in fact, and that it can have mechanical, thermal and

* This statement is not in harmony with Kapitza's hypothesis according to which the large diamagnetism of Bi begins only slightly below the melting point after the metal has already solidified. It seems dubious whether this opinion can be supported by Curie's paper on this subject,¹⁴ for he states emphatically: "... la chute (of diamagnetism) est absolument brusque et correspond exactement avec le phénomène de la fusion ..."; and furthermore: "... Un curieux phénomène se produit si l'on chauffe le Bi en petits fragments dans une ampoule fermée à une température à peine supérieure à celle de fusion. La chute des propriétés magnetiques se produit complètement; cependant si l'on refroidit quelques minutes après, on retrouve les petits fragments qui ont le même aspect qu'avant et se ne sont pas écroulés. Cependant le Bi. a été fondu, car, en cessant les morceaux, on voit que la structure interne a été complètement changée et que les plans de clivage ne sont plus placés comme avant ..."

This does not mean necessarily an indication of the existence of a transformation, since similar experiments by us showed that even a thin oxide-coat covering such fragments is very well able to preserve their exterior shape, though a pinch with a needle through this (almost invisible) coat proved the interior to be liquid. Furthermore the change of orientation within those fragments makes a melting more probable than an allotropic transformation, since, as is shown by several authors, the main orientation of a crystal is preserved in general no matter how frequently the transition between two allotropic transformations be passed. It appears also clearly in Honda's paper (16) that the rise of diamagnetism is associated with the process of crystallization and a personal discussion of this matter that one of the authors (G.) had with Professor Honda at Sendai leaves no doubt that the utmost care was taken with respect to this question.

magnetical causes.^{11,17} This proves that the anisotropic qualities do not disappear when the macroscopic crystal melts.

Thus one is forced to assume that the distortion of the mosaic structure is the result of two different influences: The orienting influence of the field and the orienting influence of the crystal grown already in an orientation enforced upon it by a seed crystal such as was always used in our experiments. As long as both influences work in the same direction (P_2) there is no distortion, whereas in case they work in different ways a distortion must occur, depending on the orientation (P_1 and P_3), as is indicated by the different signs of the described volume effects. The magnitude of these effects can obviously be ascribed partly to the degree of the distortion. Since the conditions in our experiments were kept as constant as possible the different magnitudes (Bi A , B , C , and D) especially of the thermoelectric effects of the same orientation can but indicate different degrees of distortions due to the same cause. This makes it probable that the impurities within the crystal determine the energy necessary for a certain change of the mosaic structure.

With regard to such a relation one has to go back to one consequence of Zwicky's theory of the mosaic crystal which has already been suggested by him implicitly: In case a perfect crystal contains a small amount of impurity, too small to form a homogeneous solid solution of the whole crystal, the strange atoms will accumulate in a region where their presence causes the smallest disturbance of the lattice, i.e. within the Π -planes. The chance that a certain part of the foreign atoms present in the liquid will accumulate within the Π -planes depends on the expression

$$S = \frac{\alpha}{A} \cdot [E_p - E_\pi]$$

which by applying the Boltzmann principle gives for the probability the expression:

$$P = \text{const} \cdot e^{-\alpha(E_p - E)/AkT}$$

where E_p and E_π are the respective energy contents of the same crystal first when the foreign atoms are put into the lattice at random and second when they are arranged within the Π -planes. A represents the affinity of the strange atoms for the formation of a solid solution in the crystallographic constellation under consideration and α stands for the "perfection" of the crystal, including the conditions of crystallisation, absence of external disturbances, inverse speed of growth, etc. It is apparent that the above will only hold for an amount of foreign atoms smaller than or equal to that amount necessary to fill the Π -planes with a mono- or bimolecular layer and only for one kind of atoms at the same time. Under the assumption that S is sufficiently large in our crystals one is led to think that the units of the secondary lattice are surrounded by a more or less dense hull of impurities. It is obvious that atoms

of different metals should have different effects due to different A 's, i.e., similar atoms should have smaller effects than an equal number of dissimilar ones, the correctness of which conclusion is attested for example by the negligible influence of small amounts of Sb within Bi crystals, (Sb forms the same lattice as Bi with only slightly different dimensions) and also by the surprising effect of traces of Ag and Pb (0.02 percent) as already stated by Bridgman, Goetz and Hasler.

The presence of such dissimilar impurities may greatly change the stability of the secondary lattice and thus make it more sensitive to the influence of a magnetic field applied during the formation of the crystal. The large influences that small impurities have on electric volume-effects within Bi crystals make the assumption of a two-dimensional accumulation of impurities (as in the Π -planes) necessary since it is difficult to understand that a homogeneous distribution of minute impurities over the whole crystal can produce such large effects, as have been observed by Kapitza for example in the change of conductivity in strong magnetic fields.³

It would be interesting to investigate whether or not the diamagnetic properties of these crystals are affected by impurities and also by their formation within strong magnetic fields. Assuming the correctness of Ehrenfest's hypothesis¹⁸ namely that the large diamagnetic susceptibilities are due to electronic orbits extending around more than one nucleus, a change of the mosaic constellation of a crystal would be expected to affect its magnetic qualities, i.e., one should expect that the large diamagnetic susceptibilities are structure sensitive properties. Experiments of this kind are started and the results seem to point in this direction.

Besides the investigation of the intensity distribution of the x-ray reflections on "normal" and "magnetic" crystals which has already been published⁹ briefly, another experiment should be mentioned which could throw light on the nature of the suggested distortion of the mosaic structure: namely an experiment upon the magnetostriction of perfect magnetic and normal crystals, for it is to be expected that this effect must be largely influenced by any systematic change of the secondary structure. Experiments of this kind are planned.

HYPERFINE STRUCTURE IN IONIZED BISMUTH

BY RUSSELL A. FISHER AND S. GOUDSMIT

DEPARTMENT OF PHYSICS, UNIVERSITY OF MICHIGAN

(Received March 14, 1931)

ABSTRACT

The hyperfine structure of several lines in the spectra of Bi II and Bi III have been determined. A method which facilitates the analysis of partially resolved line patterns is described. The level separations obtained from the analysis are compared with theoretical formulas showing the inadequacy of the present theory for the interaction of external electrons with nuclear spin.

EXPERIMENTAL

THE twenty-one foot eighty thousand line concave grating mounted in the third basement of the laboratory was used in this work. We have used the grating in Paschen mounting with the slit at fifty degrees from the normal. In the third, fourth and fifth orders, where we have worked, linear dispersions range from 0.47 to 0.87 Angströms per millimeter and the practical resolving power is near two hundred thousand. Although the grating shows faint Rowland ghosts this is no limitation to fine-structure work, since these ghosts always lie far outside the fine-structure pattern. In extreme exposures a faint and diffuse line appears close on the short wave-length side of a sharp line. This false line causes little difficulty, however, since it appears only in over exposure and then at a fixed distance from the parent line. Although no attempt was made at temperature control the temperature of the spectrograph room was so constant that no appreciable broadening appeared after a twenty-four hour exposure.

Since the effect of fields and pressures in broadening spectral lines is considerable for ordinary light sources, special precautions attempting to avoid these influences are necessary in hyperfine structure work. Back has employed his vacuum arc most successfully in his work in arc spectra. Schüler¹ suggests the use of a modified form of the Paschen hollow cathode tube operating at liquid air temperatures. This type of source has been used by White and Ritchie² as well as by Schüler himself.

We have used an arc between a bismuth and a tungsten electrode in hydrogen at a few centimeters pressure in making a preliminary survey of the spectrum. This source gave several of the Bi II lines with fair sharpness. Later we used a metal discharge tube similar to that described by Schüler. Our only modification of Schüler's tube is the use of a removable molybdenum cylinder as hollow cathode. This molybdenum cathode has the advantage of contributing practically no lines to the spectrum and of being cleaned of im-

¹ H. Schüler, *Zeits. f. Physik* 56, 149 (1930).

² H. E. White and R. Ritchie, *Phys. Rev.* 35, 1146 (1930).

purities quickly. The bismuth was excited in helium, the metallic bismuth being placed inside the molybdenum cathode. The tube was operated in a water bath since lower temperatures were found to be of no advantage in the case of bismuth. In the discharge the lines of Bi I and Bi II appeared with nearly equal intensity while those of Bi III were somewhat less intense. An exposure of twenty-four hours was necessary in order to obtain some of the lines in the higher orders.

ANALYSIS

The theory concerning hyperfine structure term separations predicts that hyperfine multiplets will follow the interval rule very accurately. Also the formulas for the line intensities in hyperfine line multiplets, which Hill³ has derived by means of the quantum mechanics, should hold with accuracy. The fact that the interval and intensity rules can be relied upon enables one to construct graphs which aid greatly in the analysis of hyperfine line patterns. An observed line pattern is seldom completely resolved due to small separation in one or the other of the hyperfine multiplets giving rise to the line. The graphs are of particular use in the cases of imperfectly resolved line patterns.

Fig. 1a shows such a graph representing the possible line patterns in the case of a transition between two sets of levels in Bi II, each with a total extranuclear angular momentum of one quantum unit ($J=1$). Since the nuclear angular momentum quantum number of bismuth has been shown by Goudsmit and Back⁴ to be $4\frac{1}{2}$, the resulting hyperfine multiplets should both be triple with fine quantum numbers of $3\frac{1}{2}$, $4\frac{1}{2}$, and $5\frac{1}{2}$. According to the interval rule the level separations should be $4\frac{1}{2}A$ and $5\frac{1}{2}A$, where A is called the separation factor. The distribution of the lines in the figure at any particular horizontal level gives a possible line pattern. The vertical coordinate, denoted by μ , is the ratio between the separation factors of the initial and final states. If B is the separation factor of the initial and A of the final hyperfine multiplet, $\mu = B/A$. The horizontal coordinate may be read in units of wave length or frequency as one chooses. Thus on the axis, $\mu = 0$, we have a line pattern corresponding to the case of no separation of the initial levels, that is, a line triplet with the separations of the final multiplet, the separation ratio being $4\frac{1}{2}:5\frac{1}{2}$ as the interval rule requires. Positions a little above this axis, $\mu = 0$, give line patterns due to slight separation of the initial levels as compared with the final levels. As we proceed to larger μ the graph represents the change in line pattern resulting from larger separations of the initial levels. The whole region above the axis (μ positive) gives patterns for cases in which both multiplets are regular or both inverted. Positions below this axis (μ negative) give patterns for cases in which one of the multiplets is inverted with respect to the other. The intensities of the lines are calculated from the formulas of Hill and the widths of the lines made roughly proportional to the expected intensities.

Fig. 1b gives a six-fold enlargement of the line $\lambda 5270$ of Bi II. It may be

³ E. L. Hill, Proc. Nat. Acad. Sci. 15, 779 (1929).

⁴ S. Goudsmit and E. Back, Zeits. f. Physik 43, 321 (1927).

observed that the line fits the graph precisely at $\mu = -0.261$. Because of its small intensity the line in the center of the figure does not appear on the photographic plate. The separations of the two multiplets giving rise to the line may here be read directly from the measured line separations.

Fig. 1. Diagram for transition $J=1$ to $J=1$ compared with Bi II $\lambda 5270$. $\mu = -0.261$, total $\Delta\nu = 4.93 \text{ cm}^{-1}$. The arrow indicates where the line pattern fits the diagram.

The graphs are of greatest assistance in cases in which the observed line patterns are imperfectly resolved.⁵ In such cases the level separations may be found if μ can be determined by comparing the observed pattern to the graph and one or two separations measured to give the scale. Fig. 2a gives

Fig. 2. Diagram for transition $J=2$ to $J=1$ compared with Bi II $\lambda 4705$. $\mu = +0.457$, total $\Delta\nu = 2.71 \text{ cm}^{-1}$. The arrow indicates where the line pattern fits the diagram.

the graph for the transition $J=2$ to $J=1$. Fig. 2b gives an example of a partially unresolved and poorly defined line pattern which may be analyzed by means of the graph. The pattern is a six-fold enlargement of the unclassified line $\lambda 4705$ of Bi II as it appeared in the fourth order. It is found that this line

⁵ Similar graphs applicable to Zeeman effect analysis are being prepared for publication.

† From the measurements of McLennan, McLay and Crawford.

Tables I and II give the measurements on the line patterns of Bi II and Bi III, respectively, in terms of frequency differences. The line of the pattern from which the frequency differences are measured is in general the one of lowest frequency. In the few cases in which the line of lowest frequency is faint or unsuitable for other reasons another line has been selected. The method of measurement was such that the uncertainty in frequency difference between any two components of a pattern is not greater than the larger uncertainty following one of them, i.e., the uncertainties do not add. In the tables we give the wave-lengths to four significant figures only, since the patterns are broad and we have not made precise wave-length measurements.

We have been aided greatly in the hyperfine structure analysis by a paper recently published by McLennan, McLay and Crawford⁶ in which they give the term analysis for Bi II and for Bi III and a few very wide hyperfine-structure measurements. We have included their measurements in our tables as those indicated by the symbol †.

106441	$6p_{1/2}7p_{1/2}$	15_1	-0.36 ± 0.08	-0.036
108272	$6p_{1/2}7p_{1/2}$	16_3	0.37 ± 0.15	0.012
108398	$6p_{1/2}8p_{1/2}$	17_1	-0.14 ± 0.10	-0.014
109897	$6p_{1/2}7p_{1/2}$	19_2	0.78 ± 0.04	0.039

* The configurations and term values are as given by McLennan, McLay and Crawford.

TABLE IV. *Bi III level separations.*

Term value	Configuration	Term designation	Total separation cm^{-1}	Separation factor
123143	$6s6p^2$	$1_{1/2}$	7.5 ± 0.8	0.50
116943	$6s6p^2$	$2_{2/2}$	12.5 ± 0.8	0.50
111105	$7s$	$2S_{1/2}$	2.36 ± 0.01	0.472
89765	$6s6p^2$	$3_{2/2}$	9.3 ± 0.6	0.37
89188	$7p$	$2P_{1/2}^0$	0.52 ± 0.01	0.104
84053	$7p$	$2P_{1/2}^0$	0.31 ± 0.05	0.021

Tables III and IV give the level separations as determined from our measured line patterns with the aid of the graphs. In the tables we have used the term designation as given by McLennan, McLay and Crawford. In all cases we give the total hyperfine-multiplet separation. Negative separation in the table indicates inversion of the multiplet. Although the individual level separations could usually be determined, the uncertainty was in most cases too large for the data to be a valuable test of the interval rule. The separations of two of the multiplets of bismuth II are determined with a higher degree of accuracy. They are:

Term	Total separation	Individual separations	
2_1^0	$3.91 \pm .01$	$2.15 \pm .01$	$1.76 \pm .01$
8_1	$-1.02 \pm .01$	$-.56 \pm .01$	$-.46 \pm .01$

We may say that the interval rule is obeyed to within the limit of observational uncertainty in all cases. We believe that the estimates of uncertainty given in the tables are extremely liberal.

It is evident that the hyperfine structure analysis serves to verify much of the term assignment of McLennan, McLay and Crawford from the fact that we are able to use their term designation. We find, however, no evidence of the existence of the tentative term denoted by them as 3° .

We have been able to measure the structure of three lines which without doubt belong to Bi II but which have not been classified by McLennan, McLay and Crawford. We make no attempt to classify these lines in the general term system but do give the hyperfine separations of the levels from which they originate. Two possibilities arise in such cases since there is no way of deciding which level is initial. These lines and the level separations derived from them are as follows:

Wave-length of line	Total separation of initial levels	Total separation of final levels
4705	2.48 ± 0.05 ($J=2$)	2.71 ± 0.01 ($J=1$)
	or -2.71 ± 0.01 ($J=1$)	-2.48 ± 0.05 ($J=2$)
4477	-0.85 ± 0.04 ($J=2$)	2.68 ± 0.04 ($J=2$)
	or -2.68 ± 0.04 ($J=2$)	0.85 ± 0.04 ($J=2$)
4392	0.60 ± 0.15 ($J=1$)	small ($J=0?$)
	or small ($J=0?$)	-0.60 ± 0.15 ($J=1$)

THEORETICAL DISCUSSION

In a previous⁷ paper one of us has given formulas for the hyperfine-structure separations for different states of the same atom. In that paper it was already pointed out that the theoretical results were in disagreement with the experimental data, even in the simple case of a one-electron spectrum. We now wish to discuss our material in Bi II and Bi III together with the known data for Bi I⁸ in the light of these theoretical expressions.

Bismuth I. The normal state, $6p^3$, does not yet show extreme (j,j) coupling. We may, however, apply the formulas derived on the assumption of extreme (j,j) coupling to the two levels with $J=2\frac{1}{2}$ and $J=\frac{1}{2}$, respectively, since these two quantum numbers occur only once in this configuration and the hyperfine separations of the levels are therefore independent of the type of coupling. The individual electrons of the configuration are considered as acting separately except for their screening effect upon one another. Thus the separation factor of a hyperfine multiplet is expressible in terms of separation factors for the electronic states. These considerations are similar to those used in the treatment of ordinary multiplet separations. The following table gives the observed separation factors for several states together with the formulas⁹ applying both in case of (j,j) coupling and of Russell-Saunders coupling.

⁷ S. Goudsmit, Phys. Rev. 37, 663 (1931).

⁸ P. Zeeman, E. Back and S. Goudsmit, Zeits. f. Physik 66, 1 (1931).

⁹ For all following formulas see S. Goudsmit, Phys. Rev. 37, 663 (1931).

Term	Observed separation factor	Formula	
		(j,j) coupling	Russell-Saunders coupling
$6p^3 \ ^4S_{1\frac{1}{2}}$	~ -0.005	a'	0
$\quad \quad \ ^2D_{1\frac{1}{2}}$	-0.040	$1\frac{1}{2}a' - \frac{1}{3}a''$	$\frac{16}{25}a$
$\quad \quad \ ^2D_{3\frac{1}{2}}$	0.081	$\frac{2}{3}a' + \frac{1}{3}a''$	$\frac{24}{25}a$
$\quad \quad \ ^2P_{\frac{3}{2}}$	0.375	a''	$2\frac{2}{3}a$

In (j,j) coupling the separation factor for the $6p_{1\frac{1}{2}}$ electron is denoted by a' and that for the $6p_{\frac{3}{2}}$ electron by a'' . In Russell-Saunders coupling it has no meaning to distinguish between the $6p_{\frac{3}{2}}$ and the $6p_{1\frac{1}{2}}$ states so one can only express the separation factor in terms of the common quantity, a . The quantities a' and a'' are not independent, for, according to the theory, one has the relations,

$$a' = \frac{8}{15} a \text{ and } a'' = \frac{8}{3} a, \text{ thus } a' = \frac{1}{5} a''.$$

The experimental data are not at all in agreement with these results. The last two states in the table, for which the formulas ought to hold, regardless of the type of coupling, show clearly that a' is much smaller than $1/5a''$. One finds from these two levels

$$\begin{aligned} a' &= 0.008 \\ a'' &= 0.375. \end{aligned}$$

These values do not agree exactly with those obtained from the first two levels of the table, but this may be ascribed to the deviation from the extreme (j,j) coupling. It is certainly significant that the $^2D_{1\frac{1}{2}}$ level shows a negative separation factor again indicating that a' is too small.

The next configuration of interest is $6p^27s$. The assignment of electron configuration in this case is not quite certain as this configuration is mixed with the $6p^26d$ levels. This also may cause large second order corrections which make our formulas invalid. The observed data for this configuration, which is near extreme (j,j) coupling, together with the formulas applying in (j,j) coupling are as follows:

Term	Observed separation factor	Formula (j,j) coupling
$6p^27s \ 1\frac{1}{2}$	0.166	$\frac{5}{6}a' - \frac{1}{6}a'' + \frac{1}{3}c$
$\quad \quad 4\frac{1}{2}$	~ 0	$1\frac{2}{3}a' - \frac{1}{3}a'' - \frac{1}{3}c$
$\quad \quad 5\frac{1}{2}$	-0.142	$\frac{2}{3}a' + \frac{1}{3}a'' + \frac{1}{3}c$
$\quad \quad 7\frac{1}{2}$	0.127	$\frac{9}{10}a' + \frac{3}{10}a'' - \frac{1}{5}c$
$\quad \quad 8\frac{1}{2}$	0.094	

Here the separation factor of the $7s$ electron is denoted by c . In this example the first level lies isolated from the others, hence one expects the formula to hold. The other levels form a group in which levels with $J = \frac{1}{2}$ and $J = 2\frac{1}{2}$ occur only once. For these two levels the formulas ought also to be correct. From these one obtains:

$$\begin{aligned}c &= 0.166 \\a' &= 0.026 \\a'' &= 0.390.\end{aligned}$$

These values are in fair agreement with the data for the two observed levels with $J=1\frac{1}{2}$. The value of a'' is in good agreement with what we obtain from the p^3 configuration. The value of a' agrees only in order of magnitude. However, we may not rely too much upon this value since it is so small that it may be much influenced by inaccuracy in the data as well as by second order corrections to our formulas. The significant point is that we again find a' to be much smaller than $1/5a''$.

Bismuth II. For the configuration $6p\ 7s$ we have extreme (j,j) coupling. The formulas and observed data for this case are:

Term	Observed separation factor	Formula (j,j) coupling
$6p_{1/2}7s\ 2_{1/2}^0$	0.391	$\frac{1}{2}a'' + \frac{1}{2}c$
$6p_{1/2}7s\ 9_{2/2}^0$	0.109	$\frac{3}{2}a' + \frac{1}{2}c$
$10_{1/2}^0$	-0.053	$1\frac{1}{2}a' - \frac{1}{2}c$

We expect the values of a' , a'' and c to be somewhat larger than in Bi I because the screening has decreased. This will have the greatest influence upon the outer $7s$ electron and therefore upon c . We find

$$\begin{aligned}a' &= 0.028 \\a'' &= 0.430 \\c &= 0.352\end{aligned}$$

These values are in good agreement with our expectation.

For other configurations, such as $6p\ 6d$ and $6p\ 7p$, we expect only qualitative agreement, as the separation factors for the $6d$ and $7p$ are probably smaller than the errors due to second order corrections to our formulas and errors in our measurements. In the case of the $6p\ 6d$ configuration we have:

Term	Observed separation factor	Formula (j,j) coupling
$6p_{1/2}6d_{1/2}\ 5_{2/2}^0$	0.127	$-\frac{1}{4}a'' + \frac{3}{2}d''$
$6_{1/2}^0$	-0.165	$-\frac{1}{4}a'' + 1\frac{1}{4}a''$
$6p_{1/2}6d_{2/2}\ 7_{2/2}^0$	0.099	$-\frac{1}{6}a'' + 1\frac{1}{6}d'$

Here the symbols d' and d'' denote the separation factors of the $6d_{2/2}$ and $6d_{1/2}$ electrons, respectively. The first two states give:

$$\begin{aligned}a'' &= 0.565 \\d'' &= -0.019\end{aligned}$$

It is strange to find a small negative value for d'' , but we do not know that this value is entirely reliable. The experiment result for $7_{2/2}^0$ would give a very large value for d' , which is even less understandable. Perhaps the assignment of the configuration is incorrect for this level.

As examples of the $6p\ 7p$ configuration we have:

Term	Observed separation factor	Formula (j,j) coupling
$6p_{1/2}7p_{1/2}\ 8_1$ 9_2	-0.101 0.125	$-\frac{1}{4}a'' + 1\frac{1}{4}e'$ $\frac{1}{4}a'' + \frac{3}{4}e'$

Here e' denotes the separation factor for the $7p_{1/2}$ state. We find:

$$e' = 0.012$$

$$a'' = 0.464.$$

Again a'' is in good agreement with what we expect.

For the $6p\ 5f$ configuration we have:

Term	Observed separation factor	Formula (j,j) coupling
$6p_{1/2}5f_{2\frac{1}{2}}\ 10_2$ 12_3	-0.008 -0.023	$-\frac{1}{6}a'' + 1\frac{1}{6}f''$ $\frac{1}{6}a'' + \frac{5}{6}f''$
$6p_{1/2}5f_{3\frac{1}{2}}\ 13_3$	0.065	$-\frac{1}{8}a'' + 1\frac{1}{8}f'$

Here f'' denotes the separation factor of the $5f_{2\frac{1}{2}}$ electron and f' that of the $5f_{3\frac{1}{2}}$ electron. These data give no sensible result. Perhaps the assignment of configuration is incorrect, or it may be that there are large second order effects due to the proximity of these levels to other even levels.

Bismuth III. The interesting configuration here is $6s\ 6p^2$. The hyperfine structure is known for three of the levels. For extreme (j,j) coupling, which may not be quite correct here, we have:

Term	Observed separation factor	Formula (j,j) coupling
$6s\ 6p^2\ 1_{1\frac{1}{2}}$ $2_{2\frac{1}{2}}$ $3_{2\frac{1}{2}}$	0.50 0.50 0.37	$\frac{5}{6}a' - \frac{1}{6}a'' + \frac{1}{3}b$ $\frac{2}{3}a' + \frac{1}{3}a'' + \frac{1}{3}b$ $\frac{2}{3}a' + \frac{1}{3}b$

The separation factor of the $6s$ electron is here denoted by b . The above data give us:

$$a'' = 0.66$$

$$a' = 0.01$$

$$b = 1.80.$$

Due to the fact that the screening is here much less than in the previous cases we find a'' to be larger than before. We cannot, of course, be sure that the value found is just the one expected without making complicated calculations as to screening effects. The value of a' is smaller than the uncertainty in measurement and therefore not reliable.

For the $7s$ configuration we find:

Term	Observed separation factor	Formula (j,j) coupling
$7s\ ^2S_{\frac{1}{2}}$	0.472	c

Comparing this value of c with the previous values we find the expected large increase. The experimental values for c are, Bi I:0.166; Bi II:0.352; Bi III:0.472.

We can make a similar comparison of the separations due to the $6s$ electron. The large hyperfine structure of the far ultraviolet lines $\lambda 864$ and $\lambda 1139$ observed by Arvidson¹⁰ is probably that of the $6s$ state of Bi V. Furthermore, one level of the $6s\ 6p^3$ configuration of Bi II is at present known. Assuming (j,j) coupling one obtains:

Term	Observed separation factor	Formula (j, j) coupling
Bi II $6s6p^3\ 4_2^0$	0.41	$\frac{3}{4}a' + \frac{1}{4}b$
Bi V $6s$	2.6	b

Since a' is of the order of 0.01 this gives $b=1.60$ for Bi II. Comparing the different values for b , we find, Bi II: 1.60; Bi III: 1.80; Bi V: 2.6.

CONCLUSIONS

The above discussion shows that in some respects the experimental results obey the theoretical formulas whereas in others there is distinct disagreement. It is possible to determine in more detail where the discrepancy lies. The formulas as they are given here in terms of a' and a'' explicitly are more or less independent of the type of interaction which causes the hyperfine splitting. One takes a given interaction for a definite state of a single electron and calculates by means of well-known methods the result when this electron is not alone but part of a more complicated configuration. Such formulas are based upon well-known quantum mechanical rules and can in many cases be derived by simple methods using the vector model. Similar ones have been shown to hold for multiplet separations, g -values, etc. It is therefore not surprising that the formulas are also valid here, for if they were not it would mean that ordinary perturbation theory could not be applied to our problem.

The discrepancy was found, however, in the relation between a' and a'' ,

$$a' = \frac{1}{5} a''.$$

Everywhere we find a' much too small. This relation, however, can be obtained only by considering in detail the interaction between the nuclear spin and the orbital and spin magnetism of the external electrons.¹¹ It is on this point that the present theory seems to be incorrect. We hope that the material gathered here may prove useful as a guide for the improvement of the quantum mechanics of spin-spin interaction.

POTENTIAL DROP AND IONIZATION AT
MERCURY ARC CATHODE

BY EDWARD S. LAMAR, PRINCETON UNIVERSITY

AND

KARL T. COMPTON, MASSACHUSETTS INSTITUTE OF TECHNOLOGY

(Received March 19, 1931)

ABSTRACT

By means of a movable Langmuir collector, the potential, ion concentration and electron temperature were measured at various distances from a stationary mercury cathode spot, at various arc currents. The results indicated a cathode drop of 10.0 volts, and a small negative potential gradient beyond the fall space which was more pronounced at the larger currents. The ion concentration varied between $2(10)^{13}$ and $3(10)^{11}$ cm^{-3} for distances between 0.4 cm and 1.7 cm and arc currents between 11 amp and 4.2 amp. The concentrations evidently greatly exceed these values very close to the cathode. The mean electron energies were about 1.4 volts near the cathode and fell to a little less than a volt at the greater distances. From the lack of saturation of currents to the collector at space potential, the coefficient of electron reflection at the amalgamated tungsten collector surface was found to be close to 0.5. It is shown that the thickness of the cathode fall space must be less than $1.76(10)^{-4}$ cm and that the field at the cathode surface must exceed $7.6(10)^4$ volts \cdot cm^{-1} .

INTRODUCTION

IN 1905, Stark and his collaborators¹ attempted by a probe wire method to measure the cathode fall of potential in a mercury arc, and their value of 5.27 volts has been accepted until quite recently. In 1924, Langmuir and Mott-Smith² pointed out a serious error in the old probe wire method, and developed a new method which not only gives accurate values of space potential, but also gives information regarding electron and ion concentrations and velocities. In 1928, Killian, at the suggestion of one of the authors, undertook an investigation of the potential drop and conditions of ionization near mercury arc cathodes. His results were reported at a meeting of the American Physical Society³ and were essentially as follows: The drop in potential from the cathode to a point distant 0.2 cm from its surface was 10.1 volts, and increased regularly to 11.6 volts as the distance was increased to 3.0 cm. The value of about 10 volts, as extrapolated to the cathode surface has been taken as significant of the ionizing potential of mercury within the limits of uncertainty set by the small unknown contact difference of potential between cathode and probe.⁴ Later work by Nottingham⁵ has led to similar conclusions

³ Killian, *Phys. Rev.* **31**, 1122 (1928).

⁴ Gaudenzi (*The Brown Boveri Rev.* **16**, 303 (1929)) estimated the cathode drop to be about 9 volts by a method which did not allow for the possibility of a positive or negative anode drop.

⁵ Nottingham, *J. Frank. Inst.* **206**, 43 (1928); **207**, 299 (1929).

in some arcs at higher pressures with various cathode materials. Killian furthermore found random currents of positive ions of 1.5 to 40 milliamps·cm⁻² and of electrons of 1.3 to 18 amps·cm⁻², the larger values referring to the regions closest to the cathode. The electron temperatures were 5000° to 16,500°K, or 0.65 to 2.13 volts mean energy.

In these measurements, the distances were measured from the cathode surface but do not represent true distances from the cathode spot, since it wandered rapidly and erratically all over the cathode surface. Killian there-

Fig. 1. Diagram of arc tube.

fore devised the apparatus described below in order to keep the cathode spot approximately stationary and thus to make possible more accurate measurements. Since Killian was diverted from carrying out these more refined experiments, the authors continued them as follows.

APPARATUS

A diagram of the arc tube is shown in Fig. 1. The cathode consists of three coaxial tubes. The innermost two are of Pyrex glass and constitute a water-cooling system for the cathode. The outside tube is of quartz and has a small hole drilled in its upper end. Mercury is raised to the level of this hole.

The surface of the mercury at the hole is the cathode of the arc. The small size of the pool cathode thus prevents excessive wandering of the cathode spot. The mercury outlet shown is designed to take care of the mercury that condenses on the walls of the tube and falls to the bottom.

The exploring electrode employed in the region of the cathode consists of a 60 mil tungsten wire entirely covered with glass, and then ground flat at its end. The resulting flat tungsten surface constitutes a plane collector, and the great mass of tungsten behind it makes its thermal dissipating power sufficiently great to prevent the excessive heating which has hitherto made measurements very near the cathode spot impossible. The flexible metal joint shown in the diagram permits an exploring range of about 2 cm.

The exploring wire shown near the anode is of the usual type consisting of a fine tungsten wire covered with glass over most of its length. The last few millimeters of glass are not in contact with the exploring wire. This prevents electrical contact between the exploring wire and any metal coating which may be deposited on the insulating glass.

The anode as shown is of the usual hollow cylindrical design and is made of sheet nickel.

PROCEDURE

The arc was started by means of a high frequency leak tester and the current was adjusted to the desired value by varying the resistance in series. The arc and series resistance were operated on 110 volts d.c.

The experimental procedure, after the arc had become steady, was to measure the current to the collector for different voltages applied to it at various distances from the cathode. At any given position, a plot of $\log i$ vs. V where i is the electron current to the collector and V the potential of the collector with respect to the cathode generally showed the points to be scattered between two parallel lines a half volt apart. This scattering of the points was found to arise from changes in the nature of the surface of the collector which resulted in changes in the contact difference in potential and depended on the immediately previous history of the collector. It was found that consistent results were obtained if the collector was left 100 volts negative with respect to the anode except when a reading was actually being made. Under these conditions the points fell along a curve at the lower voltage limit mentioned above, indicating a low value for the work function of the surface.

The curves shown are plotted to this lower value, which is believed to be the correct value, for reasons indicated below. Since the collector is always covered with a thin visible film of mercury, there is no further correction necessary for contact difference of potential between collector and mercury cathode.

A typical collector curve is shown in Fig. 2.

INTERPRETATION OF SHIFT IN COLLECTOR POTENTIAL

We were at first inclined to attribute the shift in collector potential, when its potential to space was changed from large negative values to small negative or positive values, to a slow deposit of alkali material coming perhaps

from the neighboring glass and depositing as ions when the collector is negative. In this case the upper curve (characteristic of the collector in its more electronegative state) would presumably be that characteristic of an uncontaminated surface and, if so, the correct values would be 0.5 volt higher than those of Fig. 2. This was our opinion at the time of our preliminary report to the American Physical Society (Washington Meeting April 24, 1930), when we reported as our best estimate that the cathode drop is equal to the minimum ionizing potential 10.4 volts. Now, however, we are inclined to interpret the results differently, and to use the lower value of potential for the following reasons.

Fig. 2. Curve showing logarithm of electron current i as a function of collector potential V_c with respect to cathode. V_s is space potential and r indicates the amount of electron reflection.

After remaining 100 volts negative for a short time, surface impurities should be sputtered off by positive ion bombardment, leaving a clean collector surface. Hence the measurements made just after this should be those characteristic of the clean surface. Furthermore Found and Langmuir (unpublished) in extending earlier work by Kenty and Turner,⁶ found that oxygen layers could form slowly on tungsten collectors even in very pure gas, causing electronegative potential shifts of about 0.5 volts in the surface potential. We think it probable, therefore, that the lower voltage values are the correct ones, indicating the value of the cathode drop to be about 9.9 volts.

INTERPRETATION OF EXPERIMENTAL RESULTS

These and similar curves are interpreted by the collector theory of Langmuir and Mott-Smith, which is now too well known to require comment further than to give the equations which we shall use:

⁶ Kenty and Turner, Phys. Rev. 32, 799 (1928).

$$I = I_0 e^{-eV_c/kT}, \quad I_0 = Ne \left(\frac{kT}{2\pi m} \right)^{1/2}, \quad i = AI$$

where I is the electron current density to the collector whose potential is $-V_c$ with respect to the space, I_0 is the random electron current density, N and T are the electron concentration and temperature, respectively, and A is the collector area. From these equations we have:

$$\log i = \log AI_0 - \frac{eV_c}{kT} = \log ANe \left(\frac{kT}{2\pi m} \right)^{1/2} - \frac{eV_c}{kT}$$

which is the equation of the straight portion of the curve of Fig. 2, when V_c is taken to be the value of V measured from the point of discontinuity which is at space potential V_s . The fact that the curve to the left of the discontinuity is straight, proves that the electrons have a Maxwellian distribution of velocities, which is assumed in the above equations.

It is observed that the electron current to the collector does not reach its maximum value at space potential, but only when the collector is a few volts positive with respect to space. This is attributed to electron reflection from the collector, and the intervening curve depends on the distribution of velocities of the reflected electrons. Such reflection, which is a well-recognized phenomenon, does not affect the slope of the straight line to the left of the break, since it is a peculiarity of a Maxwell distribution that it is not altered by a retarding field and hence the fraction of electrons reflected is constant at all values of the retarding field. The effect of reflection on the straight portion of the curve is thus simply to depress it, parallel to itself, by an amount dependent on the reflection coefficient.

This reflection coefficient may be obtained from Fig. 2 as follows. The electron current has reached saturation at about 4 volts above space potential, indicating that practically no reflected electrons can escape against as much as 4 volts. The difference between this saturation current and the current at the discontinuity represents the current of reflected electrons, and is shown by r in Fig. 2. The ratio of this reflected current to the total saturation current gives the reflection coefficient R . Owing to the foreshortening of the logarithmic scale, these values of R are determined with less experimental accuracy than the other quantities in which we are interested.

The more important results of the measurements are shown in Figs. 3 and 4. The mean electron energy \bar{V} was calculated from the relation

$$\frac{e\bar{V}}{300} = \frac{3}{2}kT$$

and represents the mean energy of the electrons in a given volume. For the mean energy of the electrons striking the collector, the fraction $3/2$ should be replaced by 2.

The data shown in Figs. 3 and 4 were all obtained with an arc carrying 4.2 amps. Similar observations on an 11.0 amp. arc yielded results which, for comparison, are shown in Table I.

Fig. 3. Space potential V_s with respect to the cathode and electron concentration N as functions of the distance d from the cathode spot to the center of the face of the 60 mil (0.15 cm) diameter collector. Arc current 4.2 amp.

Fig. 4. Mean electron energy \bar{V} in equivalent volts and reflection coefficient R as functions of distance d from cathode spot to collector. Arc current 4.2 amp.

TABLE I. V_s = space potential; N = electron concentration; \bar{V} = mean electron energy; I = random electron current density; d = distance from cathode.

$d(\text{cm})$	4.2 amp. arc		11.0 amp. arc	
	0.43	1.75	0.39	1.71
V_s (volts)	10.0	9.8	10.2	8.9
I (amp. $\cdot \text{cm}^{-2}$)	5.7	7.4	63.5	12.8
N (10^{-11})	17.1	2.8	218.	55.3
\bar{V} (volts)	1.42	0.978	1.171	0.748

DISCUSSION OF EXPERIMENTAL RESULTS

Cathode drop. From such results we conclude that the cathode drop is very near to 10 volts, from the nearest point at which we can measure (or extrapolate) to the cathode. Of course what we really wish to know is the cathode drop across the cathode fall space alone, which is an extremely small distance. This distance has never been measured, but may be estimated roughly as follows: The relations in the cathode fall space are given by the space-charge equation

$$I_+ = 0.543(10)^{-7} \frac{V_c^{3/2}}{M^{1/2} d_c^2}$$

in ordinary electrical units. The current density at the cathode⁷ is about 4000 amp. $\cdot \text{cm}^{-2}$. Langmuir and Mott Smith⁸ have shown that a negative electrode immersed in strongly ionized mercury vapor collects a positive ion current of about 1/400 of the "random" electron current, which in turn is always larger than the "drift" (or actual discharge) current. Since the drift current density is 4000 amp. $\cdot \text{cm}^{-2}$, the positive current density is therefore something greater than 1/400 of this, i.e., greater than 10 amp. $\cdot \text{cm}^{-2}$. Unfortunately we cannot say how much greater than this lower limit is the true value of the positive current. Two factors may increase it by considerably more than the factor of three or four which commonly represents the ratio of random to drift current in regions of uniform ionization. One of these is the enormous concentration of electrons and ions in the region of negative glow on account of the potential maximum which develops in this region of intense ionization, and the consequent "trapping" of electrons to build up large concentrations, and the other is the additional trapping action due to the fact that the cathode spot is a depression in the mercury surface and presents therefore the peculiarities of a hollow cathode.

Perhaps the positive ion currents may be ten, though probably not a hundred times the value given by the fraction 1/400.⁹ Using this as a lower limit, and taking $V_c = 10$ volts and $M = 200$, we find

$$d_c < 1.76(10)^{-4} \text{ cm.}$$

⁷ Güntherschulze, Zeits. f. Physik 11, 74 (1922).

⁸ Langmuir and Mott-Smith, G.E. Rev. 27, 544 (1924).

⁹ From the theory of collectors in ionized gas (Tonks and Langmuir, Phys. Rev. 34, 876 (1930)) it is impossible that the positive current density at the cathode spot can be less than

Field at cathode. Given a cathode drop of 10 volts in a distance less than $1.76(10)^{-4}$ cm, we calculate the average field in the fall space to be greater than $5.7 (10)^4$ volts·cm⁻¹. By the simple space-charge equation it is easily shown that the field E_c at the cathode surface is $4/3$ the mean field, or

$$E_c > 7.6(10)^4 \text{ volts} \cdot \text{cm}^{-1}.$$

It appears unlikely that the field can be as much as ten times this value, since this would require an ion current one hundred fold that on which the calculation is based. These results are not appreciably affected if we use the more refined equations of Mackeown¹⁰ to calculate the value of d_c .

Of course the cathode surface is highly agitated and consequently rough. Thus the fields to points may greatly exceed the values calculated above, and may very likely attain values of the order of millions of volts per centimeter. Langmuir¹¹ has already pointed out that fields of this magnitude are probably adequate to account for the observed electron emission from the cathode spot as "autoelectronic" emission, or "field current".

In the absence of information regarding the behavior of a fresh mercury surface in autoelectronic emission and in view of the uncertainty regarding the field strength at the cathode, it appears hopeless to make a direct quantitative test of this theory of emission from the cathode spot. Further evidence, however, is afforded in a revision of earlier studies of heat balance, as given in the following paper.

this. According to one theory it might be much greater (the theory of thermal ionization of the vapor by Slepian, *Phys. Rev.* **27**, 407 (1926)). As shown in the following paper, however, there are not only serious theoretical objections to this theory, but the experimental evidence based on heat balance at the cathode is inconsistent with it, and points to the correctness of the assumption that the relative current densities are at least of the order of those to be expected if the cathode acts toward the positive ions simply as a collecting electrode.

ON THE THEORY OF THE MERCURY ARC

BY KARL T. COMPTON

MASSACHUSETTS INSTITUTE OF TECHNOLOGY

(Received March 19, 1931)

ABSTRACT

The theory of *heat balance at the cathode* is extended (1) by the introduction of the accommodation coefficient of neutralized ions, (2) by evaluation of all processes which absorb the energy gained by electrons in the cathode fall space, and (3) by correction of a previous assumption that fields sufficient to extract electrons will affect the heat of neutralization of positive ions at the surface. Test of the two resulting equations by existing experimental data shows that *Langmuir's theory* of extraction of electrons by the field at a Hg arc cathode is consistent with the cathode heat equations, but cannot be uniquely proved by them on account of uncertainty in two factors whose order of magnitude only is known: the fraction F of energy brought to the cathode by un-electrified carriers, $1.0 > F > 0.5$; the fraction $1/(1+\delta)$ of positive ions formed near the cathode which go to it, $1 > \delta > 0$.

From the net rate of evaporation an equation is obtained between vapor pressure and temperature at the cathode which, when combined with the vapor pressure-temperature equation of Hg, gives uniquely the *temperature of the cathode spot* and the *vapor pressure* outside it, provided the fraction f of total current carried by electrons is known. It is shown that the temperature of the cathode spot does not exceed 200°C , and that *the thickness of the cathode fall space is less than the electron mean free path*.

It is shown that *ionization* just beyond the cathode fall space must be of the *cumulative, multiple stage type*. From this it is shown that the fraction f must exceed 0.67 (if $\delta=0$) or 0.80 (if $\delta=1$), since these minimum values depend on 100 per cent efficiency of two stage ionization.

Mechanical pressure against the cathode by the arc is explained by the fact that the accommodation coefficient a is less than 1.0. If this accommodation coefficient of Hg ions at a liquid Hg surface should be independently measured, it would give an independent method of estimating the important fraction f .

The paper points out the causes of present limitations in our knowledge of conditions at the arc cathode and also the manner in which, and the extent to which, these limitations may be removed.

INTRODUCTION

THE early theory of Stark¹ that the current at mercury arc cathodes is of thermionic origin has been pretty thoroughly disproved by the fact that the evaporation of mercury is far too slow to justify an assumption of temperatures requisite for thermionic emission. Similarly a theory of Slepian² that the current at the cathode is carried by positive ions created by thermal ionization of the vapor just outside the cathode fails to suggest any physical mechanism for the input of energy into this assumed high temperature region. The theory at present in vogue is that of Langmuir,³ who postulates "field currents" caused by the strong field which is concentrated at the

¹ Stark, Ann. d. Physik 12, 692 (1903).

² Slepian, Phys. Rev. 27, 407 (1926).

³ Langmuir, Science 58, 290 (1923); G. E. Rev. 26, 735 (1923).

cathode by the processes described by Poisson's equation, and whose minimum value was calculated in the preceding paper to be at least $7.6 (10)^4$ volts \cdot cm $^{-1}$.

A difficulty in any theory depending primarily on electron emission from the cathode has been found in attempting to calculate from the heat balance at the cathode the fraction of the current carried by electrons, since such attempts have led consistently to values of this fraction which are too small to reconcile with the necessary amount of ionization, in view of the small cathode drop. For example, substituting direct experimental values of observable quantities in the heat balance equation has led to the conclusion that about 50 per cent of the current at the cathode is carried by electrons. Certain reasonable modifications have raised this to about 70 percent. By straining every possible factor, this proportion has been raised to about 87 percent. These values are all too small to reconcile with the fact that the cathode drop is only about 10 volts (see the preceding paper by Lamar and Compton); for 50 percent current carried by electrons would require 100 percent efficiency of ionization by them in order to obtain an equal number of positive ions to carry the remaining half of the current at the cathode. Even 87 percent would require at least 12 percent efficiency of ionization, which is still far in excess of any observed efficiencies of ionization by impact of electrons whose energy is near the minimum ionizing energy 10.4 volts.

The present paper presents some new considerations of heat balance which make it compatible with Langmuir's theory, and at the same time lead to a much more definite picture of the physical conditions in the mercury arc than has previously been possible.

It may be remarked, in passing, that the entire problem of the mercury arc is concentrated at the cathode, since the work of Langmuir and Mott-Smith,⁴ Tonks and Langmuir,⁵ Eckart and Compton,⁶ and Killian⁷ have essentially explained all other regions of a low pressure arc.

HEAT BALANCE AT CATHODE

The two earliest attempts to use heat balance to investigate cathode conditions were quite unsatisfactory, the one⁸ because of faulty reasoning and the other⁹ because of lack of essential experimental data. Later refinements¹⁰ have been made both in the theory and the experiments. It will be seen in the following paragraphs, however, that there are so many factors which have not previously been considered that no validity attaches to any of the conclusions thus far drawn from arguments based on heat balance.

⁴ Langmuir and Mott-Smith, *G. E. Rev.* **27**, 449, 538, 616, 762, 810 (1924).

⁸ Güntherschulze, *Zeits. f. Physik* **11**, 74 (1922).

⁹ Compton, *Phys. Rev.* **21**, 266 (1923).

¹⁰ Güntherschulze, *Zeits. f. Physik* **31**, 509 (1925); Seeliger, *Phys. Zeits.* **27**, 22 (1927); *Elektrotech. Zeits.* **49**, 853 (1927); Compton and Van Voorhis, *Proc. Nat. Acad. Sci.* **13**, 336 (1927); Issendorff, *Phys. Zeits.* **29**, 857 (1928).

We shall express the condition of thermal equilibrium by setting the total net rate of generation of heat at the cathode equal to zero, expressing each contributing item of heating or cooling in terms of watts per ampere of current. We shall let f equal the fraction of current carried at the cathode by electrons, and $(1-f)$ the fraction carried by positive ions. The processes involved in the heat balance are schematically indicated in Fig. 1 and will be discussed briefly in order.

(1) *Heating by impacting positive ions.* These ions acquire energy V_c in falling through the cathode potential drop V_c . Since the thickness of the fall space is certainly less than $1.76 (10)^{-4}$ cm and since, as we shall see below, the ionic mean free path is considerably greater than this, we are justified in neglecting collisions of ions with vapor molecules while passing through this

Fig. 1.

fall space. Thus the entire energy V_c is available for delivery to the cathode. To this should be added the average initial kinetic energy of the ions just before they enter the fall space. Tonks and Langmuir⁴ have shown that this is negligibly small.

It is not obvious, however, that all this kinetic energy is delivered to the cathode. Let a be the fraction of it which is thus delivered, while $(1-a)$ is the average fraction which is retained by the neutralized ion after impact. This quantity a is the "accommodation coefficient" which is well known in phenomena involving the impact of gas molecules against a surface of different temperature¹¹ and whose existence in cases of ionic impact has been demonstrated by Van Voorhis and Compton.¹²

¹¹ Knudsen, *Ann. d. Physik* **34**, 593 (1911); **46**, 641 (1915); Langmuir, *J. Am. Chem. Soc.* **37**, 425 (1915); Compton and Langmuir, *Rev. Mod. Phys.* **2**, 184 (1930).

¹² Van Voorhis and Compton, *Phys. Rev.* **35**, 1438 (1930); detailed paper in preparation for physical Review.

Finally, there is the "heat of neutralization" of the positive ion, denoted by ϕ_+ , whose value has been shown by an argument involving a simple cycle¹³ to be $\phi_+ = V_i - \phi_- + (L)$, where V_i is the ionizing potential of the gas molecule, ϕ_- is the electron work function of the cathode surface, and L is the heat of condensation of the neutral molecule on the cathode surface. L should be used if the ion is actually condensed on the surface, but should otherwise be omitted. In our present problem L is completely taken care of in process (4) (Fig. 1).

In case the field appreciably reduces the work function (as in Langmuir's theory it reduces it to zero) it has previously been assumed that the reduced value should be used in this equation, i.e., that if the field changes the cooling effect of electron emission it will also affect the heating effect of positive ion neutralization. This is, however, not the case, as is easily shown by the following argument.

Fig. 2.

A positive ion, starting outside the cathode fall space and moving to the cathode delivers energy $V_c + \phi_+$, as indicated to the left in Fig. 2. An equivalent process is shown to the right. An electron escapes from the metal, cooling it by the amount ϕ_- . By the time it has passed through the fall space its kinetic energy is $V_c - \phi_0 + \phi_-$, where ϕ_- is the "effective" work function while ϕ_0 is the normal work function in the absence of an accelerating field. This is obvious since $(\phi_0 - \phi_-)$ is that part of the work done against the surface forces of the metal which is done by the applied field and ϕ_- is that part done at the expense of initial kinetic energy of the electron. If emission is purely thermionic, then $\phi_- = \phi_0$, whereas if emission is purely autoelectric (as in Langmuir's theory) then $\phi_- = 0$.

Now if this electron combines with a positive ion, there is liberated additional energy V_i , and there is a further liberation of amount L when the neutralized particle condenses on the metal.

¹³ Compton, Phys. Rev. 21, 281 (1923); Schottky and Issendorff, Zeits. f. Physik 26, 85 (1924).

Equating the net liberation of energy in the two equivalent processes gives $V_c + \phi_+ = V_i + V_c - \phi_0 + \phi_- - \phi_- + L$, whence

$$\phi_+ = V_i - \phi_0 + L.$$

Thus the heating effect by positive ions is unaffected by the field, even though the cooling effect by escaping electrons is diminished. Physically this is easily explicable, since the cooling effect is due to the fact that only those electrons escape which, while inside the metal, possess greatest kinetic energy, a situation which has no counterpart in the process of neutralizing a positive ion.

In this equation $\phi_+ = V_i - \phi_0 + (L)$, it is implicitly assumed that all the energy developed by the process is retained in the cathode, which would not be the case, for example, if a fraction $(1-r)$ of it were radiated away in the process of neutralization. Compton and Van Voorhis therefore suggested¹⁴ the modification $\phi_+ = rV_i - \phi_0 + (L)$, and announced experimental results indicating that $r \sim 0.5$. They later found,¹² however, that these results were due to the then unsuspected existence of an accommodation coefficient, so that there is no actual experimental measurement of r . From the fact, however, that direct measurement of the radiation from the cathode spot (process (3) Fig. 1) shows this to be almost negligible, it is evident that r is practically unity. Whatever error may be introduced in taking $r=1$ will be exactly corrected by introduction of the experimental value of heat loss by radiation in process (3).

Combining all these considerations, we have for process (1)

$$H(1) = (1-f)(aV_c + V_i - \phi_0)$$

(2) *Cooling by electron emission.* This process of cooling is too well known to require comment, since it is well known that the electron work function ϕ_- is a latent heat of evaporation. Expressing it as a negative heating process, we have

$$H(2) = -f\phi_-$$

(3) *Cooling by radiation* is expressed directly, in terms of the observed radiated energy per ampere·sec., by $H(3) = -R$.

(4) *Cooling by evaporation* of the material of the cathode is similarly expressed by $H(4) = -E$, in which E is the product of the mass of material evaporated per ampere·sec multiplied by its latent heat of evaporation.

(5) *Cooling by gas conduction and convection* is $H(5) = -C'$.

(6) *Cooling by conduction through the cathode* is $H(6) = -C$.

(7) *Heating by an external agency*, if any, is represented by $H(7) = H$.

(8) *Heating by energy derived by electrons in the cathode fall space and indirectly returned to the cathode* can be calculated as follows. The work done on an escaping electron is V_c . If part of this work is done in pulling the electrons out of the metal (as in Langmuir's theory), this part may be expressed by

¹⁴ Compton and Van Voorhis, Proc. Nat. Acad. Sci. 13, 336 (1927).

$(\phi_0 - \phi_-)$, where ϕ_0 is the ordinary electron work function for negligibly small accelerating fields, and ϕ_- is the actual or "effective" work function. Thus the energy with which each electron is projected out of the cathode fall space is $V_c - \phi_0 + \phi_-$.

Of the total energy $f(V_c - \phi_0 + \phi_-)$ thus fed into the vapor, $(1-f)V_i$ must be used to produce the $(1-f)$ positive ions which return to the cathode. We shall see below that altogether $(1+\delta)$ times this number of ions must be formed, where $0 < \delta < 1$, since some of the ions are formed beyond the region of potential maximum and drift toward the anode, ultimately recombining. δ is the ratio of the number of ions thus going toward the anode to the number going toward the cathode. Thus we have $(1+\delta)(1-f)V_i$ energy used in producing positive ions.

Furthermore the probe electrode measurements prove that the electrons in the negative glow near the cathode possess a considerable mean kinetic energy \bar{V}_- . Thus the energy fed into the vapor by electrons from the cathode, which is not expended in producing ions or retained by the electrons, is $f(V_c - \phi_0 + \phi_-) - (1+\delta)(1-f)V_i - \bar{V}_-$, where the factor f does not multiply \bar{V}_- since we know that in the negative glow the fraction of current carried by electrons is unity within a fraction of a percent.

Let F represent that fraction of the energy, acquired by *unelectrified* carriers from the electrons which have moved through the fall space, which returns to the cathode (as by radiation, metastable and excited atoms, high temperature neutral atoms). We have already allowed in process (1) for the energy which is brought back by positive ions, and of course none is brought back by electrons. This remaining source of heating of the cathode is therefore given by

$$H(8) = F[f(V_c - \phi_0 + \phi_-) - (1+\delta)(1-f)V_i - \bar{V}_-].$$

Equilibrium. Equating to zero the sum of all these eight contributions to the heating, and solving for f , we obtain

$$f = \frac{aV_c + V_i - \phi_0 - (R + E + C + C' - H) - F[(1+\delta)V_i + \bar{V}_-]}{aV_c + V_i - \phi_0 + \phi_- - F[V_c - \phi_0 + \phi_- + (1+\delta)V_i]} \quad (1)$$

Supplementary relation. The above expression for $H(8)$ gives us another clue to the value of f . The expression in brackets is the amount of the energy with which the electrons are shot into the vapor which is not retained by them or used in ionization. It must of necessity be greater than zero, since we know that a considerable portion of such energy is used, for example, in producing metastable or other excited atoms. In fact, we shall later discuss reasons for believing that the ionization is principally of the two stage or cumulative type. Thus from $f(V_c - \phi_0 + \phi_-) > (1+\delta)(1-f)V_i + \bar{V}_-$, we find

$$f > \frac{(1+\delta)V_i + \bar{V}_-}{V_c - \phi_0 + \phi_- + (1+\delta)V_i} \quad (2)$$

Values of the terms are given in Table I.

TABLE I.

Quantity	Value	Reference
V_c	10 volts	Lamar and Compton ¹⁵
V_i	10.4	Well known
ϕ_0	4.5	Kazda ¹⁶
R	0.04	Güntherschulze ¹⁰
E	2.21-0	" (see below)
C	2.68	"
C'	0.0	"
H	0.0	No external heating
\bar{V}_-	1.5	Lamar and Compton ¹⁵
ϕ_-	0-4.5	(see below)
F	0.5-1.0	"
a	1-?	"

$E=2.21$ is based on measurements by Güntherschulze of the rate of loss of mass of the cathode, together with the latent heat of evaporation of mercury at 123°C. However, Compton and Van Voorhis suggested¹⁴ that some of the mercury may be lost as a spray thrown out mechanically by the agitation of the surface. Such loss would not involve cooling. Issendorff¹⁷ has verified this experimentally and has shown that the actual amount of true evaporation from the cathode spot is practically negligible as a cooling process. (Much of the spray is subsequently volatilized in the arc stream by heat developed by recombination of electrons and ions on the surfaces of the droplets, but this is not a process which cools the cathode.) It appears from this that the true value of E lies much closer to 0 than to 2.21. As to the assumed temperature of 123°C, see discussion later in the paper.

$\phi_- = 0$ to 4.5, depending on the extent to which the emission is due to the field, being 0 if due entirely to the field. Perhaps a rough approximation to the right value is given by finding the effective work function which would give thermionic emission of 4000 amp·cm⁻² at 123°C, which is $\phi_- = 0.31$ volt.

F has a more restricted significance than in previous discussions owing to the more complete character of the present analysis. If the energy carried back to the cathode by unelectrified carriers is in the form of unabsorbable radiation, we should expect $F=0.5$, since the cathode subtends half the solid angle about the origin of radiation, or less than 0.5 if there is reflection at the cathode surface. Actually, however, we know such radiation to be small (see Table I). If the energy gets back by any diffusion process, as by metastable atoms or by resonance radiation, then much more than half the energy will return to the cathode since the mean free path of the diffusing particles is considerably less than the distance from the cathode to other boundaries of the vapor. Since this condition is amply fulfilled in the mercury arc, we have $1.0 > F > 0.5$, and it is extremely probable that F is very nearly equal to 1.0.

a has not been measured for mercury, but we should expect it to be $1.0 > a > 0.9$, since in other gases a approaches unity with increasing atomic weight.

¹⁷ Issendorff, Phys. Zeits. 29, 857 (1928).

Results for the various assumptions are given in Table II. Note first that f_2 involves the uncertain factors δ and ϕ_- and depends only on the direct application of the Energy Principle. Note also that the known fact that impact ionization processes are never very close to 100 percent efficient shows that the true value of f must be *considerably* larger than the lower limit set by f_2 . The values in parentheses are impossible values either because $f_1 < f_2$, or because f_1 is negative or greater than unity.

TABLE II. $f_1=f$ by Eq. (1); $f_2=f$ by Eq. (2).

Conclusions. A survey of Table II shows, first of all, the futility of attempting to determine the fraction f by heat balance methods, since the unknown parameters E , a , F , leave a great range of possibilities. Nevertheless some interesting information can be obtained.

Obviously no adjustment of ϕ_- , a , F , δ will give possible results if E is as large as Güntherschulze's value 2.21, which checks the later estimates described above, which make $E \ll 2.21$.

It is probably hopeless to try to measure F and δ . Physical considerations, mentioned above, however, place $1.0 > F > 0.5$ (with F probably nearer 1.0 than 0.5). Similarly we shall see that $1.0 > \delta > 0$.

With these possibilities in mind, we see from Table II that the most probable values of f arise from cases where *both the numerator and denominator of Eq. (1) are negative*,—which means that a very appreciable role is played by the heating effect of energy which reaches the cathode by unelectrified carriers, an observation which is suggestive of a considerable concentration of

metastable atoms and of cumulative ionization. More direct evidence of this appears later in the paper.

In the light of this study it seems hopeless to prove or disprove the Langmuir theory by heat balance arguments. *This analysis shows for the first time, however, that the heat balance may be made consistent with Langmuir's theory and with the known facts of ionization* by making the most reasonable assumptions regarding the unknown factors F and δ . In order to make the considerations still more precise, it is important to measure the accommodation coefficient a for Hg ions at a Hg surface and to obtain a more reliable estimate of evaporation E under conditions in which the other thermal quantities are also measured. Thus we may assume Langmuir's theory, with its very small value of ϕ_- , on the basis of its reasonable character and the absence of evidence for any other adequate mechanism.

TEMPERATURE AND VAPOR PRESSURE AT CATHODE

The temperature and vapor pressure at the cathode can be calculated if the rate of evaporation from the cathode is known. Early attempts to measure this led to erratic and large values. Schaefer¹⁸ found $36.7 (10)^{-3} \text{ g} \cdot \text{amp} \cdot \text{sec}^{-1}$, and Güntherschulze¹⁹ $7.2 (10)^{-3} \text{ g} \cdot \text{amp} \cdot \text{sec}^{-1}$. Compton and Van Voorhis' suggestion¹⁴ that these large values arise from mechanical spray was verified by Issendorff,¹⁷ who found $<1.3 (10)^{-3} \text{ g} \cdot \text{amp} \cdot \text{sec}^{-1}$. Recently Kobel¹⁹ devised a means for holding the cathode spot quiescent and found the rate of evaporation to be $0.017 (10)^{-3} \text{ amp} \cdot \text{sec}^{-1}$. Since this lies within Issendorff's limits, and since a quiescent spot would be expected not to eject spray, we shall take this as the best value at present available. (The device for holding the spot quiet may have made this value too small, but several considerations indicate that such an error is small, if present.) Kobel's average current density was $1912 \text{ amp} \cdot \text{cm}^{-2}$, hence the rate of evaporation was $0.0325 \text{ gm} \cdot \text{cm}^{-2}$.

It must be observed, however, that these values refer only to the *net* rate of escape of Hg atoms. The true rate of evaporation is larger than this, but a certain portion of the evaporated atoms return to the cathode as ions. The true rate of evaporation M can be equated to the observed rate M_0 plus the rate of return of ions to the cathode, which is $0.00209 (1-f) \text{ g} \cdot \text{amp} \cdot \text{sec}^{-1}$. (0.00209 is the electrochemical equivalent of Hg). If we express this in terms of evaporation per cm^2 , we have

$$M = M_0 + 0.00209(1 - f)j, \quad (3)$$

where j = current density. From the familiar kinetic theory relations

$$n = \frac{1}{4}N\bar{v}, \quad p = \frac{1}{3}Nm\bar{v}^2 = NkT, \quad M = nm$$

we find

$$p^2 = \frac{16}{3} \frac{M^2 kT}{m} \text{ dynes} \cdot \text{cm}^{-2}, \quad (4)$$

where m is the mass of an atom in grams.

¹⁸ Schaefer, Diss. Darmstadt (1910).

¹⁹ Kobel, Phys. Rev. 36, 1636 (1930).

If the experimental values of M from Eq. (3) are substituted into Eq. (4), an infinite number of pairs of possible values of pressure p and temperature T is found. Only one of these pairs of values, however, satisfies the vapor pressure relation between p and T . Thus Eq. (4) together with the vapor pressure equation, serve simultaneously to fix unique values of T and p . This value of T is the temperature of the cathode spot and from p and T we can find the value of atomic and electronic mean free paths just outside the cathode.

Fig. 3.

Here, as before, uncertainty in f prevents us from drawing definite conclusions, but here again we can set certain limits with considerable assurance. If ionization is cumulative in two stages, not more than one ion can be formed

TABLE III.

f	p	T	$\lambda(\text{electron})^{20}$	d_e
1.00	0.75 mm	123°C	0.0026 cm	(0.000176) cm
0.95	5.4	167	0.00033	0.000039
0.80	19.6	202	0.000084	0.000019

²⁰ Constants from Compton and Langmuir, Rev. Mod. Phys. 2, 208 (1930).

for every two electrons, and if half the ions move toward the anode, recombining ($\delta = 1$), we must have $f > 0.8$. Table III shows the results of three assumptions, the values being taken from Fig. 3. For comparison there are shown also the corresponding values of thickness of cathode fall space, calculated as in the preceding paper.

Three important facts are derived from this consideration of rate of evaporation: (1) the surface temperature of the cathode spot cannot exceed about 200°C ; (2) the vapor pressure there is considerably less than the value of about one atmosphere recently assumed;²¹ (3) the electron mean free path is, in any case, considerably longer than the thickness of the cathode fall space, a fact which justifies several simplifying assumptions such as the applicability of the simple space-charge equation in the fall space.

Question of high-speed ejection of vapor. Tangberg²² for a copper arc and Kobel¹⁹ for a mercury arc have called attention to the relatively large pressure on the cathode spot and have interpreted it as indicating very high speeds of evaporating atoms, speeds characteristic of temperatures of the order of $500,000^\circ\text{K}$! Among the physical difficulties of this interpretation may be mentioned the inconsistency between such a temperature and the observed rate of evaporation which, as we have seen, indicates a surface temperature of not more than 200°C . Compton²³ suggested that a more reasonable interpretation of this pressure is to be found in the existence of an "accommodation coefficient" for ions which strike and are neutralized at the surface—this accommodation coefficient having been inferred for He, Ne and A ions from thermal measurements at cathodes by Van Voorhis and Compton¹² and later measured directly for He ions by Lamar.²⁴

For the mercury arc, the pressure resulting from an accommodation coefficient $a < 1.0$ may be calculated thus, per cm^2 :

Positive ion current at cathode	$j(1-f)$ amp.
Mass of positive ions striking cathode per sec. . .	$0.00209 j(1-f)$ g
Number of positive ions striking per sec.	$0.63(10)^{19} j(1-f)$
Kinetic energy of incident ion	$1.59(10)^{-11}$ erg
Total kinetic energy of ions striking per sec. . .	$1.00(10)^8 j(1-f)$ erg
Total kinetic energy of neutralized ions leaving cathode per sec.	$1.00(10)^8 j(1-f) (1-a)$ erg
Total momentum of neutralized ions leaving cathode per sec.	$647 j(1-f) (1-a)^{1/2}$ dyne.

This last quantity is the pressure, provided the neutralized ions leave normally to the surface. We should rather expect the escaping neutralized ions to be scattered in all directions, and in fact Lamar's results indicate this

²⁴ Lamar (to be reported at Washington Meeting of the Amer. Phys. Soc.) and published in the *Physical Review*.

in the case for He ions. In this case we must use the mean normal component of momentum, which gives just half the above values. We thus have

$$\begin{aligned} p &= 0.66j(1-f)(1-a_n)^{1/2} \text{ g} \cdot \text{cm}^{-2} \\ p &= 0.33j(1-f)(1-a_r)^{1/2} \end{aligned} \quad (5)$$

depending on whether we assume a_n (normal escape) or a_r (random escape).

Kobel's results gave an average pressure of 5.75 cm Hg (78.2 g·cm⁻²) on the cathode spot whose average current density was 1912 amp·cm⁻². Substituting these values in Eq. (5) we obtain the relations shown in Table IV.

TABLE IV.

f	0.50	0.60	0.70	0.80	0.90
a_n	0.985	0.98	0.96	0.90	0.62
a_r	0.95	0.92	0.84	0.60	(—)

Since, as we have seen, experimental evidence points to a_r rather than a_n , we see that this analysis suggests that the accommodation coefficient a for Hg ions is less than the value, nearly unity, suggested by its high atomic weight, taken in conjunction with the known values of a for He, Ne and A. This again emphasizes the desirability of making a direct measurement of a for Hg ions.

MECHANISM OF IONIZATION

The fact that the cathode drop is so constantly close to 10 volts, independently of current, vapor pressure, etc., over the entire range in which a Hg arc can be struck from a liquid Hg cathode, suggests that this value is fixed by some characteristic process in the arc mechanism. It has been quite generally assumed that this process is the ionization of the Hg atoms by electron impact, and that the significance of 10 volts is, roughly, the ionization potential 10.4 volts. There are, however, three serious and probably insuperable difficulties besetting such an interpretation, as follows.

(1) The probability of ionization by an electron of 10.4 volts energy, or even a few volts more, is so small that it is difficult thus to account for the production of the requisite number of positive ions. (2) The present more refined measurements of cathode drop point to a value *less*, rather than exceeding, 10 volts, the best estimate being 9.9 volts, which makes the assumption of direct impact ionization still more unsatisfactory. (3) *If the electrons are pulled out of the cathode by the field*, the field thus does work $\phi_0 = 4.5$ volts in pulling them out, so that *the kinetic energy gained by the escaping electron is only* $9.9 - 4.5 = 5.4$ volts, *which is far insufficient to permit ionization by single impact.*

The obvious escape from these difficulties is to adopt the theory that *ionization is caused in two stages*, which is at once seen to be in excellent accord with various related facts. The electron energy is very close to the value necessary to produce excited or metastable atoms, and to ionize them when formed. We know that, unlike ionization by single impact, these processes have a high probability when the energy of the impacting electron is only

slightly in excess of the minimum energy required for the process. Furthermore, experiments with low voltage arcs have proved that the favorable conditions for arcs to operate by such cumulative ionization are large current density and vapor pressure of at least the order of 1 mm, both of which conditions are amply fulfilled in the mercury arc. *Thus it would be very surprising if the ionization were not of the cumulative type.* The reason for not having adopted this interpretation sooner was principally the difficulty, in preceding analyses of the situation, of justifying a value of f large enough to be consistent with it, and secondarily the erroneous apparent significance of a cathode drop so nearly equal to the ionizing potential.

ELECTRICAL CONDITIONS NEAR CATHODE

In Fig. 4, let the ordinates of curve N represent the relative numbers of electrons, projected out from the cathode, whose free paths terminate by

Fig. 4.

collisions at distances d . Since, as we have seen, the thickness of the fall space d_c is less than the mean free path λ , we may consider these as projected out with uniform velocities corresponding to the kinetic energy $V_c - \phi_0$. The rate of production of ions or excited atoms will therefore also be proportional to the ordinate of curve N at each distance from the cathode.

Every region of intense ionization tends to be a region of potential maximum, owing to the fact that electrons diffuse away from it more rapidly than do positive ions. There is therefore, a little way in front of the cathode, a region of potential maximum C . As a first approximation, this may be taken as being at the distance of one mean free path from the cathode, since this is the mean position at which ionization occurs.

From this region of potential maximum C , positive ions are forced by the field in both directions, half moving in to the cathode and half moving out

toward the anode and eventually combining with electrons. Since the cathode is so much nearer than the anode to this region of potential maximum, the concentration gradient on the cathode side must be greater than that of the anode side, which would tend to displace the region of potential maximum away from the cathode. On the other hand, the fact that ionization occurs at a more rapid rate nearer the cathode, as shown by curve *N*, tends partially to offset this displacement. The extent of this displacement determines the amount by which δ in Eqs. (1, 2) differs from 1.0.

The net result of these actions, including the action of space charge within the space-charge sheath (cathode fall space) is shown diagrammatically by curve *V*. The space charge equation applies within the distance d_c , to the point *B*. Between *B* and the potential maximum, the plasma considerations developed by Tonks and Langmuir²⁵ apply. Beyond *C* there is ambipolar diffusion toward the anode by both electrons and ions.

There is obviously a small uncertainty in the meaning of "cathode drop". The drop across the space-charge sheath to the point *B* is the quantity which is significant in estimating the field at the cathode. The drop to the point *C* is the maximum potential drop available to produce ionization. The drop to some point beyond *C*—i.e., to the point of nearest approach of an exploring electrode, is the nearest point to which the drop can be measured experimentally, as in the preceding paper.

In conclusion, it may be noted that this analysis indicates that the limits of uncertainty in the values of f , d_c and field at cathode may be reduced by more careful measurements of thermal relationships and of accommodation coefficient, but that the accuracy of an absolute evaluation of these quantities is limited principally by our inability accurately to measure or estimate two factors: the fraction F of the energy, imparted by electrons to unelectrified carriers, which goes to the cathode; and the fraction $1/(1+\delta)$ of the positive ions formed near the cathode which go to the cathode.

THE ELECTRODELESS DISCHARGE IN MERCURY VAPOR

BY HERSCHEL SMITH, WILLIAM A. LYNCH AND NORMAN HILBERRY

DEPARTMENT OF PHYSICS, NEW YORK UNIVERSITY

(Received March 16, 1931)

ABSTRACT

A method is described for studying the characteristics of the components of the electrodeless discharge in mercury vapor. A Hartley oscillator is used to excite the discharge, oscillating currents up to 45 amps. being obtained at frequencies from 5×10^6 to 12×10^6 oscillations per second. Shield experiments have been performed which clearly show the distinction between the dull glow discharge which is considered electric in its origin and the bright glow discharge which is shown to be electromagnetic in its origin; the dependence of the bright glow on the dull glow or on the effect of some ionizing agent is proved. The variation of the current necessary to start the discharge with the pressure of the mercury vapor has been investigated fully over the pressure range 0.002 to 0.2 mm of mercury. Curves are drawn and analyzed in terms of J. J. Thomson's electromagnetic theory of the discharge and Brasefield's electric theory. It is shown that neither theory is sufficient to explain the experimental facts; the predictions seem to hold for the bright glow with fair agreement but fail markedly with the dull glow.

INTRODUCTION

TWO opposing theories have been advanced in recent years to explain the nature of the "electrodeless" discharge which occurs under proper excitation in a gas or vapor at low pressure. The usual arrangement is to insert the bulb containing the gas in a coil in which high frequency currents are flowing.

J. J. Thomson¹ has contended that the discharge is due to the alternating e.m.f. induced around the inside periphery of the discharge tube by the varying magnetic field of the coil. Townsend and Donaldson² however have strongly supported the view that the discharge is caused by the "electric forces"³ between the ends of the coil. This second view is also held by those who have worked with external electrodes, for example Brasefield.⁴

In an attempt to reconcile the two explanations MacKinnon⁵ constructed an exciting circuit which could be energized by either damped or undamped oscillations, for the reason that Thomson had used only damped oscillations while Townsend and Donaldson had used only undamped oscillations. From his experiments, MacKinnon concluded that the discharge was of "electromagnetic" origin when excited by the damped oscillations of Thomson and

¹ J. J. Thomson, *Phil. Mag.* 32, 321, 450 (1891); 44, 293 (1897); 4, 1128 (1927).

² Townsend and Donaldson, *Phil. Mag.* 5, 178 (1928).

³ The term "electric forces" is used here to represent those forces due to the fact that two parts of the coil are at different potentials. For such a force the usual term "electrostatic" is here obviously a misnomer.

⁴ Brasefield, *Phys. Rev.* 35, 1073 (1930); 37, 82 (1931).

⁵ K. A. MacKinnon, *Phil. Mag.* 8, 605 (1929).

"electric" when excited by the undamped oscillations of Townsend and Donaldson. With large currents in the undamped oscillator coil he was able to obtain a very bright glow, not reported by Townsend and Donaldson, which he thought was related to the "ring" discharge of Thomson. This led him to believe that the electromagnetic type of discharge occurred with the damped oscillations because the instantaneous coil currents were very large, and that the undamped oscillations would also cause the characteristic "ring" discharge of the damped case if the gas used had a sufficiently low ionizing potential. The results of the present work support MacKinnon's view in many details.

An ordinary Hartley circuit was used as a generator of the high frequency oscillations employed in the experiments to be described. The resistance of the circuit was kept low by the use of copper tubing for leads and inductance coils while the ratio of capacity to inductance was high; the result was the generation of large currents in the oscillator coil which also acted as the exciting coil for the discharge; thus currents of 45 amps. at frequencies from 5×10^6 to 12×10^6 cycles per second were easily obtained. These currents were measured by a Weston thermo-ammeter placed directly in the circuit between coil and condenser or by a current transformer and thermo-ammeter as described by Campbell and Dye.⁶ All frequencies were measured by a General Radio precision wave-meter.

Over the whole pressure range studied (0.002 to 0.2 mm of mercury) the authors have observed both types of discharge described by MacKinnon; over parts of the range, however, special precautions were necessary to separate them. Mercury vapor was used in the bulb throughout the investigation except where indicated otherwise. The general procedure was as follows: The pressure in the bulb was held constant and the coil current gradually increased; at a critical value of the current a bluish white "dull glow" appeared inside the tube. When the current was increased to a second critical value, the discharge suddenly changed into an intense "bright glow"; at the same time, a large amount of power was drawn from the oscillator. At certain pressures this "bright glow" assumed the form of a ring around the inside periphery of the tube, in appearance very similar to the familiar "ring" discharge.

When no discharge was excited on inserting the tube in the coil, no change occurred in the oscillating circuit. When the dull glow was excited, no change occurred in the circuit nor was the discharge tube heated appreciably. But when the bright glow was strongly excited, the oscillating current decreased greatly, the plate current increased, the frequency remained the same and the bulb was heated appreciably.

EFFECT OF A SHIELD

The "dull glow" has been excited readily either inside or outside the coil; in fact at certain pressures, it has appeared whenever the bulb was brought anywhere near the oscillator. This action in itself indicates the "electric"

⁶ Campbell and Dye, *Proc. Roy. Soc. A*90, 621 (1914).

nature of this type of discharge. To investigate the case further a metallic shield was made by pasting narrow strips of tin-foil parallel to each other on a piece of paper and then connecting them together at one end by a transverse strip of foil. The paper was then rolled into a hollow cylinder with the axis parallel to the strips and the ends open. When this cylinder surrounded the bulb it caused very little electromagnetic loss due to eddy currents but served as an excellent shield against "electric forces." When the pressure and coil current were suitable for the excitation of the "dull glow," the presence of the shield always caused the glow to disappear whether the discharge tube was in the coil or outside. The glow never reappeared as long as the shield remained interposed between the tube and the coil, no matter how great the coil current was made (in our case up to 45 amps.).

If the "bright glow" had been existed strongly in the tube and the shield was inserted, the glow was apparently unaffected. If the bright glow was stopped however by a reduction of the current, it could not be made to reappear so long as the shield was in place even though the current reached the maximum of 45 amps. These experiments were repeated with a second cylindrical shield with closed ends; the results were the same.

When damped oscillations of approximately the same frequency as the undamped oscillations were used for excitation, the dull glow could be obtained only outside the coil; the shield affected it in exactly the same manner as before. The bright "ring" discharge which appeared inside the coil behaved toward the shield identically as did the bright glow of the undamped case.

When the conditions were right for maintaining the bright glow without a shield, it could be started and maintained inside the shield by exposing the tube momentarily to x-rays, or with a quartz discharge tube, to the radiation from a mercury arc in quartz. If a small ball of mercury was in the tube, the bright glow could be started similarly by simply twirling the tube and thus generating a faint glow of triboluminescence around the ball of mercury.

All of the above shield experiments have been repeated for air and carbon monoxide with similar results.

VARIATION OF STARTING CURRENT WITH PRESSURE

The variation of the current necessary for starting the discharge in mercury vapor with changing pressure was very difficult to observe precisely. The external condition of the tube, slight impurities in the vapor and small amounts of liquid mercury all affected the starting current and the results at first were so erratic that it seemed as though no generalization could be made. Determination of the pressure was difficult as the measurement of the temperature of a furnace in which the bulb and coil were placed was not satisfactory because of the sudden rapid increase in temperature in the closed space when the oscillating current was turned on. A thermometer placed anywhere in the field of the coil proved unreliable.

Reproducible results were finally obtained with the following apparatus and procedure. The discharge tube is shown in Fig. 1; the bulb *a* was placed within the oscillator coil and both were enclosed in a transite box and heated

by a blast of hot air; this furnace could be adjusted to any desired temperature from 120°C to about 200°C and maintained constant within a few degrees. The well *b* was outside of the furnace in a constant temperature bath which could be varied from 0°C to 100°C; it contained liquid mercury. Thus the pressure of the mercury vapor in the bulb was determined by the temperature of the mercury in the well, as read on a thermometer placed in tube *c*. The pressure corresponding to a given temperature was taken from a curve plotted from the data given by Kaye and Laby.

At the start of a run, the furnace was first raised to a temperature of say 180°C and kept there for about half an hour with the bulb and coil in place and the mercury well at a low temperature; this action insured that all the liquid mercury was evaporated from the bulb itself. The temperature of the well was then raised by adjustment of the constant temperature bath to the

Fig. 1. The experimental bulb made of Pyrex. The broken lines show the position of the transite walls of the furnace.

value corresponding to the pressure at which the run was to be made. After a wait of about fifteen minutes at this temperature, readings of the starting current were taken at one-minute intervals. When these showed no consistent change, the average of six or more consecutive readings was taken as the starting current.

Table I shows a typical set of readings for starting currents; I_1 is the start-

TABLE I. Currents necessary to start the electrodeless discharge.

Frequency = 7.2×10^8 cycles per second. Temperature of furnace = 184°C. Temperature of the mercury well = 75.5°C. Pressure of mercury vapor in discharge tube = 0.066 mm of mercury.

	1	2	3	4	5	6	Average
I_1 amps (dull glow)	5.00	4.80	4.85	5.00	4.90	4.95	4.91
I_2 amps (bright glow)	6.60	6.65	6.65	6.65	6.65	6.65	6.65

ing current for the dull glow and I_2 that for the bright glow. The values of I_2 are more consistent than those of I_1 ; this was generally the case.

Figure 2 gives the curves illustrating the variation of starting current with pressure at a frequency of 7.2×10^6 cycles per second. Curve *bcdfh* is for the bright glow and curve *acefg* for the dull glow; all pairs of curves taken were very similar to these in shape. The minima at *b* and *e* occurred at the same pressures for the different curves and at about the same currents but the rest of the curve was often shifted along the current axis. Within the pressure range from *c* to *f* of Fig. 2 the starting currents of the two discharges followed each other as described above. To the left of *c* and to the right of *f*, the bright discharge appeared at points on the curve *ac* and *fg*; the dull glow did not precede the bright glow in these regions. When the power supplied to the oscillator was decreased however the bright glow was made to disappear but the dull glow remained. When the power was again increased, the dull glow

Fig. 2. Typical curves showing the variation of starting current with pressure in mercury vapor. Curve *bcdfh* is for the "bright glow" and curve *acefg* is for the "dull glow"; the former appears again as D_1 in Figs. 3 and 3a and the latter as D_1' in Fig. 3.

still being on, the bright glow reappeared at a considerably lower current than at first, corresponding to some point in the region *bc* or *fh*. Since our experiments with the shield have shown that the bright glow does not appear at any pressure unless preceded by the dull glow or by some external source of ionization, we have taken *bcdfh* as the true starting current curve for the bright glow, and *acefg* for the dull glow. Both types of discharge exist therefore over the whole range of pressures and may be started or stopped at will.

The minimum at *b* of the bright glow appears again in the curves D_1 of Figs. 3 and 3a; the last curve shows particularly how definite the minimum is.

DISCUSSION OF RESULTS

Figs. 3 and 3a give the results of one set of experiments; many others were obtained like them. The full line curves *A*, *B*, *C* and *D* show the variation of starting current with pressure for the bright glow while the dotted curves

A' , B' , C' and D' are for the dull glow. Curves A_1 , A_2 and A_3 were all taken at a frequency of 11×10^6 cycles per second; the oscillator coil had an induc-

Fig. 3. A collection of curves illustrating the effect of changes in inductance and frequency of the oscillating circuit on the minimum starting current; the full lines are for the "bright glow" and the broken lines for the "dull glow"; the curves similarly labelled, e.g., A and A' were taken simultaneously. The region to the left enclosed by the chain lines is enlarged in Fig. 3a.

tance of 6.84×10^{-7} henries. Curve A_1 was taken on June 11 after the tube had been operated for a considerable period previously at a frequency of a 7.2×10^6 cycles per second. The minimum at 0.0028 mm of mercury is very definite but is the only case in which such a low pressure minimum has been observed; the minimum at 0.0070 mm has therefore been chosen as the proper minimum for comparison with the other curves; no explanation can be offered at this time for the appearance of the two minima. Curves A_2 and A_3

Fig. 3a. An enlarged view of the minima of the "bright glow" curves to show how sharply the minimum currents are defined.

were obtained on June 12. Figure 3a shows that their minima fall at a pressure of 0.0085 mm.⁷

Curves B_1 and B_2 were obtained on June 13; the frequency was kept at 11.0×10^6 cycles per second as for the curves A but the inductance was increased to 10.4×10^{-7} henries. The minima for B_1 and B_2 are seen to fall at

⁷ A comparison of curve A_1 with A_2 and A_3 shows that the first curve taken at a given frequency after the discharge tube has been run at a lower frequency results in a displacement of the minimum to a lower pressure than occurs with succeeding curves taken under otherwise identical operating conditions. The coil currents at the minima for A_2 and A_3 are less than for A_1 ; this whole behavior is typical.

a lower pressure than with the curves *A*, the value being 0.0065 mm. The "electromagnetic" theory of Thomson and the "electric" theory of Brasefield (for external electrodes) demand that the ratio of the frequency to the pressure at which the minimum occurs should be a constant; here, however, a shift takes place in the pressure at which the minimum occurs without a change of frequency but with a change of inductance. The values of the coil current at the minima are considerably lower with the curves *B* than with the curves *A*; this may be accounted for in terms of the change in inductance from 6.84×10^{-7} henries in the latter case to 10.4×10^{-7} henries in the former; the coils were of two and three turns, respectively. The magnetic field at the minimum should be

$$H_0 = \frac{2}{a} \left(\frac{2V}{e/m} \right)^{1/2}$$

according to Thomson, where V is the effective ionization potential for the gas and a the radius of the bulb; thus the starting current at the minimum should depend only on the gas, the bulb and the coil. The approximate value of the field inside of a solenoid is $H = 2\pi ni (\cos \theta_1 - \cos \theta_2)$ (see Starling 5th Edition p. 229); the coil current at the minimum should thus have been 16.8 amps. for curves *A* and 10.4 amps. for curves *B*, on the assumption further that the ionizing potential is 10.4 volts. If the effective ionizing potential is taken as 5.5 volts, these values become 12.2 amps. and 7.6 amps., respectively. Actually the currents were about 5.5 amps. for curves *A* and about 4.0 amps. for curves *B*.

The electric field at the minimum should be

$$E_0 = \pi f \left(\frac{2V}{e/m} \right)^{1/2}$$

according to Brasefield.⁴ The shield experiments have given evidence of only diametral electrical fields; the recent experiments of Knipp⁸ seem to confirm this observation. If this is the case

$$E_0 = \frac{\pi f L}{2Nr} I_0$$

where f is the frequency of the oscillation, L is the inductance of the coil, r is its radius and N the number of turns; I_0 is the peak value of the minimum starting current; this approximation for E_0 is based on the assumption of a linear drop in potential around the coil; a sine distribution leads to results of the same order. In effective amps. the above result becomes

$$I = \frac{2Nr}{1.414L} \left(\frac{2V}{e/m} \right)^{1/2}.$$

The coil current at the minimum should thus have been 2.24 amps. for curves

⁸ Bulletin of the American Physical Society Vol. 6, number 1, p. 22, abstract 35, February 10, 1931.

A and 1.99 amps. for curves *B*, on the assumption that the ionizing potential is 10.4 volts. If the effective ionizing potential is 5.5 volts, these values become 1.63 amps. and 1.45 amps., respectively. The currents were actually about 5.5 amps. for curves *A* and 4.0 for curves *B*.

The observed values of the currents are of the same order of magnitude as the calculated values on either theory although the electromagnetic theory values are about twice as large as those observed and the electric theory values are between one fourth and one third as great, when the effective ionizing potential is taken as 5.5 volts. The electromagnetic theory predicts a change in the minimum current from curves *B* to curves *A*, the calculated ratio being 0.62. The electric theory predicts for diametral fields a shift corresponding to the ratio 0.89. The ratio of currents actually observed is 0.71.

Curves *C*₁, *C*₂, *C*₃ and *C*₄ were run in that order on June 14. Curve *C*₁ shows a minimum at a pressure of 0.0075 mm of mercury while the minima for the other three curves fall at a pressure of 0.0055 mm. The inductance was the same as for curves *B*, 10.4×10^{-7} henries, but the frequency had been lowered from 11.0×10^6 cycles per second to 7.2×10^6 cycles per second.⁹ The ratio of the frequency to the pressure at the minimum for curve *A*₂ or *A*₃ and curve *C*₂, *C*₃ or *C*₄ is a constant within the limit of experimental error as predicted by both theories:

$$\frac{11.0 \times 10^6}{0.0085} = 1295 \times 10^6; \quad \frac{7.2 \times 10^6}{0.0055} = 1310 \times 10^6.$$

The ratio of inductance to capacity in curves *A* and *C* was constant. For curve *B*₁ or *B*₂ and curve *C*₂, *C*₃ or *C*₄ the ratios of frequency to pressure at the minimum are obviously not the same; the change in frequency resulted from a change in capacity in the circuit, the inductance remaining the same. Both theories predict that the coil currents at the minima for curves *B* and curves *C* should be equal as they are shown to be independent of the frequency. While successive values for curves *B* are increasing and those for curves *C* are decreasing, the values for the lower frequency are definitely higher than for the higher frequency.

Curve *D* was taken in an early set of experiments on May 22 and is included to show how well the results agree even after a lapse of time. The minimum falls at the same pressure as for *C*₂, *C*₃ and *C*₄; the coil current is lower than for the *C* curves but is above that for either *B*₁ or *B*₂.

The "electromagnetic" theory predicts that the minimum for curves *A* and *B* should occur at a pressure of 0.0035 mm for a frequency of 7.2×10^6 cycles per second and at 0.0054 mm for a frequency of 11.0×10^6 cycles per second, the ionizing potential being taken as 10.4 volts. We have found, however, that the dull glow or its equivalent must always be present before the

⁹ Here again on running the tube after a change in frequency of the oscillator, the minimum for the first test is displaced with respect to the minima obtained in succeeding tests under otherwise identical operating conditions. In this case however the first minimum is at a higher pressure than the following, corresponding to a change from one frequency to a lower value.

bright glow comes on; we have considered therefore, that the effective ionizing potential is 5.5 volts. The calculated values of the pressure at the minima then become 0.0048 mm for 7.2×10^6 cycles per second and 0.0075 mm for 11.0×10^6 cycles per second; the observed values were 0.0055 mm for curves *C* at 7.2×10^6 cycles per second, 0.0085 mm for curves *A* at 11.0×10^6 cycles per second and 0.0065 mm for curves *B* at the same frequency; the agreement is fair.

The electric theory predicts that the minimum should fall at 0.0031 mm for 7.2×10^6 cycles per second and at 0.0046 mm for 11.0×10^6 cycles per second; the effective ionizing potential of 5.5 volts has been used to calculate these results. The agreement here is much less satisfactory than in the electromagnetic case. Throughout the calculations for the values of the pressures at the minima the mean free path of an electron in mercury vapor at 1 mm of Hg pressure and 25°C has been taken as 0.0149 cm as given by Compton and Langmuir.¹⁰

The diametral fields set up by the currents in the coil were sufficient to produce ionization but not at the pressures corresponding to the minimum of the bright glow; the mean free path of an electron in mercury vapor is not great enough to permit an electron to acquire sufficient velocity to cause ionization.

One other point in connection with the bright glow curves should be mentioned. Indications are that the furnace temperature, and therefore the bulb and vapor temperature, affects the position of the maximum in the region above 0.05 mm. For temperatures below 170°C, the maxima occur as with curve *C*₄; for temperatures around 185°C, the curves flatten out as in *A*₂ and *A*₃ and for still higher temperatures the curves continue to rise. Further work is in progress in an attempt to determine the relation between the shape of the curve and the furnace temperature.

The curves *A*₁', *A*₂' and *A*₃' were taken simultaneously with the *A*₁, *A*₂ and *A*₃ curves and represent the variation of starting current with pressure for the dull glow corresponding to curves *A*₁, *A*₂ and *A*₃ for the bright glow; the *B*' and *C*' curves have a similar interpretation. Curves *A*₂' and *A*₃' are entirely above *A*₂ and *A*₃; this is a significant fact because an observer could readily have failed to detect the existence of two types of discharge under these conditions. The procedure described above for separating the two components of the discharge was particularly important here; at some value for the current the two discharges appeared simultaneously corresponding to a point on one of the *A*' curves; the current was reduced until the bright glow disappeared, leaving the dull glow; the current was again increased and the bright glow reappeared at a point on the *A* curve. A change of inductance from 10.4×10^{-7} henries to 6.84×10^{-7} henries was made in passing from the *B*' to the *A*' curves but the frequency was kept at 11.0×10^6 cycles per second. The shift of the curves along the current axis is about twice as great for the dull glow curves as for the bright glow; the change of inductance should have

¹⁰ Compton and Langmuir, *Rev. of Mod. Phys.* 2, 208 (1930).

affected them alike. As pointed out above for the bright glow curves the observed ratio of the minimum currents was 0.71 and the computed was 0.89 on the basis of diametral fields; according to the theory the same calculation should hold for the dull glow but the observed ratio is only 0.39. If axial fields are assumed, the computed value for the ratio is 0.99; in either case the observed values for the dull glow fail to fit the theory and the discrepancy is much greater than for the bright glow.

Curves C' were obtained with the same inductance as for curves B' namely 10.4×10^{-7} henries but the frequency was reduced to 7.2×10^6 cycles per second. On the basis of the electric theory there should have been no change in the values of the minimum currents in passing from B' to C' but actually there were very large changes. Again the shift along the pressure axis is in the wrong direction for the minimum should occur at a lower pressure as the frequency is lowered. Furthermore the currents observed at these minima were not sufficient to set up diametral fields powerful enough to cause ionization; the electrons could not possibly acquire sufficient velocity in the distance equal to the mean free path of an electron in mercury vapor at these pressures. This would seem to indicate that the process is one of multiple collisions.¹¹

Curve D' is included to show that even the dull glow curves may be reproduced after a lapse of time although it was much more difficult in general to repeat the dull glow curves than the bright glow curves.

The authors wish to thank Mr. John Mills and Bell Telephone Laboratories for the use of power tubes used in this investigation. They desire, too, to extend their grateful appreciation of the help rendered by Dr. Ann Hepburn in the experimental work.

¹¹ This is the region of pressures, too, in which the bright glow curves show their change of shape with furnace temperature; it may be possible to explain the change in shape in terms of a variation of the terminal velocity of an electron moving through mercury vapor with the temperature of the vapor, the pressure being fixed by the temperature of the liquid mercury present.

THE PIRANI GAUGE FOR THE MEASUREMENT
OF SMALL CHANGES OF PRESSURE

BY A. ELLETT AND R. M. ZABEL

PHYSICAL LABORATORY, STATE UNIVERSITY OF IOWA

(Received March 20, 1931)

ABSTRACT

The application of the Pirani gauge to the measurement of small pressure changes is discussed. Both nickel and tungsten wires are used as filaments in the gauge. Nickel wire not only has the greater sensitivity but possesses several other advantages. The theory of the gauge is developed so that it is possible to predict the effect of change in length or diameter of the wire upon the sensitivity of the gauge. The theory also predicts that there is an optimum temperature to which the wire should be heated for maximum sensitivity of the gauge. The observed and computed values of the optimum temperature are compared. In some cases the agreement is as good as can be expected and in the others the discrepancy is easily explained. The maximum sensitivity attained is a galvanometer deflection of 1 mm for a pressure change of air equivalent to 5×10^{-9} mm of mercury.

INTRODUCTION

THE possibility of using the variation in heat conductivity of a gas with pressure as a measure of low pressures was first suggested by Pirani.¹ Recent experimenters^{2,3} have shown that such a gauge is capable of responding to very small changes in pressure.

These investigators have been primarily interested in a gauge which will determine the actual pressure existing in a chamber after it has been calibrated by comparison with an absolute gauge such as the McLeod. The aim of this experiment is to develop a gauge with a high sensitivity to very small pressure changes.

THEORY

It is easily shown that the quantity of heat Q conducted by a gas when the mean free path is large compared to the dimensions of the container is

$$Q = nGA\bar{v}H/6N \quad (1)$$

where n is the number of molecules per cm^3 , G the mean molecular velocity, A the area of the heated element, t the temperature difference between the heated element and its surroundings, H the molecular heat at constant volume, and N the number of molecules per gram molecule. Experimental measurements give a value of the heat transfer which is usually less than that predicted by this equation. This is because the molecules striking the heated wire do not attain temperature equilibrium with it. The ratio of the actual amount of heat conducted from the heated element to that computed by

¹ M. Pirani, *Verh. d. Deutsch. Phys. Ges.* **8**, 24, 686 (1906).

² A. M. Skellet, *J. O. S. A. and R. S. I.* **15**, 56 (1927).

³ L. F. Stanly, *Phys. Soc. Proc.* **41**, 194 (1929).

Eq. (1) is known as the accommodation coefficient and has been measured for some gases. Soddy and Berry⁴ give the values of the actual amount of heat conducted and the values of the accommodation coefficient for gases striking a heated tungsten surface. The values of the accommodation coefficient range from 0.25 in the case of hydrogen to 1.0 in the case of argon and neon. The values of the actual amount of heat conducted by various gases deviate by less than 10 percent from a mean value for a number of the common gases. Hence we may expect that the sensitivity of the Pirani gauge will be nearly the same for this group of gases.

In the application of the above principle to the measurement of pressure changes the temperature change in the wire resulting from a change in the heat conductivity of the gas is usually measured by the change in resistance. This resistance change is in turn measured by a Wheatstone bridge. If the pressure change to be measured is not large the galvanometer deflection is the most accurate method of determining the magnitude of the change.

The bridge potential serves as a source of power to heat the wire. The energy dissipated by a heated wire must be equal to that supplied, hence neglecting conduction to the leads

$$\frac{E^2}{R} = A\gamma(T^4 - T_0^4) + A\alpha p(T - T_0) \quad (2)$$

where E is the potential across the ends of the wire, R the resistance and A the area of the wire, T and T_0 the temperature of the wire and of its surroundings, respectively, p the pressure of the gas and γ and α constants. Since the resistance change corresponding to the pressure changes normally measured is small we may assume that the power supplied to the wire is constant. Then by differentiation of (2),

$$\frac{dT}{dp} = - \frac{\alpha(T - T_0)}{4\gamma T^3 + \alpha p}.$$

At low pressures the amount of heat dissipated from the wire by radiation is large compared to that conducted by gas hence we may neglect αp in comparison to $4\gamma T^3$. Then

$$\frac{dT}{dp} = K \frac{T - T_0}{T^3} \quad (3)$$

where K is a constant.

Obviously there is a relation between T and T_0 for which the temperature change of the wire will be a maximum for a given pressure change. This relation is given by

$$\frac{d}{dT} \left[\frac{(T - T_0)}{T^3} \right] = 0$$

or

$$T = 3T_0/2.$$

⁴ F. Soddy and A. Berry, Proc. Roy. Soc. 83, 254 (1910).

Substituting this value in (3) we obtain,

$$\left[\frac{dT}{dp} \right]_{\max} = \frac{K'}{T_0^2}. \quad (4)$$

Hence the value of the maximum temperature change of the wire for a given pressure change is inversely proportional to the square of the absolute temperature of the surroundings of the wire.

Since the temperature change resulting from a given pressure change is normally small we may assume that

$$R = R_0[1 + \alpha(T - 273)]$$

or

$$dR = R_0\alpha dT.$$

Substituting this value of dT in (3) we obtain,

$$\frac{dR}{dp} = K''R_0 \frac{T - T_0}{T^3}. \quad (5)$$

Obviously dR/dp has the same maximum as dT/dp . The maximum galvanometer deflection does not necessarily correspond to the maximum resistance change, however.

The current through the galvanometer in a Wheatstone bridge circuit is given by

$$I_g = \frac{EdR}{4RR_g + 4R^2}$$

if the battery resistance is small and the four arms of the bridge are approximately equal. Substituting for dR from (5),

$$I_g = K''' \frac{R_0E}{RR_g + R^2} \frac{T - T_0}{T^3} dp. \quad (6)$$

Obviously the galvanometer deflection may be increased by increasing the potential of the bridge. This factor is limited, however, because the wire must be heated to its optimum temperature.

The relation between the potential drop across the wire and the temperature may be obtained from (2). In general the heat conducted by the gas may be neglected in comparison to that dissipated by radiation and T_0^4 in comparison to T^4 . Hence

$$E = (\gamma AR)^{1/2} T^2.$$

Substituting this value of E in (6)

$$I_g = K \frac{R_0(AR)^{1/2}}{RR_g + R^2} \frac{T - T_0}{T} dp. \quad (7)$$

The optimum temperature of the gauge wire for maximum galvanometer deflection may be determined from (7). In the general case this solution is difficult but several special cases which are of interest may be treated.

If we assume that the galvanometer resistance is large compared to the resistance of the arms of the bridge, (7) reduces to

$$I_g = K' \frac{T - T_0}{R^{1/2} T} d\phi.$$

But

$$R = R_0 [1 + \alpha(T - 273) + \beta(T - 273)^2]$$

where the terms of second order must be included if the action of the gauge is to be described over any considerable range. Hence

$$I_g = \frac{K''(T - T_0)}{[1 + \alpha(T - 273) + \beta(T - 273)^2]^{1/2} T} d\phi.$$

The optimum temperature of the wire may be determined by

$$\frac{d}{dT} \left[\log \frac{T - T_0}{[1 + \alpha(T - 273) + \beta(T - 273)^2]^{1/2} T} \right] = 0$$

or

$$2\beta T^3 + (\alpha - 546\beta - 4\beta T_0)T^2 - T_0(3\alpha - 1638\beta)T - 2T_0[1 - 273\alpha + (273)^2\beta] = 0. \quad (8)$$

If the galvanometer resistance is small as compared to the resistance in the bridge arms Eq. (7) reduces to

$$I_g = K^* \frac{T - T_0}{R^{3/2} T}$$

and the value of T for maximum I_g is given by

$$6\beta T^3 + (3\alpha - 1638\beta - 8\beta T_0)T^2 - 5T_0(\alpha - 546\beta)T - 2T_0[1 - 273\alpha + (273)^2\beta] = 0. \quad (9)$$

RESULTS

The experimental arrangement used in obtaining the results given below is shown in Fig. 1. The leak was controlled by a stopcock so that it could be opened or closed as desired. This gave a constant pressure change and the corresponding galvanometer deflection could be observed for various bridge potentials and various samples of wire.

The gauge formed one arm of a Wheatstone bridge. The other arms consisted of resistances variable in small steps so that the arms of the bridge could be kept approximately equal. The galvanometer used has a resistance of 17 ohms and a sensitivity of 11.6 mm per microvolt. Resistance was connected in series or parallel with it to obtain the high and low galvanometer resistances used.

Equation (7) shows that the galvanometer deflection should be directly proportional to the pressure change. This was verified beyond the limits of the McLeod gauge by connecting a small leak to a pump through a stopcock. This leak was adjusted to give several cm deflection of the galvanometer as

it was turned on or off. As the pressure in the gauge was increased by the use of another leak the deflection produced by opening or closing the first leak remained constant.

Equation (7) also shows that the sensitivity of the gauge is proportional to the square root of the area of the wire. It is possible to multiply the sensitivity of a nickel wire gauge by two or three merely by flattening the wire.

The effect of the length of the gauge wire upon the sensitivity may be determined from (7). Since A , R , and R_0 are all proportional to the length of the wire it is evident that the sensitivity will be directly proportional to

Fig. 1. Construction of the Pirani gauge.

the length of the wire if the galvanometer resistance is large compared to the resistance of the bridge arms. On the other hand, if the galvanometer re-

TABLE I.

sistance is small the sensitivity is independent of the length of the wire. Table I shows the effect of the length of the wire upon the sensitivity of the gauge. In each case the gauge was constructed of nickel wire 0.001 inch in diameter and the walls of the gauge were maintained at the temperature of melting ice.

The variation of the sensitivity of the gauge with diameter of the wire may also be predicted. If the galvanometer resistance is large compared to the resistance of the gauge, the diameter of the wire should be decreased and if the galvanometer resistance is low the diameter of the wire should be increased. Hence for maximum sensitivity the wire should be as long as convenient and the diameter should be adjusted so that its resistance is of the

Fig. 2. Curves showing the relation between the temperature of the gauge wire and the sensitivity of the gauge. T_0 is the temperature of the walls of the gauge and R_g the galvanometer resistance.

same order of magnitude as the galvanometer resistance. In general a galvanometer with low resistance is preferable since the corresponding lower resistance in the bridge arms permits the use of lower battery potential which decreases the tendency of the galvanometer to drift.

The relation between the sensitivity of the gauge and the temperature of the wire is shown in Fig. 2. The tungsten and nickel wires used in obtaining these curves were 20 cm long and 0.001 inch in diameter. The temperature was determined by the known relation between the temperature and resistance. For tungsten the values $\alpha = 5.24 \times 10^{-3}$ and $\beta = 0.7 \times 10^{-6}$ were used in the well-known resistance formula. The temperature of the nickel wire

was read from the curve shown in Fig. 3 which was determined for the wire used in this experiment.

It will be noted that all the temperature sensitivity curves for nickel wire (Fig. 2) have either a primary or a secondary maximum at approximately 570° after which the sensitivity decreases very rapidly. This is obviously due to the rapid increase in the slope of the temperature resistance curve and the sudden break at 615° . The observed temperature at which this break occurs should be less when the wire is used as a gauge because the ends of the gauge wire are cooled by conduction of heat to the leads. This view is substantiated by the fact that the apparent temperature at which the maximum occurs decreases when a shorter wire is used.

Fig. 3. Temperature resistance curve for nickel wire.

In Table II, T_0 is the temperature of the gauge walls, R_0 is the galvanometer resistance, R is the resistance of the wire at its optimum temperature, E is the bridge potential necessary to produce this temperature, $T(\text{obs.})$ and D the optimum temperature and the galvanometer deflection at that temperature, respectively, as determined from Fig. 2, and $T(\text{comp.})$ the optimum temperature computed from Eqs. (8) and (9). In obtaining the values of $T(\text{comp.})$ the proper equation is chosen depending upon the value of the galvanometer resistance, and the values of T_0 , α , and β are substituted after which the equation may be solved for T . For tungsten the values of α and β previously given were used and for nickel the same constants were determined from Fig. 3 to fit the curve approximately in the region in which the observed temperature was known to lie. It will be noted that the computed

temperatures when $T_0=90^\circ$ are much lower than the observed. This is partially due to heat conduction along the leads and partially to the decrease in the constant γ appearing in Eq. (2) or, in other words, a decrease in the efficiency of radiation at low temperatures. In fact with a potential of only 0.0003 volt applied to the bridge the lowest temperature attained by the nickel filament was 209° and by the tungsten 213° .

The secondary maxima in the temperature sensitivity curves of nickel wire are not predicted by the equations but they probably would be if the variation in slope of the temperature resistance curve were taken into account and the equation of the curve were expressed more accurately.

* All temperatures given on the Kelvin scale.

Table II shows that the sensitivity attained by the use of nickel wire is in all cases greater than that for tungsten. Nickel wire has the additional advantage that it may be flattened more easily than tungsten which greatly increases the sensitivity as the previous discussion has shown. Tungsten wire has the disadvantage that the slightest vibration will cause its resistance to change sufficiently to keep the galvanometer moving back and forth over several cm.

Immersing the walls of the gauge in liquid oxygen approximately multiplies the sensitivity of the gauge by two when the galvanometer resistance is high and by seven when the galvanometer resistance is low. This difference in the sensitivity ratio is to be expected for Table II shows that the resistance of the bridge arms at optimum temperature is much lower when $T_0=90^\circ$ than when $T_0=273^\circ$. Equation (7) and the preceding discussion show that this decrease in resistance will decrease the sensitivity when the galvanometer resistance is high but not when the galvanometer resistance is low.

Many factors enter into the computation of the relative sensitivity of the gauge when the walls are at the temperature of melting ice and at the temperature of liquid oxygen. For example the relation between the pressure and the heat conductivity of the gas will change both because more molecules must be present at liquid oxygen temperatures to exert a given pressure and because the mean molecular velocity is smaller. Also, as previously suggested, the radiation constant (γ in Eq. (2)) probably decreases at the lower temperature and it is reasonable to expect that the value of the accommodation coefficient depends upon the temperature. The effect of heat conduction

from the filament to the leads upon the sensitivity of the gauge has been neglected so that it is impossible to predict the change in sensitivity which will result from the reversal in the direction of this flow. Such a reversal actually occurs in some cases for when the walls of the gauge are immersed in liquid oxygen the temperature of the filament is less than the temperature of the leads. Due to the impossibility of computing the magnitude of the latter effect and the difficulty in computing some of those previously given no attempt is made to predict the increase in sensitivity when the walls of the gauge are reduced to the temperature of liquid oxygen.

Reducing the walls of the gauge to the temperature of liquid oxygen makes the reaction of the gauge very slow. For example with the gauges at the temperature of melting ice the galvanometer would reach equilibrium about 10 seconds after the stopcock was closed. At liquid oxygen temperature the time required to attain equilibrium was often several minutes. This time lag may be accounted for to some extent by the fact that there must be three times as many molecules in the gauge and their velocity must be much slower when the walls of the gauge are at the temperature of liquid oxygen so that it should take longer for the gauge to pump out. This factor cannot, however, account for the great difference observed in the time lag in the two cases and neither can it account for the observed fact that the time lag of the gauge decreases rapidly with an increase in temperature of the filament since the area of the filament is so small in comparison to the area of the walls that it can have no appreciable effect upon the mean velocity of the molecules. The observed dependence of the time lag upon the temperature of the wire suggests that it may to some extent be due to the adsorption of a layer of gas by the filament.

It is possible to obtain a galvanometer deflection of 1 mm for a pressure change of air equivalent to $5 \pm 1 \times 10^{-9}$ mm of mercury by forming the gauge from a well-flattened piece of nickel wire 25 cm long and originally 0.0015 inch in diameter and using the galvanometer specified above at maximum sensitivity.

Under similar conditions the sensitivity of the gauge for hydrogen is $4 \pm 1 \times 10^{-9}$ mm of mercury per mm galvanometer deflection.

The sensitivity and characteristics of different gauges will vary due to variations in the original size and the degree of flatness of the wire.

CONCLUSION

In order to measure pressure changes of less than 10^{-7} mm of mercury it is obvious that the zero position of the galvanometer must be steady. If the ordinary precautions necessary in connecting a Wheatstone bridge of high sensitivity are observed, if the bridge potential is constant, and if the walls of the gauge are maintained at a constant temperature such as melting ice or liquid oxygen, the zero drift of the gauge becomes negligible provided that the pressure changes take place over a short period of time.

The operation of the gauge is not satisfactory when the walls are exposed to the variations of room temperature. A compensating gauge greatly im-

proves the stability of the system but is not as satisfactory as one gauge immersed in a constant temperature bath.

The stability of the gauge may be improved by keeping the bridge potential low. This may be accomplished by proper choice of the galvanometer as previously described and by operating the gauge below its optimum temperature. The extent to which the temperature should be reduced below its optimum value depends upon the difficulty arising from zero drift and upon the rate at which the sensitivity decreases with decrease in temperature. In some cases it is possible to reduce the bridge sensitivity to one half* of its value at the optimum temperature while the gauge sensitivity is reduced only 15 percent. In such cases the decrease in bridge potential would probably be an advantage.

* That is $\Delta R/R$ for unit galvanometer deflection is doubled.

MEASURING THE INTENSITY OF
MOLECULAR BEAMS

BY A. ELLETT AND R. M. ZABEL

PHYSICAL LABORATORY, STATE UNIVERSITY OF IOWA

(Received March 20, 1931)

ABSTRACT

A Pirani gauge sensitive to pressure changes of the order of 10^{-8} mm of mercury has been developed and used to measure the intensity of molecular beams defined by two circular openings, one 0.4 and the other 0.6 mm in diameter placed 25 mm apart. The gauge is situated 40 mm from the last opening. A beam of air gives a galvanometer deflection equivalent to 600 cm with a pressure of 0.5 mm of mercury behind the first opening. Under similar conditions H_2 produces a deflection of 1800 cm. The galvanometer sensitivity is 11.6 mm per microvolt. The time lag of the gauge is less than the period of the galvanometer (7 seconds). The limits within which the beam-forming system may be expected to give a Maxwellian distribution of velocities are discussed. The final pressure in the gauge due to a given beam depends upon the dimensions of the gauge opening as kinetic theory predicts. The reduction in intensity of a beam of H_2 by collision with either air or H_2 present in the experimental chamber at various pressures has been measured. The data show that the gauge may be used to measure mean free paths and to obtain more detailed information than has previously been possible as to the probability of scattering through various angles by collision.

INTRODUCTION

IN RECENT years the angular distribution of a beam of electrons after scattering by a gas has been studied in detail. No doubt the equally interesting and important problem of the scattering of a beam of molecules or atoms has been neglected because there has not been available a method of measuring the intensity of such beams. The reflection of atoms from a crystal may also be studied advantageously by the aid of a gauge which will measure accurately the intensity of molecular beams. In order to be most efficient in this connection the gauge should have a small internal volume so that it will respond rapidly to changes in beam intensity and small overall dimensions so that it may be placed entirely within the vacuum system and controlled magnetically if this seems desirable. The experiments described in this paper were undertaken to devise such a gauge. Some very notable advances have already been made in this field.¹

APPARATUS

A Pirani gauge, discussed at length in the preceeding paper, was constructed with a small opening in one side (Fig. 1) so that the pressure inside would be affected when the opening was moved into the path of a beam of molecules. By measuring the pressure change inside the gauge a measure of the beam intensity is obtained.

¹ F. Knauer and O. Stern, *Zeits. f. Physik* 53, 766 (1929).

The ends of the gauge must be fitted carefully as experience has shown that arrangements which appear to fit well mechanically may leak considerably. The gauge has an internal volume of 0.5 cc so that it responds quickly to changes in beam intensity. The time required for the pressure in the gauge to reach equilibrium is normally less than the period of the galvanometer (7 sec.).

Fig. 1. The Pirani gauge applied to the measurement of molecular beams.

The extreme shortening of the wire seems to have no disadvantage other than decreasing the sensitivity of the gauge. The conduction of heat from the filament to the leads which would, of course, become more troublesome as the length of the filament is decreased has not interfered with the action of the gauge to an appreciable extent.

The apparatus which forms the molecular beam used in the investigation of the characteristics of the gauge consists of 3 circular openings (Fig. 2), the first of which is 0.4 mm in diameter, the second is 0.7 mm in diameter and is situated 1.75 mm from the first, and the third is 0.6 mm in diameter and situated 25 mm from the first. The second opening does not serve to define the beam but merely to prevent the spreading of the comparatively high

Fig. 2. The construction of the apparatus for the formation of molecular beams.

pressure in *B* throughout the entire distance between the first and last opening. It is made slightly larger than the other openings in order to eliminate any difficulties there might be in correct alignment. This precaution is hardly necessary here but might be in case very narrow slits were used to form the beam. The third opening was made larger than the first in order to secure a beam in which the width of the maximum intensity portion of the beam would be equal to the diameter of the largest gauge opening used. It is, of

course, obvious that the last opening could be reduced to the size of the first (0.4 mm) thus decreasing the angular divergence of the beam without decreasing its maximum intensity.

The distance between the first two openings of the beam system was adjusted experimentally to give the correct relative pressures in *B* and *C* for maximum efficiency. This distance depends upon the relative pumping speeds at *B* and *C* which are 4 and 18 liters of air per second, respectively. A change of 0.1 mm in this distance will produce an appreciable reduction in the maximum beam intensity which can be obtained.

A beam system consisting of two openings was not satisfactory for producing beams of high intensity. The impedance inherently existent in an apparatus when two slits are placed near each other makes it difficult to reduce the pressure between them sufficiently for the formation of an intense beam even if the necessary pumping speed is available.

The position of the gauge used in measuring the beam is shown in Fig. 2. It is arranged so that it may be rotated about the last opening of the beam system. The compensating gauge which is placed nearby forms the arm of the bridge adjacent to the main gauge and maintains the bridge balance for general changes in pressure as well as changes in temperature in the experimental chamber. Where high sensitivity is necessary it is advisable to place both gauges in a common metal container or form both from the same piece of metal.

PROCEDURE

The final pressure in the gauge due to a given beam will depend upon the size and shape of the opening into the gauge. The most advantageous form of opening may be predicted by a consideration of Knudsen's law of molecular flow.

Since the pressure in the gauge is always such that the mean free path is large compared to the dimensions of the container, it is evident that the gauge opening, regardless of its length or diameter, will offer no impedance to the entrance of the molecules of the beam if the apparatus is arranged so that they do not strike the walls of the opening. Hence the pressure inside the gauge will build up to such a value that the quantity of gas which flows out through the gauge opening is equal to that which enters it from the beam. The quantity of gas *Q* measured in cm³ at 1 bar flowing through a tube of length *L* and radius *r* per second is given by Knudsen² as

$$Q = \frac{1}{\rho_1^{1/2}} \frac{p_1 - p_2}{W_1 + W_2} \quad (1)$$

where ρ_1 is the density of the gas at 1 bar and at the temperature of the apparatus and the partial impedances W_1 and W_2 are given by

$$W_1 = \frac{(2\pi)^{1/2}}{\pi r^2} \quad (2)$$

and

² M. Knudsen, *Ann. d. Physik* 28, 75 and 28, 999 (1909).

$$W_2 = \frac{3L}{4(2\pi)^{1/2}r^3} \quad (3)$$

Assuming that the molecules emerge from the initial opening of the beam system with a cosine distribution, the amount of gas entering the gauge and also the amount leaving it per second when equilibrium is established is

$$\frac{Q'r^2}{D^2}$$

where Q' is the quantity of gas used in forming the beam, r is the radius of the gauge opening, and D the distance from the initial beam opening to the gauge opening. Substituting the value of Q given above and the values of W_1 and W_2 from Eqs. (2) and (3) in Eq. (1) we obtain upon solving for $(p_1 - p_2)$ the quantity actually measured by the gauge

$$p_1 - p_2 = (\rho_1)^{1/2} \frac{Q'}{D^2} \left(\frac{2^{1/2}}{\pi^{1/2}} + \frac{3L}{4(2\pi)^{1/2}r} \right) \quad (4)$$

Hence if the gauge opening is a hole in a thin wall the equilibrium pressure is independent of the radius. If, however, the gauge opening is long as compared to its radius the equilibrium pressure is proportional to its length and inversely proportional to its radius. The effect of the dimensions of the gauge opening upon the sensitivity of the gauge is shown by Table I. The

TABLE I. *The effect of the dimensions of the gauge opening upon the sensitivity of the gauge.*

Dimensions of gauge openings (mm)		Relative deflection	
Length	Diameter	Computed	Observed
12	0.37	18	18
12	0.5	11.3	11.7
12	1.0	6	6.2
4	0.37	6	6
0	0.1	0.6	1

calculated values of the relative sensitivity are obtained from Eq. (4). The agreement is well within the limits to which the dimensions were actually known except in the case of the 0.1 mm hole. Here the disagreement may be explained by the reasonable assumption that the wall has a thickness of 0.08 mm.

For many purposes it is desirable that the molecular beam under consideration have a Maxwellian distribution of velocities. Previous investigators^{3,4} have shown that a beam possesses a Maxwellian distribution of velocities if the pressure behind the first opening is such that the mean free path is several times the diameter of the opening and the pressure along the path of the beam is such that the effect of collisions may be neglected. Fig. 3 shows that the latter condition is easily satisfied. As long as the intensity of the beam is proportional to the amount of gas forming it, collisions have not

³ J. A. Eldridge, Phys. Rev. 30, 931 (1927).

⁴ I. F. Zartman, Phys. Rev. 37, 383 (1931).

become a factor. Further evidence of the same nature was obtained by plotting beams such as shown in Fig. 4 over a wide range of intensity. In the case of both air and H_2 , beams were plotted from the first point shown in Fig. 3 to

Fig. 3. Volume of gas forming beam plotted against beam intensity. Galvanometer sensitivity, for air 1/10, for H_2 1/20.

Fig. 4. The spreading of a beam of H_2 with increasing pressures of air and H_2 in its path.

the point where the curves first leave the straight lines. In neither case was there an appreciable spreading of the beam such as would result from collisions taking place between the openings.

The limitation placed upon the beam intensity by the first condition mentioned above may be obtained from Table II. A comparison of the values of the mean free path at A given in this table with the diameter of the opening (0.4 mm) show that the requirement of low pressure behind the first opening, rather than the speed of the pumps, is the limiting factor in the beam intensity which can be obtained if a Maxwellian distribution of velocities is desired. Table II also contains the values of the pressures for the various compartments of the beam system.

** These values were computed.

*** Mean free path for spherical model assuming air to be composed of oxygen and nitrogen⁵.

The equilibrium pressure in the gauge resulting from a given beam may be computed by the application of Eq. (4) and from the calibration constant of the gauge. The comparison of these two values is of interest. The physical constants and the dimensions of the apparatus appearing in Eq. (4) have the following values: $\rho_1 = 1.16 \times 10^{-9}$ (air); $D = 6$ cm;⁶ $L = 1.2$ cm; and $r = 0.0185$ cm. The quantity of gas Q' used in forming the beam in the case of the third point on the air curve in Fig. 3 is 8.1×10^{-3} cm³ at atmospheric pressure or 8.1×10^3 cm³ at 1 bar. Substituting these values $p_1 - p_2 = 0.154$ bars or 1.15×10^{-4} mm of mercury. Computing the excess pressure in the gauge from the calibration constant (5.8×10^{-8} mm of mercury per mm galvanometer deflection) and the deflection we obtain $p_1 - p_2 = 1.03 \times 10^{-4}$ mm of mercury.

The error is approximately 10 percent and is within the limits of accuracy to which the Pirani gauge had been calibrated by comparison with a McLeod gauge.

Similar computations for H_2 yield values of the observed pressures which are approximately 30 percent greater than kinetic theory predicts.

With the aid of a gauge of the type discussed above it should be possible to obtain more detailed information about the nature of molecular collisions.

⁵ Dushman, Gen. Elec. Rev. 18, 952, 1042, 1159 (1915).

⁶ This value is slightly less than the one given in Fig. 2 because of the increased length of the gauge opening.

The following brief discussion of the decrease in intensity and the scattering of molecular beams by increased pressure in the gauge chamber shows some of the possibilities of the gauge.

The scattering of a beam of H_2 in the experimental chamber is shown in Fig. 4. The beam travels 4 cm in this chamber before striking the gauge opening. In order to eliminate any directional preference of the gauge to the incident molecules a 0.1 mm hole in a thin wall formed the opening into the gauge. This is desirable for as the gauge is turned to one side of the main beam a long opening will permit scattered molecules to enter the gauge with zero impedance only if they are scattered from the portion of the beam which is in line with the gauge opening and at the proper angle to strike that open-

Fig. 5. Beam intensity as a function of the pressure in the experimental chamber.

ing. The hole in the thin wall will, on the other hand, permit the entrance of molecules scattered from any point along the beam. The long opening might be used advantageously for a detailed study of the probability of various scattering angles.

Since the beams shown in Fig. 4 are circular and the readings were taken across a diameter, the actual areas covered by the beams are proportional to the square of the width of the curve.

In Fig. 5 the curves represent the decrease in the maximum intensity of the beams with increasing pressures of air and H_2 in the experimental chamber. The value of the mean free path of H_2 in H_2 as determined from this figure is 3.8 cm at a pressure of 10^{-3} mm of mercury. A comparison of this decrease in maximum intensity and the decrease in the percentage of the

molecules of the original beam which can be found near the center of the beam is of interest. The relative number of molecules found within this limit can be determined by a comparison of the area intensity summations of the curves of Fig. 4. These summations are represented in Fig. 5 by the triangles for H_2 and the squares for air, where the summation of the original beam is represented by 32 and the summations of the scattered beams are relative to the original. For example with an H_2 pressure of 5.3×10^{-4} mm of mercury in the experimental chamber the maximum intensity of the H_2 beam is reduced to 54 percent of its original value while 80 percent of the original number of molecules can be found near the center of the beam. With a slightly higher pressure of air the maximum beam intensity is reduced to 46 percent and 57 percent of the molecules can be found near the center of the beam. This indicates as would be expected that there is greater probability of large angle scattering in air than in H_2 .

CONCLUSION

The only difficulty encountered in the use of these gauges is the elimination of the zero drift. This drift seems to arise principally from unequal evolution of gas from the walls of the beam and compensating gauges, and from changes in room temperature. The latter effect becomes less the more nearly the two gauges are alike but it seems impossible to eliminate it entirely. The drift due to unequal outgassing is, of course, increased with increase in the impedance of the opening. In any case it may be eliminated to a great extent by baking out the gauges so that it is possible to reduce the drift of the galvanometer at maximum sensitivity to one cm in fifteen minutes.

The data given in Fig. 2 and Table II show that a beam of air formed by a pressure of 0.5 mm of mercury behind the first opening of the beam system produces a galvanometer deflection equivalent to 200 cm. H_2 under similar conditions produces a deflection of 600 cm. Since the above results were obtained, gauges have been constructed with three times the sensitivity of those used in taking the above readings merely by an improved method of flattening the wire and an increase in the length of the wire. Hence we may say that it is possible to form beams of air and H_2 which have approximately a Maxwellian distribution of velocities and produce galvanometer deflections of 600 and 1800 cm, respectively. Allowing a large margin of safety, we may assume that the galvanometer deflections are accurate to 0.5 mm. Then the relative intensity of beams of air may be determined with an accuracy of 0.08 percent. Likewise the intensity of a beam of H_2 may be determined to an accuracy of 0.03 percent. This sensitivity is ample for the determination of the mean free path of gases, for the investigation of the probability of various scattering angles resulting from collision, and for a study of the reflection of atoms from crystals. A scattered beam of H_2 with an intensity of 1 percent of the initial beam may be measured with an accuracy of 3 percent.

LUMINESCENCE DUE TO RADIOACTIVITY

BY D. H. KABAKJIAN

RANDAL MORGAN LABORATORY OF PHYSICS, UNIVERSITY OF PENNSYLVANIA

(Received March 16, 1931)

ABSTRACT

Results of several investigations on luminescence due to radioactivity carried on under the direction of the author are reviewed. It is shown that these results cannot be explained on the well-known active center theory advanced by Rutherford, or any modification of the same such as that proposed by Walsh. In certain substances, including zinc sulphide, there is an initial rise in brightness of the irradiated samples followed by a decay which cannot be represented by a simple exponential curve. It is also found that the rate of decay of brightness is not strictly proportional to the rate of emission of luminous energy as required by the theory. The observed facts can be explained qualitatively by assuming that the alpha, beta and gamma-rays produce excited molecules in the luminescent material. Return of these molecules to their initial state of more stable equilibrium results in emission of luminous energy. The rays also affect the transmission coefficient of the materials, and the apparent decay of brightness is explained as due to the increased absorption of light by the material itself, rather than to the destruction of the hypothetical active centers. This is evidenced also by the fact that in the materials studied, heating the samples usually restores the initial brightness. Quantitative application of these suggestions to the experimental curves was not possible, since the nature of the change in light absorption coefficients resulting from irradiation is not definitely determined.

LUMINESCENCE of certain chemical compounds under the excitation of rays from radioactive substances has been studied by various investigators and theories have been advanced to explain the gradual decay of brightness in these materials.

Rutherford in 1910¹ advanced a theory to explain Marsden's observations on the decay of brightness of phosphorescent zinc sulphide under the action of alpha rays from radon and its decay products. According to his theory, which we shall call the active center theory, phosphorescent zinc sulphide contains initially a number of molecular aggregates known as active centers. Passage of alpha-rays through the compound destroys a number of these active centers resulting in flashes of light known as scintillations. Active centers once destroyed cannot be reformed and since the number of such centers hit by an alpha-ray would be proportional to the number present at any time, the brightness of the compound for a given steady source of radiation should decay in accordance with a simple exponential law.

Chemically pure zinc sulphide does not exhibit this phenomenon to any great extent. The presence of a small quantity of some foreign element such as copper or manganese seems necessary to obtain a maximum effect. This fact lends force to the active center theory since the molecules of foreign matter might act as nuclei for such aggregations.

¹ E. Rutherford, Proc. Roy. Soc. 83A, 561 (1909-10).

The theory has the virtue of extreme simplicity but none of the subsequent investigators have been able to obtain a simple exponential decay curve of brightness in such compounds, especially when the measurements extended over a considerable period of time. Therefore various modifications have been suggested, from time to time, to make the original theory conform to the observed facts.

Patterson, Walsh and Higgins² found that the theory in its simple form did not agree with their measurements of brightness of luminous paints extending over 450 days. There was a distinct slowing up of the rate of decay as time went on, which could be explained if it was assumed that the active centers were capable of recovery in accordance with an exponential law.

In a more recent article Walsh³ gives additional data on the decay of brightness of luminous paints. The paints consisted of mixtures of zinc sulphide and radium bromide. Measurements of brightness extended over 4000 days.

In this article Walsh, after reviewing various theories advanced on the subject, comes to the conclusion that Rutherford's original theory agrees with his and others' results if the absorption of light by the luminous material itself is taken into consideration.

It is a well-known fact that many transparent substances are colored by the rays from radium. Zinc sulphide used in luminous paints is also colored gradually and its absorption for light progressively increased.

In combining this factor of light absorption with Rutherford's simple theory, Walsh finds, however, that the observed values of brightness agree better with the modified theory if the change in transmission constant of the material due to ionization of inactive centers be put equal to zero; i.e., if the increased absorption be considered as resulting from the destruction of active centers only.

This conclusion can not be justified unless it can be shown that the transmission constant of nonluminescent (inactive) zinc sulphide remains unchanged by the passage through it of ionizing rays. This, however, is not the case. A qualitative test made in this laboratory showed that a film of chemically pure zinc sulphide, exposed to alpha-rays from radium for a short time, is distinctly colored with resulting increase in absorption constant, although practically nonluminescent. Therefore even if in a luminescent compound the ratio of inactive molecules to active ones may be considered small at the start, evidently this ratio is constantly increasing due to the transformation of active molecules to inactive ones as required by the theory. And since these undergo a similar change in transmission constant, their effect on the decay of brightness cannot be neglected in the final analysis.

A number of researches on luminescence due to radio-activity have been carried on in this laboratory. An attempt to explain the results of these observations on the active center theory, with such modifications as have been suggested, was unsuccessful.

² Patterson, Walsh and Higgins, *Proc. Phys. Soc. Lond.* **19**, 215 (1916-7).

³ J. T. Walsh, *Proc. Phys. Soc. Lond.* **39**, 318 (1926-27).

Karrer and Kabakjian⁴ showed that mixtures of radium bromide and barium bromide acquired the property of luminescing with an intense bluish light by simply heating the compounds to a suitable temperature and then cooling. The luminescence decayed in time but could be completely regenerated by heating the compound to the original temperature. Addition of foreign substances was not necessary in this case. In fact addition of minute quantities of copper or manganese seemed to reduce the brightness.

Rodman⁵ investigated the decay of brightness of pure radium bromide, and also of some mixtures of radium bromide and barium bromide. Two points were brought out in her paper. First that the decay of brightness did not conform to a simple exponential law. Second, that although the decay was very rapid at the start, the curve representing the brightness became finally parallel to the time axis, giving a constant value of brightness which was not zero. Both of these facts are at variance with the active center theory.

For example, the brightness of pure radium bromide decayed to about one percent of its initial value in 24 hours. It reached a constant value in about 300 hours and did not show a measurable variation in the following 200 hours.

Smith⁶ investigated the luminescence of pure barium bromide exposed to alpha, beta and gamma-rays. In his case the source of the rays and the luminescent material were kept separate so that it was possible to observe the variation of brightness from the start. Smith's results showed an initial rise in brightness of barium bromide on exposure to the rays from radium. This rise continued for several hours reaching a maximum value and then decaying to a final constant value.

It is quite evident that Smith's results cannot be explained by the active center theory which fails to account for the initial rise in brightness. The final approach of brightness to a constant value instead of zero is also in agreement with Rodman's results.

Since the original active center theory was formulated by Rutherford to explain the decay of luminescence in zinc sulphide, it was considered desirable to investigate this compound by a similar method.

Gessner⁷ undertook this investigation by means of an improved type of apparatus. The constant source of rays was well separated from the luminescent material and the apparatus so arranged that readings of brightness could be taken within two minutes after the exposure.

The results obtained by Gessner were similar to those of Smith. In every case there was an initial rise in brightness, followed by a decay which was not exponential. Neither did any part of the curves conform to the modified theory developed by Walsh.

This initial rise in brightness of zinc sulphide was also observed by Marsden for beta-ray excitation, but no attempt was made to explain this fact in formulating the active center theory.

⁴ E. Karrer and D. H. Kabakjian, *Jour. Frank. Inst.* **186**, 317 (1918).

⁵ J. Rodman, *Phys. Rev.* **23**, 478 (1924).

⁶ L. E. Smith, *Phys. Rev.* **28**, 431 (1926).

⁷ G. S. Gessner, *Phys. Rev.* **36**, 207 (1930).

Since the alpha-rays produce individual scintillations, while the beta-rays produce more or less diffuse illumination, it may be assumed that the mechanism of light emission is different for the two rays. Chariton and Lea⁸ have found, however, that scintillations similar to those produced by alpha-rays can be obtained from beta-rays under favorable conditions, showing clearly that the only difference between the two types of excitations is the energy carried by the individual rays.

That the rise observed in Gessner's samples was not due to beta-rays was evidenced by the fact that a polonium plate used to excite the compound gave the same type of brightness curve.

In attempting to check Walsh's latest explanation on the decay of zinc sulphide paints, Gessner had used thin films of zinc sulphide and a more intense source of radiation, hoping thereby to accelerate the rate of decay. The brightness of his samples were uniformly greater than those of Walsh. If the emission of light results from destruction of active centers, evidently these

Fig. 1. Curves showing the decay of brightness in zinc sulphide. A, alpha, beta and gamma-rays from radium. B, beta and gamma-rays. Thickness of material, 0.022 cm.

were being destroyed at a greater rate, and since the volume of the material used, and presumably the initial number of active centers was very small, one would expect the brightness of these samples to decay much faster than those of Walsh. The results were quite the opposite. Walsh's brightest sample (Sample H, initial brightness 0.28 candles per square meter) shows a decay of over 85 percent in 400 days whereas one of Gessner's samples (Sample 4, Maximum brightness 0.4 candles per square meter) shows a decay of less than 50 percent for the same interval. This disagreement with the theory can hardly be explained by possible differences in the materials used by the two investigators.

It was also found that in the same material of approximately the same thickness the rate of decay was not in direct proportion to the rate of emission of light but depended on the nature of exciting rays.

Fig. 1* illustrates this point. Although the total amount of light emitted

⁸ J. Chariton and C. A. Lea, Proc. Roy. Soc. A122, 335 (1929).

* Curves represented in Fig. 1 and Fig. 2 were obtained by Mr. Gessner. For apparatus and the method of measurement, refer to his article, Phys. Rev. 36, 207 (1930).

by sample *B*, due chiefly to beta-ray excitation is greater than that from sample *A* where alpha-ray excitation predominates, the rate of decay of brightness is in the reverse order. Assuming that the mechanism of light emission is the same for the two types of radiation this difference in the rates of decay of the two samples cannot be explained on the active center theory.

Another check on the theory could be obtained by estimating the number of active centers in zinc sulphide from the data given in Fig. 1, on the assumptions made by Walsh in estimating the number of active centers in his samples.

By integrating the area under curve *A*, the total amount of luminous flux produced in a quantity of zinc sulphide having a thickness of 0.022 cm and an area of one square cm can be computed from the formula

$$F = \frac{4\pi a I}{1 - e^{-0.022a}}$$

where *F* is flux in lumens; *I* is brightness in candles/cm²; and *a* is the coefficient of absorption of freshly prepared zinc sulphide.

Taking the value of *a* as 32 and the mechanical equivalent of light for the wave-length emitted as 660 lumens per watt, the amount of luminous energy radiated by this sample during the first 350 days is roughly equal to 1.5×10^{10} ergs.

If *N* is the number of active centers destroyed during this interval of time and if it be assumed that each active center emits, on destruction, one quantum of energy corresponding to a wave-length of $550m\mu$, the total amount of energy radiated by the destruction of *N* active centers will be equal to $N \cdot 3.6 \times 10^{-12}$ ergs. Equating this with the above expression we have

$$N = \frac{1.5 \times 10^{10}}{3.6 \times 10^{-12}} = 4.16 \times 10^{21}.$$

But the number of molecules in this quantity of zinc sulphide is approximately 5.5×10^{20} . Therefore the number of active centers destroyed in this sample during the first 350 days comes out more than 7 times the number of molecules present. Since the brightness of the sample has decayed to 56 percent of its maximum value and the rate of decay has become very much slower it must be assumed that the original number of active centers present is many times the number of molecules present in the material if the active centers once destroyed cannot be regenerated.

The active center theory of luminescence, therefore, seems inadequate to explain, among other things:

- (1) The initial rise in brightness of all the samples investigated;
- (2) The difference in the rate of decay of brightness in luminescent material for alpha and beta-ray excitations;
- (3) The general nature of brightness decay curves.

In view of these facts it seems more reasonable to assume that the passage of the rays through luminescent materials results, not in destruction of any hypothetical active centers, but rather in producing excited molecules which emit light on returning to their normal energy levels. As this is a reversible change this phenomenon can continue indefinitely.

The rays may also produce a certain amount of ionization or dissociation resulting in a more stable change such as coloration, due to the inability of the ions to recombine at ordinary room temperatures. The two phenomena are not strictly interdependent. It is possible to have coloration with very little luminescence and vice versa.

Light emission by excited molecules can take place in two distinct ways, giving rise to two types of luminescence. If the whole absorbed energy is re-emitted instantaneously, unaffected by the temperature of the absorbing material, the phenomenon is known as fluorescence. If, however, the absorbed energy is re-emitted gradually and the absorption and emission are more or less dependent on the temperature of the absorbing material, the phenomenon is known as phosphorescence. What is known as thermoluminescence is really phosphorescence at higher temperatures.

In this paper the term phosphorescence is used in a general sense without regard to the nature of the exciting rays. Its characteristic feature is the inability of the excited molecules to return at once to their normal state, consequently a phosphorescent material will continue emitting light after the exciting rays have been removed.

If the luminescence produced by alpha, beta and gamma-rays in the investigated materials is of the phosphorescent type, the initial rise in brightness of these samples could be explained. This would mean that all the energy absorbed from the rays is not radiated at once. It can be shown that this is generally true for the materials under discussion. Even in the case of alpha-ray excitation of zinc sulphide a diffuse radiation lasting several minutes follows each scintillation. This can easily be demonstrated by exposing a zinc sulphide screen to a strong source of alpha-rays for a few seconds. When the source is removed the screen will continue to glow in the dark for several minutes, its brightness gradually decaying to zero. It can also be shown that this is due to slow radiation of the energy absorbed from the alpha-rays and not to a possible absorption of its own luminous energy.

At ordinary room temperatures the ratio of energy radiated as diffuse light to that radiated as scintillations is small and has usually been overlooked, but this ratio is dependent on the temperature of the absorbing material. If a zinc sulphide screen in contact with a polonium plate is cooled to the temperature of liquid air its brightness is considerably diminished. When after a few minutes of exposure the polonium plate is removed and the screen is allowed to reach the room temperature, it glows much more brightly, showing that a larger percentage of the energy of the rays is absorbed and retained at the lower temperatures and released only with the aid of heat agitation of the molecules.

These experiments justify us in regarding the absorption and emission of

energy by luminescent materials when excited by alpha, beta and gamma-rays, as essentially a phosphorescence phenomenon. If this view is correct then the brightness of these materials, when excited by a constant source of rays should rise to a maximum where the rate of absorption and emission balance each other, and if there is no physical or chemical change in the material, it should remain constant at this value indefinitely. But it is well known that the coefficient of light absorption of these materials increases as a result of irradiation, therefore the brightness must decay in time, not necessarily because of a decrease in the amount of light produced but due to the fact that more and more of it is absorbed by the material itself as time progresses.

Again if the coefficient of absorption never becomes infinite but tends to approach a constant as time approaches infinity, the brightness would never decay to zero.

Fig. 2. Luminosity curve. Capsule A, beta, gamma-rays. Calcium sulphate Mn activated.

These conclusions are qualitatively in agreement with the observed facts on all materials investigated in this laboratory.

Fig. 2 represents the rise and decay in brightness of a typical thermoluminescent material which is also phosphorescent at ordinary room temperatures. The material consists of crystalline calcium sulphate activated by manganese. It will be noted that the brightness increases in time reaching a maximum in about 70 hours and then begins to decay. The decay curve is not a pure exponential and final brightness will never become zero. The similarity between the characteristics of this curve and those obtained by Smith and Gessner is quite apparent.

The factor controlling the decay of brightness seems to be the change in the transmission constant of the material. In pure barium bromide this change is small and its rate of decay is also small. The final constant value of brightness for samples investigated by Smith varied from 40 percent to 60 percent of their maximum. On the other hand in pure radium bromide, which becomes

almost black, the rate of decay is very large and the final constant value of brightness is about 0.1 percent of its maximum. Both radium bromide and barium bromide completely recover their maximum brightness on heating to an adequate temperature. The heating results also in complete disappearance of any coloration.

According to this view luminous paints which have decayed should also regain their brightness if the coloration of the crystals is removed. This was attempted on some samples of zinc sulphide paints which had been allowed to decay for over eleven years in sealed tubes. The paints contained 50 and 100 micrograms of radium element, respectively, per gm of zinc sulphide. On heating the tubes over a bunsen burner the brightness was promptly restored but the degree of restoration could not be determined since no record of the initial brightness of the paint was available. The coloration of the samples disappeared at the same time and their photosensitiveness was also revived.

It is not claimed here that there is no chemical decomposition in the irradiated samples resulting in a decrease of light emission. But it has been shown that an attempt to explain the decay of luminescence as due to disappearance of active centers gives inconsistent results, and since it has been shown that the change in transmission constant plays such an important part in the apparent decay of brightness, a quantitative application of any theory of luminescence becomes difficult until the exact nature of this change is determined experimentally.

It has already been shown that the increase in absorption constant cannot be considered as due to the destruction of hypothetical active centers. On the other hand the curves representing the rise and decay of brightness do not furnish sufficient data to determine the nature of this change. Experiments are under way to determine directly the variation in the transmission constant of some of these materials as a result of irradiation, when a quantitative application of the assumptions made above to the experimental curves will become possible.

If the absorption coefficient a is defined by the expression $I_x/I = e^{-ax}$ where I_x/I is the fraction of light transmitted through thickness x of the absorbing material, it is quite evident that a is a variable quantity in this case, its value depending upon the nature and intensity of the radiation and the time.

$$a = f(R, t).$$

In correcting for the absorption of light by the walls of the glass containers Walsh assumes a transmission factor, due to the coloration of glass, of the form

$$T = e^{-pt}$$

where p is a constant for a given tube and t is the time. This is based on the assumption that the coloration of the glass is produced by the destruction of certain molecules in the glass. On this view the transmission should become zero when t is put equal to infinity. If, however, the coloration of transparent materials is due to ionization of the molecules, such ionization might have a

saturation value, in which case the transmission factor would be represented by an expression of the form

$$T = a \cdot e^{-\beta(1-e^{-ct})}$$

where a , b and c are constants for a given material and a given intensity of radiation of one type. In this expression the value of T is never equal to zero. This is more in accordance with the experimental facts. However this may prove to be, it has been shown that experimental results recounted in this paper cannot be satisfactorily explained on the active center theory of luminescence without further modification.

The writer wishes to acknowledge his indebtedness to Mr. Gessner for the use of data obtained by him and to Dr. H. C. Richards and Dr. E. E. Witmer for many valuable suggestions and criticisms during the preparation of this paper.

THE ELECTRIC FIELD, ATMOSPHERE AND
EFFECTIVE TEMPERATURE OF THE SUN

BY ROSS GUNN

NAVAL RESEARCH LABORATORY
WASHINGTON, D. C.

ABSTRACT

The study of important electromagnetic effects in the solar atmosphere undertaken in previous papers is continued. It is shown that the large observed spread of effective temperatures of the sun's radiation can be accounted for by the presence of electric and magnetic fields in the solar atmosphere. The magnitude of the electric field at a level where the magnetic field is 25 gauss, calculated from the observed spread of temperatures, is found to be 0.015 volts/cm and agrees well with 0.013 volts/cm calculated earlier from the observed anomalous motions of the solar atmosphere. Gravitational equilibrium is found to be unnecessary in all regions of the atmosphere and it is shown that the "support" and stability of the chromosphere and its anomalous eastward motion are evidences of precisely the same electromagnetic mechanism. An electric field of the value given above is shown to account qualitatively for certain bright line spectra in the chromosphere of the sun. The strange observed relation between bright line spectra and rapid axial rotation of stars, just pointed out by O. Struve of the Yerkes Observatory, confirms in a striking manner some of the conclusions of this and earlier papers.

IN A series of papers it has been shown that the anomalies of the solar rotation arise from electromagnetic effects which take place in the crossed electric and magnetic fields existing in the ionized solar atmosphere. The magnitude and direction of the magnetic field is readily determined by observation, but the magnitude of the electric field is much too small to produce measurable Stark effects and must be inferred from the observed atmospheric motions. In the present paper we consider a method of calculating the magnitude of the electric field from spectroscopic data and will show that the departures of the solar radiation from that of black-body radiation lead to a value for the electric field which agrees with that calculated in earlier papers. Measurements show that the effective solar temperature calculated from the quality of solar radiation is over 1000° higher than that inferred from measurements of the density of radiation. The difference of the effective temperatures is so great that we must conclude that processes other than thermal must be present which add energy to the ions. It is clear that an electric field of sufficient magnitude might add energy to the ions during their free path so that on collision they would have energies higher than that indicated by the temperature of the region. A rough calculation shows that a radial electric field alone will not account for the observed features of the solar radiation, for if there were no solar magnetic field the conductivity of the atmosphere would be so great that electric fields would be very small. However, if we consider both electric and magnetic fields the difference in the effective temperatures is readily accounted for.

EFFECT OF CROSSED ELECTRIC AND MAGNETIC FIELDS

In earlier papers¹ we considered the effect of crossed electric and magnetic fields on the electrical conductivity, diamagnetism and mass motion of an ionized gas. It has been shown¹ that diamagnetism limits the solar magnetic field and the resulting distribution is such that the field is nearly tangential to the surface over most of the sun. The electric field, by symmetry, must be radial so that in the following we may assume for simplicity that the electric and magnetic fields are always perpendicular.

The path described by an ion in perpendicular electric and magnetic fields is a cycloid.² An ion starting from rest is initially acted upon only by the electric field which accelerates the ion; as the velocity increases the magnetic force at right angles to its motion increases until the ion is moving at right angles to the electric field. The magnetic force continues to act and the ion is forced by its inertia to move against the electric field, whereby it loses energy till it comes to rest. The process then repeats itself again and again. The net result of this process is that the ion progresses in a direction perpendicular to both the electric and magnetic fields and on the average does not advance in the direction of the electric field.

It is clear that in certain parts of the cycloidal path the ion has much more energy than at other points, and if the ion collides at a point in its path where its energy is large, ionizing effects will be greater than if the ion collided in a part of the path where the energy is small. In the general case the ion starts its path with a certain thermal energy and in tracing its cycloidal path it acquires and loses energy repeatedly from the electric field. If R is the radius of the generating circle of the cycloidal path, E the average electric field encountered by the ion in its path, and e the ionic charge in e.m.u., then the difference in energy W of the ion between the top and bottom of its path is

$$W = 2REe. \quad (1)$$

This energy is obviously supplied by the electric rather than the magnetic field, for the motion of the ion is always at right angles to the magnetic force and hence the magnetic field cannot transfer energy to the ion or the ion energy to the magnetic field. It is of importance to note that Eq. (1) gives the maximum energy difference and no matter how long the free path, the ion cannot acquire more. We neglect the less frequent case of successive collisions where an ion of initially large energy collides with another at a favorable point in its path and this ion in turn picks up additional energy and passes it on to still another.

The radius of the cycloidal generating circle R is given by

$$R = \frac{mv}{Be} \left[1 - \frac{2u}{v} \cos \delta + \frac{u^2}{v^2} \right]^{1/2} \quad (2)$$

where m is the mass of the ion, v the initial ionic velocity in a plane perpen-

¹ R. Gunn, Phys. Rev. 32, 133 (1928); 33, 614 (1929); 33, 832 (1929); 34, 335, 1621 (1929); 35, 635 (1930); 36, 1251 (1930); 37, 283 (1931).

² L. Page, Phys. Rev. 33, 55? (1929).

dicular to the magnetic field B , u the ion drift velocity resulting from the crossed electric and magnetic fields and δ the angle between u and v . When the free paths are long and the electric and magnetic fields are perpendicular, u is given by

$$u = E/B. \quad (3)$$

A few of the ions will acquire and expend the maximum energy given by Eq. (1) and some will lose energy. To get the mean gain in energy for a typical ion we will simply take an arithmetical average and therefore we have from Eqs. (1), (2), and (3) that

$$W_1 = mvu \left(1 + \frac{u^2}{v^2} \right)^{1/2} = \frac{E}{B} \left[2mkT \left(1 + \frac{mE^2}{2kTB^2} \right) \right]^{1/2} \quad (4)$$

where W_1 is the approximate mean increase in energy and $(2mkT)^{1/2}$ has been written for mv . The mean increase in energy W_1 may, for convenience, be expressed in terms of an equivalent effective temperature and be equated to $3k\Delta T/2$ where k is the Boltzmann constant and ΔT is the change in effective temperature due to electrical effects. Making this substitution and transforming Eq. (4) we have

$$\frac{\Delta T}{T} = \frac{2u}{3} \left[\frac{2m}{kT} \left(1 + \frac{mu^2}{2kT} \right) \right]^{1/2} \quad (5)$$

or if we solve this for the electric field E we have

$$u^2 = \frac{E^2}{B^2} = \frac{kT}{m} \left[\left(1 + \frac{9}{4} \left(\frac{\Delta T}{T} \right)^2 \right)^{1/2} - 1 \right]. \quad (6)$$

In Eq. (5) we note that the difference in the effective temperatures is proportional to the square root of the ion mass. This indicates that the ions rather than the electrons are the particles effective in increasing the apparent temperature of the solar atmosphere although there is no reason why the ions cannot transfer their high energies to electrons by collision.

DEPARTURE FROM BLACK-BODY RADIATION

Several writers^{3,4,5,6} have studied the solar radiation and found it to depart markedly from a black body distribution. At one time it was thought the departures were due to varying general absorption in the radiating layers but Milne⁴ concluded that this was quite inadequate. Eddington⁶ has reworked some of the data and gives 4660° for the effective temperature of the sun as calculated from the density of radiation and 5740° as the effective temperature calculated from the quality of the radiation. It is clear that the emitted light is much richer in high frequency radiation than would be the case if the sun radiated like a black body. The differences in the effective temperatures, or 1080°, is so great that the energies of some of the ions must be considerably more than that of the mean value. If we are not particularly

⁶ Eddington, *Internal Constitution of the Stars*.

concerned with the detailed mechanism of the radiation process, Eq. (5) of the preceding section permits a test of our prediction that the effects arise from an electric field in the solar atmosphere. Earlier work¹ showed that the mean atomic weight of the solar atmosphere in the region of the reversing layer was 6.6 if no account were taken of the electrons, or calling the mass of the hydrogen atom h , the mean mass of the ions in the reversing layer is $6.6h$. Moreover, the superposed atmospheric drift velocity u is known from astronomical data to approximate 0.5 km/sec. Substituting in Eq. (5), $m = 6.6h$; $h = 1.64 \times 10^{-24}$ gm; $u = 5 \times 10^4$ cm/sec; $k = 1.37 \times 10^{-16}$ and $T = 4660^\circ$ we find $\Delta T/T = 0.197$ so that $\Delta T = 920^\circ$. This value is to be compared with the observed value 1080° and is considered satisfactory because the method of averaging to get statistical values is rough. The agreement is greatly improved if we select a mean value for the effective temperature rather than the lower value derived from the density of the solar radiation. Observation shows that the superposed drift velocity u does not change rapidly with altitude in regions which can be observed so that according to Eq. (5), ΔT also changes but little with altitude. This is consistent with the observed fact that the intensity-frequency curve decreases very rapidly on the high frequency side of the maximum. Our calculations clearly indicate that the observed spread of effective temperatures can be accounted for by the presence of electric and magnetic fields in the solar atmosphere.

MAGNITUDE OF THE ELECTRIC FIELD

In other papers¹ the relation of the mechanical motions of the solar atmosphere to electromagnetic effects was considered and it was concluded that the observed motions required that the solar atmosphere have an electric field directed radially inward and amounting to 0.013 volts/cm in the region where the magnetic field was 25 gauss. The magnitude of the electric field cannot be checked by Stark effect observations and it becomes necessary to look elsewhere for supporting evidence. The spread of observed effective temperatures provides an independent method of calculating the magnitude of the field and we turn at once to Eq. (6) which connects observed quantities with the electric field. We follow earlier work and take $m = 6.6h$; $h = 1.64 \times 10^{-24}$ gm; $k = 1.37 \times 10^{-16}$; $T = 4660^\circ$; $\Delta T = 1080^\circ$ and $B = 25$ gauss. Substitution in Eq. (6) gives $E = 0.0148$ volts/cm. The agreement of this value with the earlier calculation¹ is most satisfactory and it is evident from the form of Eq. (6) that the agreement will be equally satisfactory at all other levels of the solar atmosphere. The present method of calculating the field is apparently incapable of determining the sign of the electric field, but, as we have pointed out previously, the sign inferred from the solar motions is precisely the sign observed on the earth, i.e., negative or radially inward. The agreement of the two methods of calculating the magnitude of the field strongly supports the conclusion that a solar electric field exists and that the mass motions of the atmosphere and the differences observed in the effective solar temperatures are simply different aspects of the same fundamental physical phenomena.

STABILITY OF THE SOLAR ATMOSPHERE

Eclipse spectra show that large amounts of material, notably calcium, exist high in the chromosphere and the distribution of this material is such that it cannot well be in gravitational equilibrium with a supporting gaseous pressure. Milne⁷ has attempted to account for the support and stability of this material by assuming that radiation pressure was great enough to overcome the gravitational forces. His calculations show that the calcium must absorb selectively in what appears to be a highly artificial manner. A still more serious objection to his theory is the fact that once sufficient absorption is built up by special assumptions the atom will be blown away from the sun because the radiation pressure does not decrease as rapidly as gravity. Thus Milne's atmosphere is unstable.⁶

Our study of electromagnetic effects suggests that the stability of the chromosphere does not depend on a specialized type of dance on a sunbeam but does depend on very real and sufficiently large electric and magnetic forces. Although the force on a positive ion in the solar atmosphere is vertically downward and hence in the same direction as gravity, we have seen that the ion does not move downward but on the average moves parallel to the solar surface. Thus ions executing long free paths in crossed magnetic and electric or gravitational fields are "supported" and can progress in the direction of the force field only by numerous collisions. It is therefore clear that it is not necessary to think of the very long free path ions in the solar atmosphere as being in gravitational equilibrium. To illustrate, suppose that neutral molecules of all materials are shot, undeviated by the magnetic or electric fields, by thermal processes to high altitude regions of low pressure where they immediately become ionized. The recombination coefficient will be different for different kinds of ions and those particles that remain neutral for an appreciable time will be acted on by gravity and drop to lower levels. The ions with very small recombination coefficients (calcium for example) will spend most of their life in an ionized condition and therefore will be "supported" and at the same time swept parallel to the solar surface with a velocity dependent on the ratio of the crossed electric and magnetic fields. Eventually an equilibrium condition will be reached and the supply of neutral calcium atoms will balance the loss of those dragged down by the electric field as the result of a large number of collisions and the few which are neutralized and fall under the action of gravity. We thus see that no special mechanism is necessary to account for the "support" of the chromosphere and that it is supported by precisely the same mechanism that produces its observed anomalous eastward drift.

BRIGHT LINE SPECTRA

Doubly reversed, or bright line spectra, are characteristic of certain types of stars but there have been theoretical difficulties in accounting for their presence. Eddington⁶ has reviewed the subject and he concluded without attempting to make the statements quantitative, "that bright lines in the spectrum of a static star indicate that either (a) the star is greatly disturbed

⁷ E. A. Milne, *Monthly Notices* **84**, 354 (1924).

by "thunderstorms" or (b) it is a nebulous star." The sun can hardly be called a nebulous star and we should be able to account for certain lines of the flash spectrum by electrical excitation of the type we have considered. The electrical field will add considerable energy only to an ionized particle and more analysis will be necessary to determine the exact mechanism by which an atom is excited to radiation. In another place we have expressed the ratio of the energy added to an ion, to its thermal energy in terms of temperatures and, as a numerical example, we will calculate the ratio of the energies for a helium ion. In Eq. (5) we will take $m = 6.56 \times 10^{-24}$ gm; $u = 5 \times 10^4$ cm/sec; $T = 4660^\circ$ and we find $\Delta T/T = 0.16$; that is to say, all the helium ions periodically acquire energies 16 percent greater than their thermal energies. Similarly the added energy for calcium is 50 percent while that of hydrogen is only 8 percent. Thus we are led to believe that the additional energy available is adequate to produce bright line spectra. For the purpose of this paper, which is primarily concerned with the solar electric field, the rough value given above is adequate, but it is evident that a complete study of the bearing of an electric field on the ionization equilibrium relations in stars is necessary to give a complete description of the events. Saha's⁸ theory of stellar ionization will be readjusted to take account of the fields and it is expected that such a readjustment will improve the agreement of his formula with observation.

CONCLUSION

We have indicated in outline that spectroscopic data regarding the sun bear out our earlier conclusion that electromagnetic phenomena are important in the solar atmosphere. It is rather surprising that the apparent solar rotation should be so closely related to the spectral distribution of radiation from the sun but we have had a suggestion that this might be true in a recent paper by Struve.⁹ Dr. Struve has noticed a remarkable correlation between the rotation of stars and their spectral class. The early type stars rotate with great rapidity and several are apparently on the verge of rotational instability. The considerations of the present paper indicate that the early type stars have electric and magnetic fields of considerable magnitude and that our sun is probably a fair representative of stellar bodies. A complete study of the sun is therefore of the greatest importance if we are to understand and correctly interpret the physical phenomena which astronomers observe. *Note added March 24, 1931:*

The March issue of the *Astrophysical Journal* has just appeared and contains another paper by O. Struve giving observational data which is in remarkable accord with the theory developed above. Dr. Struve states "Excessive rotations, estimated at 9 or 10 (. . . 250 km/sec.), are frequent. Apparently bright lines occur preferentially in stars having rapid axial rotation."

The relation of Eq. (5) shows that the ratio of the additional excitation energy to the thermal energy is directly proportional to the superposed drift velocity u . Thus theory predicts a strict parallelism between high *apparent* rotations and bright line spectra. Struve's results appear to be a beautiful confirmation of the material of this and preceding papers.

MOLECULAR ASSOCIATION

BY J. ALBERT WEHRLE

PHYSICAL LABORATORY, UNIVERSITY OF PITTSBURGH

(Received March 20, 1931).

ABSTRACT

To study the molecular association of nitrobenzene, the dielectric constant of mixtures of this substance with benzene (nonpolar solvent) and polar liquids (ethyl ether, chlorobenzene and acetone) was measured. The molar polarizations of the two polar substances were calculated as a function of the concentrations. If the dependence of the molar polarization of one polar liquid on the concentration of the other is taken as a measure of the association, the experiments show that the larger the electric moment of the molecule, the stronger is the association. They also show that association takes place not only between the molecules of a given substance, but also between two substances that may be quite different, provided they are both polar.

INTRODUCTION

THE polar liquids or gases, i.e., those whose molecules have an electric moment, show some deviation from simple additive or linear laws at certain concentrations. The explanation for these deviations is that the molecules associate, i.e., form complexes bound not by chemical forces but mainly by the electric fields of the dipoles.

From the dielectric constant point of view, this behavior may be described as follows: if a polar liquid (say nitrobenzene) is dissolved in a nonpolar liquid (say benzene) the variation of the polarization of the mixture as a function of the concentration of the polar liquid is, in general, not linear. In certain cases the apparent electric moment of the molecules is larger and in other cases smaller than that obtained from an extrapolation at infinite dilution, but is always variable with the concentration. The simplest theory of this effect is that the polar molecules associate to produce a sort of polymerized molecule having a smaller or larger moment depending on the relative orientations of the dipoles forming the complex.¹

Debye² has proposed a simple theory of this effect corresponding to the theory that he and Hueckel have given for electrolytes. However the assumptions he had to make, for instance spherical molecules with the dipole at the center, seem too far from reality to confer much value to the theory according to which the polarization per mole should increase with concentration if association takes place. This however is true experimentally only for alcohols. Another theory apparently less general and with looser foundations has been given by Wolfke.³

¹ C. P. Smyth, *Chem. Rev.* **6**, No. 4, (1929).

² Debye, *Handbuch der Radiologie*, Vol. 6.

³ Wolfke, *Phys. Zeits.* **29**, 713 (1928).

It seemed thus commendable to accumulate data on the phenomenon of association before the theory could be advanced very much, hence this investigation.

If an electric field is responsible for the association one would expect it to depend (a) on the temperature, because it controls the motion of the molecules, (b) on the magnitude of the electric moment and (c) on the shape of the molecules. Data available at the present time give information concerning the association of a substance with itself alone.⁴ Our experiments investigate the association of one type of molecule with another, in particular with respect to factor (b). Special consideration was given to the association of

STRUCTURAL FORMULAS

Fig. 1. Structural formulas of the compounds used. Probable polarity indicated.

nitrobenzene⁵ ($\mu = 3.90 \times 10^{-18}$) with ether ($\mu = 1.24 \times 10^{-18}$), chlorobenzene ($\mu = 1.52 \times 10^{-18}$) and acetone ($\mu = 2.70 \times 10^{-18}$), μ being the electric moment, in e.s.u. \times cm. The final results of our experiments give some indication of the effect of the electric moment as well as that of the shape of the molecule on the degree of association. The structural formulas, Fig. 1, may be of service when considering the effect of the position of the moment in the molecule.

SIMPLE THEORY OF THE DIELECTRIC CONSTANT OF MIXTURES

Debye² has shown that the dielectric constant, ϵ , of a mixture under all conditions satisfies the equation

$$\frac{\epsilon - 1}{\epsilon + 2} = \frac{4\pi}{3}(n_1\alpha_1 + n_2\alpha_2 + \dots) \quad (1)$$

⁴ Rolinski, Phys. Zeits. 29, 658 (1928).

⁵ J. W. Williams, Phys. Zeits. 29, 178 (1928).

where n_i is the number of molecules of type i per unit volume, and α_i is given by

$$\alpha_i = a_i + \frac{\mu_i^2}{3kT} \quad (1a)$$

where a_i comes from the deformation of the molecules, μ_i is the permanent electric moment, k is Boltzmann's constant and T the absolute temperature.

If we introduce as new variables the mole fraction $f_i = n_i / \sum n_i$ and the polarization $P_i = 4\pi N\alpha_i/3$ we get from (1)

$$P = \frac{\epsilon - 1}{\epsilon + 2} \frac{\sum f_i M_i}{d} = \sum P_i f_i \quad (2)$$

where M_i is the molecular weight and d the density of the mixture.

Fig. 2. Sectional view of test condenser and cell.

The theory underlying this formula requires a complete independence of the molecules. If however there is association, we can retain the same expression, assuming then that the apparent moment μ_i varies. Thus the P_i 's which are really molecular constants vary also, and their variation may be taken as a measure of the degree of association.

Our experiments consisted in measuring the dielectric constant, ϵ , of mixtures of known concentration f_i . After determining the density, d , the value of P could be obtained.

APPARATUS AND PROCEDURE

A simple resonance circuit was used in the measurement of the dielectric constant of the mixtures investigated. A standard condenser of $2500\mu\mu\text{f}$ and a test condenser (Fig. 2) of approximately $40\mu\mu\text{f}$ connected in parallel, constituted the capacity of the absorbing circuit. A quartz crystal oscillator (Fig.

3), wavelength 525 meters, supplied the energy. Resonance was determined by the maximum galvanometer deflection in a galena crystal rectifier circuit tapped across a few turns of the inductance of the absorbing circuit. There

Fig. 3. Oscillator and absorption circuits.

was usually enough energy absorbed from the oscillator to obtain a maximum deflection of 30 to 40 cm, even when only one-tenth of the current passed through the galvanometer.

Fig. 4. Calibration curve of test condenser.

The procedure of a test involved the determination of resonance with (a) the standard condenser and the leads of the test condenser in the circuit; (b) the empty test condenser included in the circuit; (c) the mixture under investigation in the test cell.

The uncorrected experimental value of the dielectric constant of any particular solution studied was calculated from the relation

$$\epsilon_s = \frac{C_s}{C_a} = \frac{\frac{\epsilon_s A n}{4\pi d}}{\frac{\epsilon_a A n}{4\pi d}}$$

where C_a , C_s , are capacities of the test condenser with air and with the solution, respectively; ϵ_a , ϵ_s , the corresponding dielectric constants; A , the area per plate of the test condenser; n , the number of plates of dielectric; d , the plate spacing.

Values of dielectric constant for various concentrations of carbon disulphide and nitrobenzene were plotted (Fig. 4) against values, assumed true for the same concentration as reported by J. W. Williams.⁶ This plot was taken as the calibration curve of the test condenser and was used in correcting ϵ_s values.

Measurements of ϵ_s were made at a temperature of $25^\circ\text{C} \pm 0.5^\circ$ and could be reproduced in practically all cases to within less than 1 percent. It is to be observed that while the method is quite convenient and of fair accuracy, it proves, in its present form, unsatisfactory for values of dielectric constant above ten. This may be due to any one or possibly both the following causes: (a) once this region of dielectric constant has been attained, the galvanometer deflection has materially decreased and, due to a lack of sensitivity, the motion of the mirror has become relatively sluggish; (b) the introduction of a solution of dielectric constant of the order specified above gives rise to appreciable displacement currents in the dielectric. This is equivalent to adding an effective resistance to the L and C of the pick-up circuit, resulting in a flattening of the resonance peak.

The solutions tested consisted of several series composed of a nonpolar type, benzene, and two polar types, ether and nitrobenzene, chlorobenzene and nitrobenzene or acetone and nitrobenzene. From the stock solutions, test solutions of 150 cc each were prepared containing nitrobenzene in concentration of 0, 2, 4, 6, 8, 10 percent by volume, respectively.

Densities were obtained by means of a Mohr balance. An Abbe refractometer served for the refractive index determination.

PURIFICATION OF MATERIALS

As it was not the purpose of these experiments to conduct an investigation of the highest precision, but rather to discover some facts about molecular association, the materials used were subjected only to the following purifications.

Benzene. The first sample, thiophene free, was frozen out twice and fractionated. In the case of the second sample, drying with phosphorus

⁶ Williams and Ogg, Jour. Amer. Chem. Soc. 50, 96 (1928).

pentoxide and fractionation yielded a product whose constants were practically identical with those of the sample originally prepared.

Ether. The best grade obtainable was used as supplied by the manufacturer.

Carbon disulphide. After a preliminary agitation with mercury, to remove foreign sulphides, it was dried with phosphorus pentoxide and fractionated.

Chlorobenzene. A sufficient quantity of a high grade material was secured to meet all the needs of the contemplated experiments and was used as supplied.

Acetone. To secure a water-free product, the material was refluxed for three hours over potassium hydroxide and distilled. A further drying over night with fused calcium chloride, refluxing for two hours and fractionation completed the process.

RESULTS

Results are given in Tables I-III. The curves shown are illustrative of the data on benzene, ether and nitrobenzene.

f_1, f_2, f_3 are mole fractions of benzene, acetone and nitrobenzene, respectively; ϵ, n, d are corrected dielectric constant, index of refraction and density, respectively; P_{123} the polarization of the three-component solution calculated from Eq. (2); P_{23} the polarization of acetone and nitrobenzene alone, calculated from $P_{23} = P_{123} - f_1 P_1$.

Values of P_{23} were plotted against mole fraction of nitrobenzene at constant ether, and against mole fraction of ether at constant nitrobenzene. They were obtained from P_{123} by subtracting the polarization due to benzene, which is known to remain constant, as it is nonpolar and does not associate. P_{23} then represents the polarization due to the polar substances and can be expressed as

$$P_{23} = f_2 P_2(f_2, f_3) + f_3 P_3(f_2, f_3). \quad (3)$$

P_2 and P_3 are written explicitly as functions of f_2 and f_3 because they associate and because the association depends upon the concentration. Differentiating (3) with respect to f_2 and putting $f_2 \rightarrow 0$, we obtain

$$\left(\frac{\partial P_{23}}{\partial f_2} \right)_{f_2 \rightarrow 0} = (P_2(f_2, f_3))_{f_2 \rightarrow 0} + \left(\frac{\partial P_3(f_2, f_3)}{\partial f_2} \right)_{f_2 \rightarrow 0}$$

and a similar expression for

$$\left(\frac{\partial P_{23}}{\partial f_3} \right)_{f_3 \rightarrow 0}.$$

Illustrative curves are presented in Figs. 5, 6, 7, 8. The fact that the curves vary with f_3 or f_2 shows definitely that P_2 and P_3 are both functions of f_3 and f_2 ,

Fig. 5. Polarization, P_{23} , of nitrobenzene and ether in benzene against percent ether for several constant percentages of nitrobenzene.

Fig. 6. The data of Fig. 5 differently presented showing polarization, P_{23} , of nitrobenzene and ether in benzene against percent nitrobenzene for several constant percentages of ether. The curve for 100 percent ether is plotted from extrapolated physically impossible, portions of Fig. 5.

which means that nitrobenzene does associate with ether. If there were no association,

$$\left(\frac{\partial P_{23}}{\partial f_2}\right)_{f_2 \rightarrow 0} \quad \text{and} \quad \left(\frac{\partial P_{23}}{\partial f_3}\right)_{f_3 \rightarrow 0}$$

should be constant as P_2 would then not be function of f_3 nor P_3 function of f_2 .

Fig. 7. Plot of the slopes of the curves of Fig. 6 at f_3 , the concentration of nitrobenzene approaching zero. The slope of Fig. 7 is an approximate relative measure of the association of ether and nitrobenzene.

Fig. 8. Plot of the slopes of the curves of Fig. 5 at f_2 , the concentration of ether approaching zero. The slope of Fig. 8 is an approximate relative measure of the association of nitrobenzene and ether. Note the corresponding value in Fig. 7.

Thus the curves are a definite proof of the association of nitrobenzene with ether, chlorobenzene and acetone. We can take the slopes of these curves, at

zero concentration, as an approximate relative measure of the degree of association. For this slope we write

$$a = \left(\frac{\partial^2 P_{23}}{\partial f_2 \partial f_3} = \frac{\partial P_2}{\partial f_3} + \frac{\partial P_3}{\partial f_2} \right)_{f_2=f_3 \rightarrow 0} \quad (4)$$

This quantity furnishes us a numerical estimate of the extent to which the polarizations depend on the concentration. From our data these results follow:

TABLE IV.
Association of nitrobenzene with

Substance	$\mu 10^{18}$	a
Nitrobenzene	3.90	1185
Acetone	2.70	690
Chlorobenzene	1.52	270
Ethyl ether	1.24	94

As was expected, the larger the moment, the more pronounced was the association. It seems that the most important factor determining the degree of association is the electric moment of the molecule.

Another question presents itself at this point. Do the association molecules share their electrons or not? The relation $\epsilon = n^2$ allows an answer. The calculation of P_∞ from Eq. (2), replacing ϵ by n^2 and omitting the term $\mu_i^2/3kT$ of (1a) gives

$$P_\infty = \frac{n_1^2 - 1}{n_1^2 + 2} \frac{M_1 f_1}{d_1} + \frac{n_2^2 - 1}{n_2^2 + 2} \frac{M_2 f_2}{d_2} + \frac{n_3^2 - 1}{n_3^2 + 2} \frac{M_3 f_3}{d_3} \quad (5)$$

calculated on the basis that the components act individually and

$$P_\infty' = \frac{n_1^2 - 1}{n_4^2 + 2} \frac{M_1 f_1 + M_2 f_2 + M_3 f_3}{d_4} \quad (6)$$

on the basis that the components act collectively, where n_1, n_2, n_3, n_4 , and d_1, d_2, d_3, d_4 are the refractive indices and densities of benzene, ether, nitrobenzene, and the mixture of the three under consideration, P_∞ is the polarization at infinite dilution. The comparison results in values which check within the limits of experimental errors. An illustrative example of the comparison of P_∞ , from Eq. (5), and P_∞' , from Eq. (6), for a mixture of benzene, ether and nitrobenzene is given in Table V.

TABLE V.

f_1	f_2	f_3	n_1	d_1	P_∞	P_∞'
0.6374	0.3626	0.0000	1.4418	0.8141	24.87	24.89
.6259	.3560	.0184	1.4440	.8220	25.02	25.05
.6138	.3492	.0369	1.4464	.8301	25.16	25.18
.6026	.3428	.0555	1.4489	.8384	25.33	25.35
.5908	.3361	.0731	1.4516	.8473	25.44	25.46
.5783	.3290	.0927	1.4541	.8557	25.59	25.61

Hence it is to be concluded that there is no sharing of electrons in this process.

CONCLUSION

Before anything more definite can be obtained from the measurements, a working hypothesis as to the true nature of association must be formulated. Such a project is at present under investigation.

NOTES ON THE EFFECT OF DISTANCE FROM THE SOURCE ON THE VELOCITY OF SOUND AT ULTRASONIC FREQUENCIES

BY CHARLES D. REID

CRUFT LABORATORY, HARVARD UNIVERSITY

(Received March 20, 1931)

ABSTRACT

Measurements of the velocity of ultrasonic waves have been made at a greater distance than heretofore. It is found to be independent of frequency within 0.01 per cent which is the error of measurement.

IN A previous paper¹ a method of obtaining the velocity of ultrasonic waves was described. It was found that when measurements were taken in proximity to the face of the sound-emitting crystal the resulting velocity was higher than that calculated from data obtained in a region more remote from the face. It was also noted that this effect was more marked as the frequency decreased. Hence it seemed desirable to continue the measurements in a region still more remote from the sound source, since the previous work indicated that an asymptotic value had almost been reached.

Fig. 1. Direct current amplifier.

With this in mind, the length of the sound chamber was doubled, and a direct current amplifier (shown in Fig. 1) was constructed in order to detect the sound energy at this increased distance. By using the proper grid bias on the amplifier tube the change in plate current produced by the motion of the reflector was increased by a factor of ten.

With the use of this amplifier, the measurements recorded here were made from the data secured in the region between 50 centimeters and 100 centimeters from the sound source.

To obtain satisfactory stationary wave-trains in this region it was found necessary to pad the inside of the sound chamber with acoustic felt to reduce

¹ C. D. Reid, Phys. Rev. 35, 814 (1930).

the effect of reflected energy from the walls. This prevented the use of dry air in the present experiments as it has been found difficult to dry out the felt. However, the felt lining does maintain the humidity at a constant value and the experimental results have been corrected for this humidity.

In order to determine the value of the humidity thus obtained, a hair hygrometer was calibrated over a small range of humidities by placing it under a bell jar with two different saturated salt solutions and assuming that the motion of the hygrometer needle in the interval between these fixed humidities to be a linear function of the humidity.

The results of these measurements are recorded in Table I.

TABLE I. *The velocity of sound in moist air free from carbon dioxide.*

Frequency	No. of runs	Velocity at 0°C
140	2	332.09
105	7	332.05
84	3	332.12
70	4	332.05
60	2	332.01
42	4	332.15

Average velocity at 0°C 332.08 ± 0.02 meters/sec.

Relative humidity 32 per cent

Velocity in dry air at 0°C $V_H - 0.014 H = V_0$

$$332.08 - 32 \times 0.014 = 331.63 \text{ meter/sec.}$$

From the figures recorded in Table I it may be concluded that the velocity of sound in the frequency range included is constant within 0.01 percent when the measurements are carried out in a region sufficiently remote from the source.

When the velocity obtained in this manner is corrected for humidity by use of the relation determined by previous experiments it is found to agree with the former results within experimental error. This serves as a check on the humidity formula.

The above experiments have been carried on under the direction of Dr. G. W. Pierce.

THE POLARIZATION AND THE ELECTRIC MOMENT OF TUNG OIL¹

By A. A. BLESS

UNIVERSITY OF FLORIDA

(Received March 12, 1931)

ABSTRACT

The molar polarization of tung oil was determined by the method of mixtures using the relation $P_{1,2} = [(\epsilon - 1)/(\epsilon + 2)] (M_1 f_1 + M_2 f_2)/d = P_1 f_1 + P_2 f_2$ where ϵ is the dielectric constant; d the density of the solution; f_1, f_2 , M_1, M_2 , and P_1, P_2 are respectively the mole fraction, the molecular weight and the polarization of the two components. The molar polarization of tung oil is 360 cc and the moment is 2.29×10^{-18} e.s.u. Eq. (1) is derived with the simplifying assumption that the internal field of the molecules may be neglected. It applies only to gases and to very dilute solutions, where the molecules are far apart. It is found that in the case of tung oil Eq. (1) applies for all concentrations, showing that the clustering of the molecules is such as to neutralize the internal field. The values of the moment of tung oil and of ethyl ether were determined from the variation of the polarization with temperature using the relation $P = (4\pi N/3)(\alpha + \mu^2/3KT)$ where P is the molar polarization, α the molecular polarization, N Avogadro's number, K Boltzmann's constant, T the absolute temperature and μ the electric moment. The values do not agree at all with those obtained by the method of mixtures. Similar disagreement was observed by other experimenters. The explanation is suggested that the internal field is never completely eliminated, and that the residual field being a function of the temperature makes Eq. (2) inapplicable even to dilute solutions.

METHOD OF MIXTURES

THE molar polarization of a mixture of two substances is given by²

$$P_{1,2} = \frac{\epsilon - 1}{\epsilon + 2} \frac{M_1 f_1 + M_2 f_2}{d} = P_1 f_1 + P_2 f_2 \quad (1)$$

where f_1, f_2 and M_1, M_2 and P_1, P_2 are, respectively, the mole fraction, the molecular weight and the polarization of the two components; d is the density and ϵ the dielectric constant of the solution. Since $f_1 = 1 - f_2$, Eq. (1) may also be written in the form

$$P_{1,2} = f_2(P_2 - P_1) + P_1. \quad (2)$$

showing that $P_{1,2}$ is a linear function of f_2 . Eq. (1) is deduced from the Clausius-Mosotti relation, that the quotient $(\epsilon - 1)/(\epsilon + 2)$ is proportional to the density. This relation is derived with the simplifying assumption that the internal electric field of the molecules may be neglected. In case of polar substances, equation (1) would be applicable only when the molecules are far

¹ Paper read at the meetings of the Committee on Electrical Insulation of the National Research Council, November 7, 1930.

² P. Debye, Polar Molecules, the Chemical Catalog Co., 1929.

apart, as in gases or in dilute solutions of a polar substance in a nonpolar solvent. $P_{1,2}$ is proportional to f_2 only when f_2 is a small fraction. The departure from proportionality between $P_{1,2}$ and f_2 for high concentrations of the polar substance may be taken as indicating the interaction of molecular fields. To find the polarization of a liquid substance the procedure is to dissolve the polar substance in a nonpolar solvent, determine the polarization for increasing mole fractions of the solute and then extrapolate for infinite dilution. This method was used to determine the electric moment of tung oil using benzene as the nonpolar solvent.

The quantities which are measured experimentally are the density and the dielectric constant of the solutions. The density was determined by the pycnometer method with an accuracy of about 0.02 percent. The dielectric constant was found in the usual manner, from the measured capacity of the test cell in air and in the liquid, the capacities being determined by the substitution method.

Fig. 1. The circuit for measuring the capacity of the cell.

Two different circuits were used for finding the dielectric constant of the solutions. In the first circuit a Hartley oscillator was used as a source of oscillations, the frequency being measured with a standard General Radio wave meter. In the receiving circuit a small aluminum condenser of known capacity placed in a vessel containing the solution was connected in parallel with a standard General Radio precision condenser. The receiving circuit was first tuned to resonance with the oscillator with both condensers in parallel and then retuned again to resonance with the standard alone in the circuit. The difference between the two readings of the condenser gave the capacity of the aluminum cell. These measurements were made for three different frequencies, 10^5 , 3×10^5 , 10^6 . The accuracy of this method was about 1 percent.

The accuracy was very greatly increased when a heterodyne beat method was substituted for the above. The oscillations were kept at a constant frequency by the aid of a quartz crystal oscillator. A Hartley oscillator containing the test cell and the precision condenser was tuned to beat with the crystal set, the disappearance of the note indicating resonance. The capacity of the test cell was found in the same manner as in the first circuit. The polarization

of the solution was then calculated from the data using relation (1). The circuit is shown in Fig. 1.

The tung oil used in these experiments was obtained from the Chemistry Department of this University. Several samples of the product were tried, all giving very consistent results.

Data obtained using the Hartley oscillator are given in Table I.

1.0000	.9356	3.230	361.5

In Figs. 2 and 3 the polarization of the solutions is plotted against the mole fraction of the tung oil. The value of the polarization is about 360 cc.

The polarization of a substance is the result of the distortion of the molecules due to electronic displacements produced by the field, and of the orientation of the polar molecules in the impressed field. At very high frequencies the molecules are no longer able to follow the field and the contribution to the polarization due to the oriented molecules vanishes. At optical frequencies only the electrons are affected and the dielectric constant may therefore be identified with the square of the refractive index. The contribution to the polarization due to the orientation of the polar molecules may be found by subtracting from the total polarization the part which is due to the distortion effect of the field, and which is given by:

$$P_0 = \frac{r^2 - 1}{r^2 + 2} \frac{M}{d}$$

where *r* is the refractive index of the solution, and the electric moment of the molecules may be found from the relation

$$\mu = 0.0127 \times 10^{-18} [(P - P_0)T]^{1/2}$$

giving a value for $\mu = 2.29 \times 10^{-18}$ e.s.u.

It must be observed that as tung oil in itself is a mixture of at least two substances, the value of the electric moment found above must be considered as a weighted mean of the component molecules.

Fig. 2. Polarization vs. mole fraction of tung oil for $\gamma = 5 \times 10^6$ cycles/sec.

Fig. 3. Polarization vs. mole fraction $\gamma = 1.47 \times 10^6$ cycles/sec.

VARIAION OF POLARIZATION WITH TEMPERATURE

The graph of the polarization versus mole fraction is a straight line showing that the Clausius-Mosotti relation may be applied for all concentrations of tung oil in benzene. The tung oil molecules are evidently present in the solution in clusters so formed as to neutralize the internal field. This clustering is probably similar to the one observed by Stewart³ and his collaborators. It seemed interesting to investigate the effect of temperature on the clustering of these molecules. Some of these experiments will now be described.

It is possible to find the electric moment in another manner. From the Debye theory it follows that the polarization of a substance is given by:

$$P = \frac{4\pi N}{3} \left(\alpha + \frac{\mu^2}{3kT} \right) \quad (3)$$

where N is Avogadro's constant, α the molecular polarization, k Boltzmann's constant, T the absolute temperature. If a substance is polar its polarization will be directly proportional to the reciprocal of the absolute temperature.

³ G. W. Stewart and R. M. Morrow, Phys. Rev. 30, 232 (1929).

If the polarization is measured in the manner described above for a range of temperatures the molecular moment may be calculated from the slope of the straight line obtained when P is plotted against $1/T$, since $P = a + (b/T)$, where b is the slope of the line $= 4\pi N/9(\mu^2/K)$.

The condenser used in these experiments is shown in Fig. 4. It consisted of two concentric nickel cylinders placed in two concentric glass tubes, A and B , sealed at the bottom. The glass tubes were of such a diameter that the outer nickel cylinder was just large enough to fit inside the outer glass tube while the smaller nickel cylinder fitted tightly around the inner tube. This arrangement gave a condenser of fairly large capacity for a very small volume of fluid between the nickel cylinders. A third glass tube C for housing the thermometer was sealed to B . A small tube D was sealed to the junction of B and C . It provided a vent for the escape of the air entrapped between B

Fig. 4. Diagram of condenser.

and C when the condenser was lowered into the cooling solution, thus enabling the solution to reach every part of the condenser.

A solution of alcohol and solid carbon dioxide was used as the cooling solution. The air capacity of the cell was 69.3 cm. The cooling solution was kept in a large Dewar flask. Measurements of the capacity of the cell were taken only when the temperature shown by the thermometer placed in C differed by a fraction of a degree from the reading of the thermometer placed directly in the solution.

Eq. (3) just like Eq. (1) applies only when the internal field of the molecules may be neglected. And to use this relation dilute solutions must be employed. However, as tung oil showed no molecular interaction the substance was used in the undiluted state.

Fig. 5 is the graph of the data. The plot is sensibly a straight line. The moment calculated from the slope of the straight line was about twice as large as the value found from the method of mixtures. No shifting of the straight line could account even for a fraction of the discrepancy.

Ethyl ether is another substance the molecules of which show no interaction at ordinary temperatures. Its moment as determined by Krchma and Williams⁴ using the method of mixtures is 1.24×10^{-18} e.s.u. Experiments were made to measure the moment of ethyl ether using the method of the variation of the polarization with temperature. The value of the moment comes out about 60 percent higher.

These experiments show that the peculiar arrangement of the molecules which neutralizes the internal field at a given temperature is modified when the temperature is changed. The molecular field is not completely eliminated.

Even dilute solutions of a substance, where the molecules are relatively far apart, show some interaction, which varies with temperature. The discrepancy between the value of the moments of some molecules, using the method of mixtures and the method of variation of the polarization of dilute

Fig. 5.

solutions with temperature in the experiments of Smyth and Morgan⁵, is probably due to this cause, and not, as these authors suggest, to the inaccuracy of measurements. A similar discrepancy was observed by Morgan⁶ in his measurements of the moments of some methyl halides by the two methods. The difference in the values obtained is much larger than the experimental error. One is forced to the conclusion, therefore, that even in dilute solutions, which at a given temperature seem to show no interaction, the internal field is not completely absent, and the field manifests itself in the variation of the moment with temperature. It is of interest to find the degree of dilution needed to show no temperature effect of the polarization. Experiments along this line are now being carried out in this laboratory.

Some of the apparatus used in these experiments were purchased by the aid of the Sigma Xi grant. The author wishes to express his gratitude to the Committee on Awards for the grant.

AN EXPERIMENTAL STUDY OF KUNDT'S
TUBE DUST FIGURESBY E. HUTCHISSON AND F. B. MORGAN
UNIVERSITY OF PITTSBURGH, PITTSBURGH, PA.

(Received February 24, 1931)

ABSTRACT

An experimental study of the dust striations in a Kundt's tube has been carried out using a loud speaker, operated from a vacuum tube oscillator, as a source of sound. It is found that the positions of the vibrator for maximum agitation of the dust is different for the case in which a loud speaker is used from that obtained when a stroked rod is used. The formation and behavior of the striations is described in detail. It is found that the spacing between the striations increases with the intensity of sound, decreases with an increase in pressure of the gas, and decreases with an increase in density of the dust material. A minimum spacing is found when the size of the dust particles is changed. The relation suggested by Cook that the ratio of the separation of the striations to the mean free path is a constant was tested but the results obtained indicated that such a simple relation does not exist.

I. INTRODUCTION

IN 1866 Kundt¹ showed that when standing sound waves were excited in a closed resonance tube, dust particles in the tube arranged themselves in the form of striations perpendicular to the axis of the tube. Since that time however, very little information has been obtained on these striations due to the fact that accurate measurements could only be made after the vibrations had ceased. With the general introduction of the loud speaker as a source of sound² and the use of a vacuum tubes oscillator as a means of excitation, it has become possible to examine the phenomena in the Kundt's tube in a far more accurate manner.

The cause of the striations in the Kundt's tube has never been completely determined. The hydrodynamical theory of the oscillations of the air column has been studied by König and others, but after reading these papers, one still wonders how the striations are really produced. However before a rigorous quantitative theory can be developed it is necessary to have accurate measurements of the positions of the striations under different experimental conditions. It is the purpose of this paper to help bridge this gap in our experimental knowledge of the behavior of dust striations.

Before the experimental procedure is taken up it must be emphasized that there is a distinct difference in the behavior of the striations when produced by a stroked rod and when produced by a loud speaker operated from a vacuum tube oscillator. If a stroked rod is used, the maximum agitation of the dust occurs when the vibrating end of the rod is placed at a node, and the

¹ A. Kundt, Pogg. Ann. 127, 497 (1866).

² A. B. Wood, A Textbook of Sound, New York, 1930.

agitation is minimum when the vibrator is at an antinode. However, when the loud speaker is used maximum agitation is obtained when the vibrator is one-third of a segment from a node and a minimum when the vibrator is at a node. Furthermore, after continued stroking of a rod the dust particles in the tube gather into small heaps at the nodes³ while with the loud speaker there is no indication of this phenomena at all even after long periods of operation. In the work of E. J. Irons⁴ in which a stroked rod was used, the formation of rings or disks extending across the diameter of the tube at the nodes is very beautifully shown.

With a loud speaker unit, it was found possible to produce such rings⁵ but they were always at the antinodes instead of at the nodes. By using extremely light dust and greater intensity of sound, these rings could be made to assume the appearance of disks with much greater density at the periphery than at the center of the tube. Each ring always lies in the plane of the central stria and seems to be a continuation of it. These rings mark the midpoint of the

Fig. 1. Experimental arrangement to obtain dust figures in a resonating tube under various pressures. *LS* indicates the loud speaker held in place by springs, *a* and *b* represent short pieces of heavy rubber tubing used to hold the tubes in place.

antinodal region very sharply and are therefore of great value in determining the length of a segment. The motion of the dust particles constituting a ring is from the extremities of the central stria around the wall of the tube toward the top. Neighboring striae usually have dust particles streaming off from their extremities also and these are continually fed into the antinodal ring. Sometimes neighboring striae can be made to produce these rings but they are never so perfect as the central one. After a central ring has been established, it is possible by shifting the stop slowly to drive all the dust from the antinodal region, except that constituting the ring and its disk. In this way, an antinodal ring without the accompanying striae may be obtained.

II. APPARATUS AND PROCEDURE

The apparatus used in this investigation is shown diagrammatically in Fig. 1. A Temple radio loud speaker unit, actuated by a Hartley vacuum tube oscillator, was used as the source of sound. To permit variation of the pres-

³ Cf. E. J. Irons, *Phil. Mag.* **7**, 523 (1929).

⁴ Reference 3, plate IX, Figs. 2c and 2d.

⁵ These disks were first discovered by the writers in 1928. Since then E. Andrade and S. H. Lewar have published independently an account of these disks in *Nature*, **124**, 724 (1929). See also the recent note of R. V. Cook, *Phys. Rev.* **36**, 1099 (1930).

sure and to facilitate the changing of the gas in the tube, the loud speaker unit was mounted in a glass cylinder as shown. The frequency of the sound emitted could be varied throughout a sufficiently wide range to secure almost any wave-length desired. Observations were made both under conditions of resonance and of nonresonance.

Pith, cork, Kieselsaure and white sand were found to be the most satisfactory materials for dust. Mustard seed and timothy seed served very well for small spheroids and ellipsoids, respectively. Uniformity of size of dust particles was obtained by sifting the dust through a nest of sieves ranging from 10 to 120 meshes to the inch. A metric scale was placed alongside the tube and when photographed simultaneously with the dust, made measurements of length convenient. The tubes used were 22 mm and 30 mm in diameter, respectively. Their lengths varied from 2.5 to 4 ft. Two 400-watt in-

Fig. 2. The appearance of the striations formed when a Kundt's tube is operated by means of a loud speaker. These striations were obtained under atmospheric pressure with a frequency of approximately 1500 sec. The diameter of the dust particles in the middle photograph is intermediate between those in the outer photographs showing that the spacing between the striations does not increase monotonically with the size of the particles.

candescent lamps, equipped with reflectors, were used to illuminate the tube from above for the taking of the photographs. A 4"×5" plate camera was used and exposures were usually from 1/50 to 1/100 of a second. A dividing engine was used for measuring the distance between striae.

III. GENERAL APPEARANCE AND PROPERTIES OF THE STRIAE

The general appearance of the striae produced by means of a loud speaker element is shown in Fig. 2. With the aid of a lens the striae are often found to be just one layer of particles in thickness. According to the observations of Cook,⁶ these particles have a repulsion for each other and are always slightly separated from each other during the continuance of the sound. The present

⁶ S. R. Cook, *Phil. Mag.* 3, 47 (1902).

investigation failed to substantiate Cook's observations. In every case, whether the particles used were dust, pith spheroids, pith cylinders, sealing-wax spheroids, mustard seed spheroids, or timothy seed ellipsoids, the particles remained in contact during the continuance of the sound, just as if there were a force of attraction between them. This is in conformity with König's² theory which assumes a force of attraction between particles whose line of centers is at right angles to the direction of the sound propagation. Ellipsoidal particles always aligned themselves so that their major axes are at right angles to the direction of sound propagation.

Similarly, if thin pith disks about the size of a dime are used in the place of dust, they come to a verticle position in the tube and are rotated till their planes make a right angle with the direction of propagation of the sound. They space themselves much like the dust striae, except that they are farther apart. Usually three or four of these disks are drawn into the middle of the antinode to form the central stria edge to edge and rotate about the axis of the tube like a Dutch windmill. Often other disks, spaced along the tube will also rotate; some turning clockwise, others counter-clockwise.

The dust particles, constituting a stria seem to be in continual oscillation so that some are always freeing themselves from one stria and joining a neighboring one. This interchange of particles is more or less mutual, so that a stria receives just about as many particles as it loses and therefore maintains a rather constant size. Striae tend to diminish both in length and height in going from the antinode to the node.

The position of a stria in a segment may be either constant or variable, depending on the adjustment of the vibrator relative to a node and the stria may form either a straight line across the tube or a curved one, depending on the above adjustment and also on its position in the segment. The central stria always extends straight across the tube, forming a right angle with its axis. This is usually true also of a relatively large number of striae on either side of the central one. The striae near the extremities however, tend to be more or less curved; sometimes being concave toward the nodes and sometimes concave toward the antinodes, depending on the position of the vibrator relative to a node.

When cork dust (size 80-100 mesh) is piled at the nodes and the vibrator of the loud speaker is placed about one-third of a segment from a node and operated, striae begin to form on either side of the dust piles and move toward the antinodes. The first stria to reach the midpoint of a given segment stops and the next one coming up approaches within a certain distance of the central one, when it too stops. The third stria approaches within a similar distance of the second and likewise stops. This is continued till the dust figures occupy perhaps eight-tenths of a segment. The extreme striae (that is, the ones nearest the nodes), in this case are decidedly concave toward the nodes and the concavity falls off gradually in going toward the antinodes. In an extreme case, the only stationary stria is the one at the middle of the antinode; all others gradually moving along the axis of the tube from the nodes toward the antinodes, the terminal ones having the more rapid motion. These

overtake the more slowly moving ones and finally unite with them. At the same time, dust is leaving the more stable striae and moving back along the walls of the tube toward the nodes. Much of this returning dust seems to move underneath the advancing striae, while the rest of it streams back higher up on the sides of the tube, above the striae. This returning dust forms new striae near the nodes, which again advance toward the antinodes. By shifting the vibrator toward an antinode, the forward motion of the striae can be greatly reduced; and when the vibrator is at the antinode, only two or three of the terminal striae show any forward motion at all. These terminal striae are now concave toward the antinodes instead of toward the nodes and the dust occupies about half as much of the segment as before. If the vibrator is moved to a node, the dust leaves the antinodal region entirely and forms striae about the nodes which are concave toward the nodes. The excitation of the dust is now a minimum and these striae exhibit no apparent forward motion at all.

The above observations, therefore, seem to lend credence to the conclusion of Dvorak,⁷ based on his observations of the behavior of both liquids and dust, and to the mathematical deduction of Lord Rayleigh⁸ that there is a current through the central portion of the tube from the nodes to the antinodes and a return current contiguous to the walls of the tube. It also seems quite probable that these currents have something to do with the concavity of the striae, though the case of striae concave toward the antinodes would be difficult to explain on that assumption.

The distance between successive striae of a given dust figure is not a constant. Robinson⁹ found that in going from an antinode to a node the spacing gradually diminished and he succeeded in deriving an expression for this spacing distance, which he confirmed experimentally. Irons³ attempted to verify Robinson's equation but his results failed to support it. In the present work, the spacings of many dust figures were measured and the most promising ones were used for testing Robinson's law. In no case was the agreement satisfactory. At normal atmospheric pressure, there was usually, but not always, a slight diminution in the spacing distance in going from an antinode to a node; but at pressures considerably below atmospheric, the spacing distance actually increased. It was noticed, however, that the average spacing between successive striae was much greater under some conditions than under others and an attempt was therefore made to determine the factors which exert an important influence on the spacing distance.

IV. FACTORS AFFECTING THE DISTANCE BETWEEN STRIAE

1. Sound intensity.

This is probably the most important factor. There are two ways in which the intensity of the sound can be varied: (a) by varying the energy input to

⁷ Dvorak, Pogg Ann. CLIII, 102 (1874); CLVII, 42 (1876).

⁸ Lord Rayleigh, Phil. Trans. CLXXV, Part I, 1 (1884) or Scient. Papers II, 239.

⁹ J. Robinson, Phil. Mag. 18, 180 (1909); 19, 476 (1910).

the vibrator, (b) by shifting the position of the vibrator relative to a node. If a rod is stroked gently with the vibrator at a node, the striae will be close together, but if the rod is stroked vigorously, the striae will be few in number and much farther apart. If the vibrator is placed at an antinode, the most vigorous stroking will be required to produce a very meager spacing. An intermediate position of the vibrator will produce an intermediate spacing.

2. Size of dust particles.

This investigation failed to substantiate the work of Cook¹⁰ who found that the spacing increased with the size of the dust particles. Minimum spacing was always obtained with medium sized particles. If either larger or smaller particles were used, the distance between striae was increased. The photographs of Fig. 2 and the curves of Fig. 3 show this very clearly. They

Fig. 3. Curves showing the effects of particle size on the relative separation of the striations.

also show that the size of the particle required to produce minimum spacing probably decreases as the density of the dust increases.

3. Gas pressure.

The pressure to which the gas in the tube is subjected not only affects the spacing between the striae but it also affects the number of striae in a segment, the amount of dust in each striae, and the compactness of this dust. As the pressure is reduced the striae near the nodes are the first ones to be noticeably affected. Not only do they get fewer in number and farther apart but also the particles composing them oscillate through a greater distance

¹⁰ S. R. Cook, reference 6.

and move about with greater freedom. Thus the dust in these striae is much more greatly agitated than in the central ones. However, as the pres-

Fig. 4. Effect of gas pressure on the average distance between successive striae (pith dust, 80-100 mesh).

Fig. 5. Effect of gas pressure on the average distance between successive striae (cork dust, 80-100 mesh).

sure is decreased, more and more of the central striae behave in the same way till finally all are greatly agitated save the one at the middle of the segment.

With a further decrease in pressure, even this central one succumbs and behaves like the others. Finally when the pressure is reduced to 10 cm of Hg, the striae are broken up and the dust is swept from the antinodal region to the nodes. The curves of Figs. 4 and 5 show clearly that the spacing increases as the pressure decreases.

4. Density of particles.

The curves of Fig. 6 show that the density of the dust has a decided influence on the spacing between the striae so long as the density is less than 0.3

Fig. 6. Effect of density of dust material on the average distance between successive striae.

gm/cm³. Beyond 0.3, the slopes of the curves are much more gradual, but even within that range the decrease in spacing with the increase in density is sufficient to be measurable.

V. RATIO OF DISTANCE APART OF STRIAE TO MEAN FREE PATH OF THE GAS MOLECULES

Cook¹⁰ worked out this ratio for amorphous silica in air. The results were not conclusive, but they were sufficient to indicate a probability that the distance apart of the striae is directly proportional to the mean free path of the gas molecules.

Similar computations were made with the data obtained in this work. The results, shown in Table I are no more conclusive than were those of Cook.

TABLE I.

Material (in all cases, 80-100 mesh)	Pressure p cm of Hg	Distance apart of striae (d) mm	Mean free path (l) cm	d/l $\times 10^{-4}$

VI. CONCLUSIONS

An experimental investigation of the properties of the striations in Kundt's tube dust figures was made. With a loud speaker for a source of sound, it was found that position of the vibrator which produced maximum intensity was different from that obtained when a stroked rod was used as a source. The changes in the spacing between the striations caused by altering the pressure, the size of the particles, the intensity of the sound, and the density of the particles, were investigated.

WAVE-PARTICLES AS TRANSMITTED POSSIBILITIES: QUANTUM POSTULATES DEDUCED FROM LOGICAL RELATIVITY

BY WILLIAM BAND

DEPARTMENT OF PHYSICS, YENCHING UNIVERSITY, PEKING, CHINA

(Received September 24, 1930)

ABSTRACT

General relativity is logically unsatisfactory because it bases measurement on infinitesimals, and absolute infinitesimals do not exist. A standard of comparison being a logical necessity, we propose to provide it by the new fundamental hypothesis: "The physical world is composed of elementary events of identical and definite non-zero four-dimensional extent." The photon is a possibility of absorption-event initiated by an emission event; it is exhibited as a set of superposed moving volumes or three-dimensional sections of the four-dimensional possibility. The electron is a possibility transmitted with smaller velocities. Mass or energy is proportional to the time-duration of the event-possibilities, and obeys thence, the relativity rules. A wave function is postulated for the possibility being realized, and from Doppler's principle the quantum rule necessarily follows: mass proportional to frequency, and group-velocity equal to particle velocity. The "particle" exists only when the transmission is parallel the time-edge of the possibility; in atomic orbits presumably the condition does not apply, and the parallel-displacement tracks of relativity which are shown to be required outside, do not apply within the atom. The finite extent of the events which exhibit the particle necessitates an indeterminacy in the situation of the particle.

§ 1. LOGICAL WEAKNESS OF THE GENERAL THEORY OF RELATIVITY

IN UNIFIED field theory, particularly the form given by Eddington, tracks of all particles, and straight lines, are defined by means of infinitesimals, or infinitesimal displacements. Thus at the basis of the theory rests a set of equations of the form^{1,6}

$$dA_i = (ij, k)A_k dx_j \cdots i, j, k = 1, 2, 3, 4.$$

The displacement dx_j is supposed to be infinitesimal, and the corresponding increment dA_i must also be infinitesimal. It is however a mathematical fact that there are no absolute infinitesimals, and that the property of being small is only relative. In applying the relativity to experience, we have to fix arbitrarily what shall be small. Thus there is nothing in the relativity theory of geodesics to say that the orbits shall not represent electron tracks round atoms rather than planetary tracks, and nothing but a pragmatic test to give the verdict. This elasticity may be satisfactory from the experimenter's point of view, but the theoretician cannot be satisfied until the theory can tell itself whether its findings are to apply to microscopic or macroscopic phenomena. Relativity at present finds that phenomena on the minute can be only a replica of phenomena on the grand scale; there is in its very fundamental constitution no absolute infinitesimal, it is the merely relative infinitesimal

¹ Eddington, *Mathematical Relativity*, p. 213, Eq. 91.1.

of mathematics in which any contortion of curvature may exist and which is merely a class of finites.²

Herein is not only a logical defect of the theory, but also the reason why the theory fails to include atomic phenomena within its unifying field. Classical physics I suppose would have unanimously supported the view that phenomena on the minute were replica of those on the large scale; but with the advent of atomic physics this attitude has died, and the principle of indeterminacy has introduced an absolute standard of minuteness into physics that is not in pure mathematics.

Thus, to give it logical completeness, relativity requires an added postulate over and above the postulates made by Einstein at the foundation of the theory. Einstein's postulates concerned with observers, the fact that all observers were on the same footing for erecting descriptions of the external world; but the new postulate must concern the means whereby the knowledge of the external world is derived by all observers. We postulate that "The observations of every observer can be analyzed into a complex of minute events each with the same four-dimensional extent." The old postulates asserted that differences between observers were only relative, while the new postulate asserts that the differences between the minute events observed are also only relative. It carries the relativity a step further into the heart of physics; and incidentally provides a standard of minuteness for relativity, raising that theory to a more completely logical status.

Other postulates, of course, suggest themselves as alternatives; for instance the postulate that space-time is itself discontinuous, or that there is a minimum quantum of action, where action is defined from the usual relativity equations. We may justify our actual choice by appealing to Whitehead's philosophy of space-time.³ This philosophy, generally accepted by those who have taken the trouble to study it, at least in general idea, shows that space-time may be logically defined from the extensive properties of events. Thus the world of events is fundamental, and space-time comes out of it by an abstractive process actually carried through with some success by Whitehead. Thus we cannot lightly postulate a discontinuous space-time after Whitehead has erected a continuous one, until someone succeeds in erecting a discontinuous one and elucidates what the meaning of such a construct really is. Again, accepting Whitehead's philosophy, we immediately see that our fundamental postulate must concern with events rather than with such entities as mass or action, or for that matter with space-time either. If there is a minimum action or mass, or a discontinuous space-time, it should come out of the theory since relativity defines mass and action from functions in space-time, and not need tacking on to the theory as an *ad hoc* assumption. The properties of space-time that give a minimum action must be derivable from the events in terms of which the space-time is defined; hence our fundamental hypothesis must concern with events.

² Whitehead, *Process and Reality*, p. 465.

³ Whitehead, *Process and Reality and Principles of Natural Knowledge*.

We claim therefore that our postulate is logically required to make the theory satisfactory at its foundation, and does not add anything *ad hoc* to the after structure of the theory.

§ 2. GEOMETRY OF FOUR-DIMENSIONAL REGIONS

We propose to examine the representation of minute four-dimensional regions representing the minimum events of the world on the Minkowski diagram. In drawing Minkowski diagrams the beginner generally has to remind himself that a point on the diagram represents a definite and unalterable event with definite coordinates in both space and time for each system concerned. But in representing the minute events postulated here on a scale that shows the boundaries of the events as lines in the diagram, we can no longer assume that each point on the diagram represents a definite event for every system; there are no events of such precise coordinates. This lends a certain elasticity to the diagrams that is not familiar, and that must be carefully remembered in following the argument given below; the same event may be represented, if convenience dictates it, by differently shaped areas in the different systems of reference.

In some particular system S' the simplest four-dimensional region is a volume stationary and existent for a definite time; suppose it represented by $AB'CD'$ where AB' is along X' axis, and AC along T' axis, giving a two-dimensional section. We shall suppose that the same event is in a system S represented by $ABCD$ where $B'D'$ cuts the X axis in B ; this will be a moving volume, for S , existent for a definite time.

Let dt, dt' be the time durations of the event, and dV, dV' the two volumes proportional to the X, X' sections. Then simple relativity transformations show that, taking velocity of light unity for convenience,

$$dt' = (1 - v \cdot v)^{1/2} \cdot dt; dV' = dV \cdot (1 - v \cdot v)^{-1/2}; \quad (1)$$

where v is the velocity of S' relative to S . Thus the four-dimensional extent $dt \cdot dV = dt' \cdot dV'$ is a constant or invariant for this transformation.

In the particular case when v is unity, these formulae are no longer of use, for there are no systems S, S' with this relative velocity. If we call the velocity given by the gradient of the edge AC of the event the "self-velocity" of the event, then there may be events with self-velocity unity but which can therefore never be exhibited as volumes stationary in any coordinate system. Such an event could be represented by $ABCD$ for S , where AC is along the light-track gradient unity, and AB along the X axis. This would transform to $AB'CD'$ for S' with C still on the light track and B' at the intersect of BD with the X' axis. Here we can easily see that

$$dV' = dV(1 + v)/(1 - v \cdot v)^{1/2} \quad (2)$$

$$dt' = dt(1 - v \cdot v)^{1/2}/(1 + v) \quad (3)$$

and again the four-dimensional extent of the event is invariant. Alternatively the formulae may be written

$$dV = dV'(1 - v)/(1 - v \cdot v)^{1/2} \quad (2')$$

$$dt = dt'(1 + v)/(1 - v \cdot v)^{1/2} \quad (3')$$

with

$$dt = k/dV, \quad dt' = k/dV'. \quad (4)$$

These of course hold only when the self-velocity of the event is parallel the relative velocity of S, S' . If the relative velocity v is along the Y, Y' axes, and the self velocity of the event is along the X , axis, then by drawing the appropriate figure it can easily be verified that

$$dt' = dt/(1 - v \cdot v)^{1/2} \quad (5)$$

$$dV' = dV(1 - v \cdot v)^{1/2} \quad (6)$$

with again

$$dt' = k/dV', \quad dt = k/dV; \quad (4')$$

the most general case being easily deducible from these two.

§ 3. TRANSMISSION OF FOUR-DIMENSIONAL REGIONS

(a). Regions with unit self-velocity. Photon theory.

Suppose that the region $ABCD$ of the previous article represents one stage in the process of transmission of a possible event, the transmission being with the same vector velocity as the self-velocity of the possible event. The region $ABCD$ is a section (X -axis) of the region that would be occupied by the event were it to be realized at that stage, and examined by the system S . The fact that it is being transmitted along the X -axis means that the boundary AB is moving along the X -axis with the velocity of transmission, and the boundary CD is also moving along the X -axis with the same velocity. Since this velocity is the same as the velocity given by AC or BD we see that the boundary AB reaches the stage CD after the time dt which is the duration of the possible event. Thus in the realized event CD is ahead in space, but behind in time compared with AB , but in the transmission AB and CD coincide, for the occurrence of CD is simultaneous with the arrival of the transmitted AB . Were the transmission to materialize into an event, the edge AB would be realized first, and leave the edge CD travelling on for the time dt before it was realized.

Thus the transmission looks like a simple moving volume travelling with the velocity of light; all the volumes which would occur in succession in the event appear as coincident in an instantaneous picture of the transmission, and if we had not started from the complex, we should have mistaken the process for a simple moving volume, albeit with something corresponding with a pseudo-density of the overlapping volumes.

To picture a region that has extension in space and in time that is itself being propagated with velocity through space, is a new and perhaps rather difficult concept, and the results of investigating it in detail seem to be of considerable interest.

Thus suppose that a quantum emission corresponds to a four-dimensional event with self-velocity unity, and that this originates a possible absorption transmitted with this self-velocity. This transmission will appear as a moving volume, or particle; in other words it is the photon of recent optical theory. But the photon and the transmitted possibility both differ from mere moving volumes: the one in having mass or energy, and the other in having the pseudo-density of the superposed volumes corresponding to different stages of the possible event. Identifying these differences we assume next that the energy of the photon is proportional to the time-duration of the possible event; this may be taken as a definition of the energy of a particle on the new theory.

$$E \text{ is prop. to } dt$$

and hence from Eq. (3')

$$E = E'(1 + v)/(1 - v \cdot v)^{1/2} \quad (8)$$

if E is the energy of the photon for S , and E' for S' .

The probability that the event will occur or that the possibility will be realized cannot be deduced *a priori*; but since the wave-theory of radiation has been interpreted statistically, we may assume that there will be a probability wave-function whose phase-velocity equals the velocity of transmission. From wave theory it then follows that in transforming between the frequencies, the generalized Doppler principle⁴ will necessarily hold:

$$n = n'(1 + v)/(1 - v \cdot v)^{1/2} \quad (8')$$

and comparison with Eq. (8) therefore shows that

$$E = hn \quad (9)$$

where h is a universal constant, the quantum theory rule. Eq. (4) shows that the volume dV is proportional to the period, and thence the wave-length of the waves; or the section of the volume in the direction of the transmission is proportional to the wave-length.

(b). Regions with any self-velocity. Electron theory.

From the results of the foregoing we are naturally lead to expect transmitted possibilities of normal velocities to have the same properties as material particles. Let an event possibility of self-velocity u be transmitted with that velocity, then the energy of the particle it appears as, is again defined as proportional to the time dt of the event-possibility, or the pseudo-density of the superposed volumes. Eqs. (1) then give

$$E' = E(1 - v \cdot v)^{1/2} \quad (10)$$

which is the usual relativity form for the energy, since here E' is the rest-energy of the particle. Translated into the usual notation it is of course

⁴ Cunningham, Principle of Relativity.

$$mc^2 = m_0c^2(1 - v^2/c^2)^{-1/2}. \quad (10')$$

If it is questioned whether the electron is but a transmitted possibility, we may point to the usual interpretation of the matrix mechanics; the electron connects quantum events, and is in effect a transmitted possibility of an absorption. From this point of view it is natural to seek for a wave-function that shall give the probability of the event being realized at any stage. But to obtain the frequency transformation of these waves we must pursue a slightly different track from that which gave us the formulae for light waves; here the velocity is not an invariant and the problem is less simple. The familiar reasoning⁵ is however perfectly satisfactory and conclusive. A stationary particle must correspond with a stationary wave system, say of the form for S' ,

$$P = A \exp (2\pi n'it'). \quad (11)$$

The Lorentz transformation gives

$$P = A \exp (2\pi nit - x/w) \quad (12)$$

relative to the S system, where

$$n = n'(1 - v^2/c^2)^{-1/2} \quad (14a)$$

and

$$w = c^2/u. \quad (14b)$$

Comparison of Eq. (14a) with Eq. (10) again gives the quantum rule

$$E = hn \quad (9)$$

while combination of Eqs. (14a), (14b) shows in the usual way that u is the group velocity of the waves.

We thus reach a satisfactory interpretation of the wave theory of matter, of the nature of the electron, and the similarity, yet difference between the photon and the material particle.

§ 4. EQUATIONS OF MOTION OF PARTICLES

At the outset of this work we made the simplifying assumption that the transmission of the possibilities was parallel to the self-velocity of the event-possibility transmitted. Only with this assumption is the transmission exhibited as a particle, for only then will the various volume-sections of the event be superposed on one-another. When therefore the particle exists, their tracks are necessarily given by parallel displacement; for by our assumption the edges AC , CC' of consecutive possible events are parallel, and hence the edge, which is parallel to the velocity vector of the particle, is moved by parallel displacement. This leads immediately to the unified field theory already given mathematical expression by the present writer⁶; the most general

⁵ Haas, *Wave Mechanics and New Quantum Theory*, Chap. 2.

⁶ Band, *Phys. Rev.* **36**, 1405 (1930).

rule for the parallel displacement of the velocity vector gives the tracks of the particles actually agreeing with the experimental tracks. The small displacements of the theory must obviously be of the same order as the dimensions of the events, and the equations will be meaningless if we attempt to apply them to smaller orders of length.

But we have already seen that the existence of the particle is by no means a necessity; so far as our theory is concerned, there may be transmissions in directions other than the self-velocity of the events, and what we may vaguely call the track of the transmission will then have appreciable curvature within the extent of one possible event, and the parallel displacement rule no longer applies. These "tracks" are not then tracks of particles at all, and the usual wave-theory interpretation of quantized orbits seems to be the most natural one here.

In passing, we remark that on the present theory we have refused to regard the particle as fundamental; the whole structure of relativity is erected from events of finite four-dimensional extent, and a particle is an abstract or recognized permanency among the extensive relations between events. Thus our postulate of finite extent to the ultimate events at once forbids the accurate estimation of the position or motion of the particle when it actually exists; for the particle can only be observed through the events which exhibit it, and these do not give exactitude.

In conclusion, we cannot claim to have treated more than an elementary set of cases; but it seems sufficient to show that it is possible by recognizing a logical weakness of Relativity to deduce from the most natural additional hypothesis to remove this weakness, the essential basis of the new quantum theory; to illuminate the meaning of and deduce the assumptions of the unified field theory; and finally to suggest an interpretation of the physical world that will harmonize the two great fields of theoretical research of recent years, relativity, and atomic physics.

THE GENERAL EQUATIONS OF ENERGY AND ENTROPY OF GASES

By TZU CHING HUANG

DEPARTMENT OF CHEMISTRY, NATIONAL TSING HUA UNIVERSITY, PEIPING, CHINA

(Received March 9, 1931)

ABSTRACT

By substituting the general equation of state for any gas, $p = T\Psi(v) - \Phi(v) - F(v, T)$ in the thermodynamic equation, $Tds = du + pdv$, and by applying the principle of exact differential, the following general equations of energy and entropy have been obtained,

$$u = \int \Phi(v)dv + \int \left[F - T \frac{\partial F}{\partial T} \right] dv + \alpha(T)$$

$$s = \int \Psi(v)dv - \int \frac{\partial F}{\partial T} dv + \beta(T).$$

The values of $\alpha(T)$ and $\beta(T)$, both arbitrary functions of temperature, are found to be

$$\alpha(T) = \int c_{v\infty} dT + k_1,$$

$$\beta(T) = \int \frac{\alpha'(T)}{T} dT + \text{const} = \int c_{v\infty} \frac{dT}{T} + k_2,$$

where $c_{v\infty}$ = heat capacity of the gas at constant volume and at infinite dilution. The equations are applied to a perfect gas as well as to gases obeying van der Waals', Clausius' and Dieterici's equation of state and are found to give results in agreement with those obtained from other thermodynamic equations.

PHILLIPS,¹ by employing the characteristics of exact differentials, showed that both the energy and entropy of a fluid are the sum of a function of volume and a function of temperature, if its equation of state belongs to the type,

$$p = T\Psi(v) - \Phi(v), \quad (1)$$

in which p is the pressure, T the temperature of the fluid, $\Psi(v)$ and $\Phi(v)$ are functions of volume. Eq. (1), however, is not general enough. Beattie and Bridgeman² pointed out that practically all the equations of state can be generalized in the form

$$p = T\Psi(v) - \Phi(v) - F(v, T) \quad (2)$$

where $F(v, T)$ is a function of volume and temperature. The purpose of the present paper is to find the general equations of energy and entropy of any

¹ Phillips, Jour. Math. and Phys., M.I.T. 1, 42 (1921).

² Beattie and Bridgeman, Proc. Am. Art. Sci. 63, 231 (1928).

fluid belonging to type (2), and the method of derivation is essentially an extension of that of Phillips.

ENERGY EQUATION

From thermodynamics we have

$$Tds = du + p dv \quad (3)$$

in which u and s are the energy and entropy of the substance. Combining with Eq. (2) we get

$$\frac{du}{T} - ds + \Psi(v)dv - \frac{\Phi(v) + F}{T} \cdot dv = 0 \quad (4)$$

where $F = F(v, T)$ for short.

As the result of straightforward calculation we have finally

$$u = \int \Phi(v)dv + \int \left[F - T \frac{\partial F}{\partial T} \right] dv + \alpha(T). \quad (5)$$

ENTROPY EQUATION

By combining Eqs. (2) and (3), we get

$$du - Tds + [T\Psi(v) - \Phi(v) - F]dv = 0. \quad (6)$$

Proceeding as before, we find

$$s = \int \Psi(v)dv - \int \frac{\partial F}{\partial T} dv + \beta(T). \quad (7)$$

DETERMINATION OF $\alpha(T)$ AND $\beta(T)$

The relation between $\alpha(T)$ in Eq. (5) and $\beta(T)$ in Eq. (7) can be easily derived. From Eqs. (5) and (7) we get

$$du = \left[\Phi(v) + F - T \frac{\partial F}{\partial T} \right] dv - \left[\int T \frac{\partial^2 F}{\partial T^2} dv - \alpha'(T) \right] dT \quad (8)$$

$$ds = \left[\Psi(v) - \frac{\partial F}{\partial T} \right] dv - \left[\int \frac{\partial^2 F}{\partial T^2} dv - \beta'(T) \right] dT. \quad (9)$$

Substituting these values of du and ds and that of p in Eq. (2) in Eq. (3) and collecting terms, we get

$$T\beta'(T) = \alpha'(T) \quad (10)$$

or,

$$\beta(T) = \int \frac{\alpha'(T)}{T} dT + \text{const.} \quad (11)$$

In the determination of $\alpha(T)$, the energy equation presents no difficulty, but in the case of $\beta(T)$, the integral of the entropy equation becomes infinite at the lower limit because of the presence of a term $\ln v$ or $\ln(v-b)$. In the pres-

ent method $\alpha(T)$ is evaluated from the initial condition, while $\beta(T)$ is found from Eq. (29). A common method³ of finding $\alpha(T)$ is to assume that at infinite dilution (i.e., $v \rightarrow \infty$) the gas approaches the perfect state

$$u_{v=\infty} = \alpha(T) = \int c_{v=\infty} dT + k_1 \quad (12)$$

and Eq. (11) gives

$$\beta(T) = \int c_{v\infty} \frac{dT}{T} + k_2 \quad (13)$$

where $c_{v\infty}$ is the heat capacity of the gas at constant volume and at infinite dilution, and k_1 and k_2 are arbitrary constants.

APPLICATION TO SOME EQUATIONS OF STATE

1. Perfect gas:

$$p = \frac{RT}{v}.$$

Referring to Eq. (2), we see

$$\Psi(v) = \frac{R}{v}, \quad \Phi(v) = 0, \quad F(v, T) = 0.$$

Eqs. (5), (7), (12), and (13) give

$$\begin{aligned} u &= \alpha(T) = c_v T + k_1 \\ s &= R \ln v + c_v \ln T + k_2 \end{aligned}$$

in which $c_v = c_{v\infty}$ for perfect gas.

2. van der Waals' equation:

$$p = \frac{RT}{v-b} - \frac{a}{v^2}.$$

Here

$$\Psi(v) = \frac{R}{v-b}, \quad \Phi(v) = \frac{a}{v^2}, \quad F(v, T) = 0.$$

Assuming $c_{v\infty}$ to be independent of temperature, Eqs. (5), (7), (12), and (13) give

$$\begin{aligned} u &= -\frac{a}{v} + c_{v\infty} T + k_1 \\ s &= R \ln(v-b) + c_{v\infty} \ln T + k_2. \end{aligned}$$

3. Clausius' equation⁴

$$p = \frac{RT}{v-a} - \frac{c}{T(v+b)^2}.$$

³ See, for instance Schaefer, *Einführung in die Theoretische Physik*, Walter de Gruyter and Co., Berlin, 1929, Band II p. 189; van der Waals-Kohnstamm, *Lehrbuch der Thermodynamik*, Verlag von Johann Ambrosius Barth, Leipzig, 1908, 1. Teil, p. 44.

Here

$$\Psi(v) = \frac{R}{v-a}, \quad \Phi(v) = 0, \quad F(v, T) = \frac{c}{T(v+b)^2}.$$

The same set of equations gives

$$u = -\frac{2c}{T(v+b)} + \int c_{v\infty} dT + k_1$$

$$s = R \ln(v-a) - \frac{c}{T^2(v+b)} + \int \frac{c_{v\infty} dT}{T} + k_2.$$

4. Dieterici's equation⁵

$$p = \frac{RT}{v-b} e^{-a/vRT}$$

which, on expansion, becomes

$$p = \frac{RT}{v-b} - \frac{a}{v(v-b)} + \frac{a^2}{2RTv^2(v-b)} + \dots$$

Taking only the first three terms and referring to Eq. (2) we find

$$\Psi(v) = \frac{R}{v-b}, \quad \Phi(v) = \frac{a}{v(v-b)}, \quad F(v, T) = \frac{-a^2}{2RTv^2(v-b)}$$

Eqs. (5), (7), (12), and (13) give

$$u = \left[\frac{a}{b} - \frac{a^2}{b^2 RT} \right] \ln \frac{v-b}{v} - \frac{a^2}{bRTv} + \int c_{v\infty} dT + k_1$$

$$s = R \ln(v-b) - \frac{a^2}{2b^2 RT^2} \ln \frac{v-b}{v} - \frac{a^2}{2bRT^2 v} + \int \frac{c_{v\infty} dT}{T} + k_2.$$

The above results are checked by integrating the following thermodynamic equations, after substitution of the values of $(\partial p / \partial T)_v$ and p in each equation of state

$$\left(\frac{\partial u}{\partial v} \right)_T = T \left(\frac{\partial p}{\partial T} \right)_v - p$$

$$\left(\frac{\partial s}{\partial v} \right)_T = \left(\frac{\partial p}{\partial T} \right)_v$$

Eqs. (5) and (7) can be applied to any other equation of state, but the above examples are sufficient to show their usefulness.

Dr. D. Sun of the Department of Mathematics gave most valuable assistance for which the author is grateful.

LETTERS TO THE EDITOR

Prompt publication of brief reports of important discoveries in physics may be secured by addressing them to this department. Closing dates for this department are, for the first issue of the month, the twenty-eighth of the preceding month; for the second issue, the thirteenth of the month. The Board of Editors does not hold itself responsible for the opinions expressed by the correspondents.

Aluminum May Have A Nuclear Spin

In a recent letter to the editor of the Physical Review, R. C. Gibbs and P. G. Kruger, (Phys. Rev. **37**, 656 (1931)) report a negative result in their search for hyperfine structure in the arc and first spark spectrum of aluminum. Due to the importance of this result it should be pointed out that the evidence is not conclusive and that aluminum may have and is predicted to have a nuclear spin.

The arc lines investigated involving the transitions ${}^2P_{1\frac{1}{2}}(3p) - {}^2S_{\frac{1}{2}}(4s)$ would not be expected to give very large *hfs* separations since the penetrating electron is a somewhat loosely bound *4s* and not a tightly bound *3s* electron. One would expect very narrow *hfs* for both the 2P and 2S terms.

In the first spark spectrum of aluminum, Al II, a *3s* electron is involved in both the initial and final states of the lines investigated. The hyperfine structure separations of the ${}^3D_3(3s4d)$ term and the ${}^3F_4(3s9f)$ term should, due chiefly to the *3s* electron, be large, normal, and almost identical in separation. The result is that the strong *diagonal lines* should fall together and give a strong sharp line and the faint *off diagonal lines* not be observed.

Using a nuclear spin of $3/2$ the *diagonal components* of 4226 (${}^3D_3 - {}^3P_4$) should have a total intensity sixteen times that of the *off diagonal components*. A very similar known case is 4823, ${}^8P_{4\frac{1}{2}} - {}^8S_{3\frac{1}{2}}(3d^5 4s 4p - 3d^5 4s 5s)$ of manganese, (White and Ritschl, Phys. Rev. **35**, 1155 (1930)), in which the six diagonal lines fall close together, the term separations being due chiefly to the tightly bound and penetrating electron *4s*. The same should be true for the ${}^1D_2(3s3d)$ and ${}^1P_1(4s4p)$ term except that here the wide *hfs* terms should be inverted. The strong *diagonal lines* should again fall together and give a fairly sharp line.

A better test than the one chosen would be combinations between levels having widely different separations, e.g. the *off diagonal multiplet lines* ${}^3D_3 - {}^3F_3$ or ${}^3D_2 - {}^3F_2$ ($3smd - 3smf$). The 3D_2 and 3F_3 terms should have very narrow separations and the 3D_1 and 3F_2 terms should have *inverted* but rather wide separations.

The Fundamental Assumptions in Akulov's Papers on Ferromagnetism

In a series of papers¹ Akulov has developed a mathematical theory capable of quantitatively describing a good many ferromagnetic phenomena. The success of his work is some what marred by two fundamental assumptions: (1) That ferromagnetic atoms in a crystal have quadrupole moments. (2) That the Weiss-Heisenberg theory is incorrect (spontaneous magnetization in zero field does not exist).

It is the purpose of this note to point out that these assumptions are arbitrary only in their wording, and that their physical con-

tent may be retained without having to assume any new or unexplained physical processes.

As to the first point, quadrupole moments are assumed in order to account for the fact that *I* and *H* are not, in general, parallel in a cubic crystal. Heisenberg has suggested²

¹ N. S. Akulov, Zeits. f. Physik **67**, 794, (1931). References to previous articles are given in this paper.

² W. Heisenberg, Metallwirtschaft **9**, 843, (1930).

that this is due to a coupling between spin and orbital moments. The idea has been carried out mathematically by Powell³ who obtains essentially the same formulae as Akulov for the dependence of the energy on the direction of magnetization. In other words, one might express Powell's result by saying that, by taking into account the interactions of the type $(s-l)$ a ferromagnetic lattice is in certain respects equivalent to a lattice of quadrupoles.

Secondly, to account for the low hysteresis in single crystals, Akulov finds it necessary to assume that there are no regions of spontaneous magnetization. In one of his papers he has what purports to be a proof of the impossibility of spontaneous magnetization.⁴ That this proof is not valid is evident from the argument in the ensuing communication.

It is possible to have spontaneous magnetization in various regions and at the same time negligible hysteresis losses, provided the regions are sufficiently small. In other words, by assuming the regions of spontaneous magnetization to be small, it is possible to satisfy Akulov's assumption of demagnetization (Schrumpfprozess) in a single grain without destroying the Weiss-Heisenberg theory.

Block Structure and Hysteresis Phenomena

In a previous communication¹ I have pointed out the possibility that the regions of spontaneous magnetization in the Weiss-Heisenberg theory are very small, containing very roughly 10^5 atoms, and that perhaps they are related to Zwicky's block structure.² Since then it has been possible to make some of the calculations more precise. The details will be published elsewhere. At present I wish to point out how a magnetization curve is to be described. Consider a single crystal made up of blocks and let the energy per block be given by an expression,³ for instance, of the type

$$\Phi = A + B \cos(\theta + \alpha) + C \cos 2\theta + D \cos 4\theta$$

The above expression for Φ is written in this form to indicate, first, a dependence on the orientation of the magnetization with respect to the crystal axes, and secondly, the existence of several minima for Φ . The depth and position of these minima depend on the values of A, B, C, D , which, in turn, depend on constants of the material, on the internal strains, and on the applied magnetic field. For equilibrium, the probability of finding a block magnetized in the direction θ is given by an expression of the form $\exp(-\Phi/KT)$. If the depth of the minima of Φ is large compared to KT , the directions of magnetization will be almost entirely confined to these minima, and a transition from one minimum to another will be very improbable. This gives rise to hysteresis and magnetic viscosity. The

procedure for handling this problem is being presented at the Washington meeting of the American Physical Society. If, however, the depth of the minima is of the same order of magnitude as KT , transitions from one minimum to another are reasonably probable, and we have, practically, the above exponential distribution at all times. Thus, to state the case crudely, if the shape of the potential Φ is slowly varied by varying H , the resulting intensity will be independent of the previous history of the sample provided the depth of the minima of Φ is of the same order of magnitude as KT . Akulov⁴ estimates the depth of the minima in unstrained single crystals of iron to be 10^5 ergs/cm³, and points out that the hysteresis of single crystals is negligible. That is, I is independent of the previous history of the sample. Then, according to the above, if v is the volume of a block, we must have

$$\Phi \sim v \times 10^5 \text{ ergs/cm}^3 \sim KT = 1.37 \times 10^{-16} \times 300 \\ v \sim 4 \times 10^{-19} \text{ cm}^3.$$

³ N. S. Akulov, Zeits. f. Physik, 67, 794, (1931); F. C. Powell, Proc. Roy. Soc. A130, 167, (1930); R. Becker, Zeits. f. Physik 62, 253, (1930).

⁴ N. S. Akulov, Zeits. f. Physik 64, 559 (1930).

If v_0 is the average volume per atom, and $n = v/v_0$ = the number of atoms per block, we have that $v_0 = M/N\rho = 56/6 \times 10^{23} \times 8 = 1.2 \times 10^{-23}$ cm³ and hence $nv_0 \times 10^{-19}/1.2 \times 10^{-23} = 35,000$ atoms or roughly the same number as

that previously deduced.

Electron-pair Bonds versus Polarization in Crystals

In a letter in the March 15th number of the Physical Review (37, 775 (1931)) Mr. W. H. Zachariasen states, "So far the application of the principles of shared electron pairs on the atomic arrangement in inorganic crystals has proved unsuccessful, while considerations of the crystal structure from point of view of ions, ionic dimensions, ionic polarizability, and crystal energy . . . have given very valuable and important results." Such a statement I can hardly let go unchallenged.

Certainly the concepts of ions, ionic dimensions and crystal energy have proven very useful, especially in the theoretical treatment of such structures as the alkali halides, in which without question the structural units are simple ions. That however does not justify the consideration of XO_3^- ions as composed of O^{--} and distorted X^{+5} ions, when much chemical and physical evidence points to the existence of non-polar bonds between the atoms in such groups. We can agree that polarization does exist in an ion of this sort, but it seems to me more logical to consider it a *result* of the fact that completion of the valence shells of all these electronegative atoms by the formation of shared electron-pair bonds produces an unsymmetrical arrangement, rather than the *cause* of that arrangement.

The polarization concept has been used to "explain" many things¹ which are probably little related to it,—for instance the irregularities in melting and boiling points of the alkali halides, later given a satisfactory quantitative treatment by Pauling² on the basis of "radius ratios." On the other hand the Lewis theory of shared electron-pairs is now generally agreed to for molecules and for ions (including XO_3^-) in solution and I see no reason why it should not apply equally well to crystals. One can predict from it in the first place whether or not any electronegative atoms will be adjacent to each other in the crystal and in the second place not only the number of "contacts" between electronegative atoms but also the approximate angles between them. How else can one explain such structures as

those of I_2 , Se, Te, As, Sb, Bi, FeS_2 , SiO_2 , As_4O_6 , $\text{K}_2\text{S}_2\text{O}_6$ ³ (in which pairs of sulfur atoms are surrounded at corners of a distorted octahedron by oxygen atoms), and many more? I can imagine no satisfactory explanation in terms of "ions, ionic dimensions, ionic polarizability and crystal energy" alone. The "tetrahedral" XO_3^- structure, indicated in the early work on NaClO_3 and NaBrO_3 and beautifully proven by Mr. Zachariasen's researches, furnishes still another example of a prediction directly from Lewis' postulates which has been experimentally verified.

Mr. Zachariasen states that "Until one is able to treat the quantization of the electrons in polyatomic groups completely on the basis of wave mechanics, we must be satisfied with rough approximations." In view of Pauling's recent very satisfactory wave-mechanics treatment of electron-pair bonds in crystals⁴ perhaps he will now be willing to abandon his rough approximations in favor of the point of view I have been upholding.

In order that there be no misunderstanding regarding the rule given in the next to the last paragraph of Mr. Zachariasen's communication, I might mention that for every example given the predictions on the basis of the Lewis theory would be precisely the same. Moreover Lewis' conceptions are much more general in their application than is this rule and so more useful.

Perhaps after I have read Mr. Zachariasen's

¹ For a summary see Grimm, Handbuch der Physik 24, 561-568 (Springer, Berlin, 1927).

² Pauling, Zeits. f. Krist. 67, 377 (1928).

³ The analysis of this structure, by Glenn O. Frank and the writer, was reported at the Toronto Meeting of the Mineralogical Society of America last December and will soon be submitted for publication in the American Mineralogist.

⁴ Pauling, J. Am. Chem. Soc., April 1931; also in a forthcoming article in the Zeitschrift für Kristallographie.

forthcoming article on XO_3 groups in crystals (which I shall be much interested in doing) and he has read one of mine on "Principles Determining the Arrangement of Atoms and Ions in Crystals," to be published soon in the Journal of Physical Chemistry, as well as the

articles of Pauling's mentioned, we can come to a better mutual understanding.

Evidence of the Detection of Element 85 in Certain Substances

With a magneto-optic method of analysis (Allison and Murphy, Jour. Amer. Chem. Soc. 52, 3796 (1930); Phys. Rev. 36, 1097 (1930)) we have made a search for element

several of their compounds, increasing scale readings representing decreasing time lags. These acids as do other inorganic acids which we have studied, produce each two charac-

Fig. 1.

85 in various substances in which its presence might be suspected. Out of a considerable number of substances examined, we have found evidence which seems to us to indicate, to a high order of probability, the presence of element 85 in the following: sea water, fluorite, apatite, monazite sand (Brazilian), kainite (Stassfurt), potassium bromide, hydrofluoric acid and hydrobromic acid. The evidence is presented in the data displayed in the accompanying graphs, and is supported by certain chemical reactions.

In Fig. 1 are plotted the atomic weights of the halogens against the scale readings of the minima of light intensity characteristic of

teristic minima, while the salts, as do other inorganic salts, produce in general minima equal in number to the known isotopes of the metallic element of the salt.

The two lower curves (Fig. 1) show our observations for hydrofluoric, hydrochloric, hydrobromic, hydriodic acids and what we will call provisionally "85" acid, each acid forming two minima of light. The other curves, in order, exhibit the data obtained for the halides of lithium, aluminum, magnesium, ammonium, iron, calcium, and sodium. It will be seen that we find minima in each case appropriate to an "85" salt, that the number of these minima is without exception

the same as that of the other halides and that they lie well on the extended curves.

The same data are shown somewhat differently in Fig. 2, in which the chemical equivalents of the isotopes of the metallic radicals

five series beyond sodium, except in the case of the chlorides, because of the difficulties introduced by the overlapping in these regions of the scale of the minima produced by the halogen salts of the heavier elements.

Fig. 2.

are plotted against the scale readings of the characteristic minima of the compounds. The upper curve represents the fluorides of hydrogen, lithium, aluminum, magnesium, ammonium, iron, calcium and sodium. The next three curves represent, respectively, the chlorides, the bromides and the iodides, while the last curve represents what we have termed the "85"-ides, of the same elements. We have not as yet extended our observations for the

According to our quantitative estimates, the greatest abundance of the element found in any of the above mentioned substances, in unconcentrated form, is of the order of 1 part in 10^9 . Concentrations in the form of Li85, using monazite sand as a source, are now in progress and have already met with considerable success. The characteristic minima of H85 disappear on the addition of aqua regia, bromine or iodine to the solution. These

minima are restored by the addition of sulphur dioxide or stannous chloride. These are the only oxidizing and reducing agents which have been tried. All reagents used gave negative tests for H₂S.

These investigations have been under way since the middle of the past summer. More recently they have been repeated and extended by one of us (F.A.) in a somewhat

more precise manner, while the chemical investigations have been carried on by two of us (E.R.B. and A.L.S.).

The Principle of Continuity and Regularity of Series of Atom Nuclei (Atomic Species)

While what may now be called the principle of continuity and regularity of the series of atomic species, has been used by the writer in the prediction of isotopes, and has been presented in the form of diagrams for 10 years, the complexity of the diagrams seems to have prevented the recognition of this principle by others. It therefore seems important to give a name to the principle and to illustrate it by simple drawings.

The first figure is taken, with five minor changes which do not affect the general pattern, from a diagram of the helium-thorium series which was used to predict numerous isotopes, most of which have now been found or shown to be probable. The maximum number of isobaric species given in this 1923 figure (J. Franklin Inst. 195, 554) is 3, as is shown in Fig. 1.

The uranium series (Fig. 2) exhibits at

Fig. 1.

Fig. 2.

present a very simple pattern. The atomic masses (diagonal lines) for both the uranium ($4n+2$) and the thorium ($4n$) series are even, and the general increment of isotopic number or atomic mass between levels in either series is 4, which represents an increment of 2 in the number of cementing or β -electrons. Among the non-radioactive elements a single isotopic number in no case represents species of both

the atomic number. The minor differences are explained by other relations presented earlier. These cannot be discussed, on account of lack of space, except that it may be stated that the fact that species of isotopic number 3 are not as yet found in the lithium series, but are found in the beryllium series, is in accord with these relations. These two series thus occupy odd isotopic lines in common, and the

Fig. 3.

Fig. 4.

series, with the exception of three species of the uranium series on the base line, of the writer's class 4, which have the isotopic number zero, which is normally that of the helium-thorium series. Here a fluorine isotope of mass 18 is indicated as probable.

The $4n+3$ or lithium series (Fig. 3), and the $4n+1$ or beryllium series (Fig. 4) represent odd atomic weights, and the two patterns are made almost identical if the lithium series is plotted with $Z+1$ as abscissae, where Z is

general increment in isotopic number in either series is 2.

If the lithium and beryllium series together are considered as a single or "odd" series, very simple relations are exhibited, or the principle of continuity and regularity still holds. Along a given isotopic line the increment of atomic number is one, of atomic mass 2, and of number of electrons, one. Thus the common increment is represented by the formula p_e in which p represents a proton and e an electron.

This corresponds to an increment of a half alpha-particle. Thus for isotopic number 1 every atomic number from 3 to 17 represents a known species of the combined series.

The fact that the number of superposed levels in each of the even helium and uranium series is larger than in the odd lithium series is in accord with the relation (Proc. Nat. Acad. 2, 216 (1916) and later papers) that higher nuclear stability is found in general for even than for odd nuclear charge. The smaller number of levels in the beryllium series is in accord with the even more general rule (J. Am. Chem. Soc. 39, 859 (1917), 42, 1991-2 (1920) that the electrons in atom nuclei are in general associated in pairs, and an odd num-

ber of electrons gives to a nucleus a relatively low stability as compared with that associated with adjacent even numbers, since the beryllium series is the only one in which the number of nuclear electrons is odd, when the atomic number is even (except the class 4 species of Li, B, and N).

The diagonal lines in the charts give the atomic masses. While chlorine of isotopic number 5 and atomic weight 39 is indicated as already discovered, the discovery is not as yet confirmed.

Anomalies in Hyperfine Structures

In a recently published paper Goudsmit¹ points out that the empirically observed hyperfine structure patterns show in some cases very marked deviations from theoretically expected relationships. The discrepancy is observed in the region of high atomic numbers

Dirac's equation shows in fact that such a difference is to be expected. A calculation exactly similar to the one made by the writer² for s terms shows that (r^{-2}) of the ordinary formulas for $p_{1/2}$, $p_{3/2}$ must be replaced by $(2\pi/\Lambda)I, -(4\pi/\Lambda)I$, $I = \int \phi_1 \phi_2 r^{-2} dr$. Here ϕ_1 ,

Fig. 1. I is $\phi_1 \phi_2 / x^2$ for $P_{1/2}$. II is $\phi_1 \phi_2 / x^2$ for $P_{3/2}$. III is $\phi_1 \phi_2 / x^2$ for s .

and is usually such as to make it necessary to ascribe an anomalously large separation to the $p_{1/2}$ term of the single electron spectrum. The interval rule appears to be obeyed in the case of Bi rather accurately. It is logical therefore to look for an explanation in the manner in which the $p_{1/2}$ and $p_{3/2}$ states interact with the nucleus.

ϕ_2 are the two radial functions of Dirac-Gordon (denoted by Gordon as ψ_1, ψ_2). The normalizing factor is chosen so as to have $\int (\phi_1^2 + \phi_2^2) dr = 1$. In the neighborhood of the nucleus the "term-value energy" and screening

¹ S. Goudsmit, Phys. Rev. 37, 663 (1931).

² G. Breit, Phys. Rev. 35, 1447 (1930).

effects may be neglected. Under these conditions

$$\begin{aligned}\phi_1 &= J_{2\rho}(2x^{1/2}) \\ \alpha\phi_2 &= (j' - \rho)J_{2\rho}(2x^{1/2}) + x^{1/2}J_{2\rho+1}(2x^{1/2}) \\ \alpha &= 2\pi Ze^2/\hbar c, \rho = (j'^2 - \alpha^2)^{1/2}, x = 2Zr/a_H\end{aligned}$$

The J_n are Bessel functions of order n ; $j' = -1, 1, -2$ for $s, p_{1/2}, p_{3/2}$. The results of calculation with the above formulas are represented graphically for $\alpha=0.661, Z\leq 91$. The region close to the nucleus is seen to contribute more to the I for $p_{1/2}$ than for $p_{3/2}$. The contribution to the effective value of $\langle r^{-3} \rangle$ due to this region is expected to be large for $p_{1/2}$ and of the same order as the customary $2\pi\psi^2(0)$ of Fermi. In fact in the approximation of Schroedinger's non-relativistic equation we have to replace $\alpha\phi_2$ for s terms by $-x^{1/2}J_1(2x^{1/2})$. This is also plotted on the figure as $(\alpha\phi_2)_s$. The scale of all curves is seen to be roughly the same. The normalizing factor is approximately K given by $K^2(\phi_2(r)/r)^2 = 4\pi\psi^2(r)$. Hence $K^2 = 2\pi\psi^2(0)$ and $K^2 4\pi I/\Lambda \leq 4\pi^2 (a_H/\Lambda Z)\psi^2(0) \int \phi_1\phi_2 x^{-2} dx$. The integral in x is seen to be of the order of 1 and the whole of the order of $2\pi\psi^2(0)$. For comparison we

have also given the $\phi_1\phi_2/x^2$ curve for s terms in the non-relativistic approximation. Dirac's equation gives higher values for s terms as well.

We may say therefore that for the calculation of the hyperfine structure intervals the $p_{1/2}$ states of heavy atoms should be considered as penetrating orbits in the neighborhood of the nucleus. For this reason alone their hyperfine structure may be anomalously great. Other effects must of course also be considered. According to Goudsmit's estimates there is no special reason to believe that they are very important. Nevertheless their effect and the contribution of regions of higher r to I must be taken into account before a quantitative comparison with experiment may be made. At present the observed deviations from simple approximate formulas are qualitatively in agreement with theory being in the correct direction and of the proper order of magnitude.

On the Infrared Absorption by Hydrogen Sulphide at 8.0μ

Papers published by Rollefson¹ and Mischke² on the infrared absorption spectrum of hydrogen sulphide report the presence of an absorption band at about the wave-length 8.0μ . In a more recent paper, one of the authors working with E. F. Barker³ at the University of Michigan, reported that a diligent search for this band had failed to confirm it. Each time when it was looked for and not found, the existence of the other two bands reported, at 2.65μ and 3.8μ respectively, were first checked. It was therefore concluded that the region at 8.0μ could not be attributed to hydrogen sulphide.

A series of measurements have been carried out with a Wadsworth prism spectrometer, especially in the region from 7.0μ to 9.0μ further to investigate the nature of the effect observed by Rollefson and Mischke. For this purpose a cell eight inches long, and equipped with rock-salt windows was used; so arranged that it could be tipped in and out of the beam. The cell was first filled with air passed through wash bottles containing KHS and then dried through towers containing successive layers of glass wool on which was sprinkled phosphorus pentoxide. A curve was first made from data taken between the dried air and the

atmosphere, then a similar curve was run with the cell filled with hydrogen sulphide, purified and dried as before, and the curves were plotted for comparison. These two curves were very similar in appearance, at first glance much resembling absorption bands. It was noticed, however that the ratio of the radiation apparently transmitted through the cell to that of the beam when the cell was removed (i.e. the apparent percentage absorption) was much less on the short wave side than on the long wave side. This suggested the possibility that the observed effect might be ascribed to water vapor falsification arising from the water vapor band at 6.2μ which in moist weather may well extend out beyond 8.0μ . The object of the remainder of this experiment was to test this point.

Water vapor falsifications may be very annoying, especially when long cells are used. The cell used in this experiment was equiva-

¹ A. H. Rollefson, Phys. Rev. **34**, 604 (1929).

² W. Mischke, Zeits. f. Physik **67**, 106 (1931).

H. H. Nielsen, and E. F. Barker, Phys. Rev. **37**, 1931.

lent to about one tenth of the entire light path. Consequently it is to be expected that in regions of water vapor absorption, when the cell, filled with very dry air, is tipped into the beam that more energy may be transmitted than when the cell is out of the beam, since by inserting the cell the path through which atmospheric water vapor absorption may occur has actually been shortened. Hence in regions of strong atmospheric absorption, one may observe what appears to be negative absorption, while in regions of less intense absorption this is less apparent or disappears entirely. These falsifications may however be quite deceiving, giving the appearance of an absorption band in the dry gas in the cell—maxima in the water vapor spectrum producing what appear to be minima in a spectrum of the gas under observation, and vice versa. To compensate for the windows, the final readings were plotted against transmission through the cell filled with atmospheric air. Curves for comparison representing percentage absorbed were made from data taken on hydrogen sulphide and dried air against atmospheric air and these were found to reproduce one another even in minute details. A similar curve was plotted of data taken on wet hydrogen sulphide against atmospheric air. The resulting curve appeared as a mirror image of the previous ones.

In Fig. 1 curve *A* represents ratios of transmission through the cell filled with dry hydrogen sulphide and through the cell filled with dried air. On another occasion a curve was made representing ratios of data taken on transmission through dry hydrogen sulphide and dry air. In spite of the fact that the data were all taken on the same day it was found that the humidity had changed a great deal during the time of the experiment. This curve was very similar to *A*. It indicated that the amount of water vapor displaced by the cell was less in the measurements made on dry air than those made on dry H_2S . This was actually the case since hygrometer readings showed the humidity at this time to be much higher than when the data on dry air were taken. Curve *B* is a sketch of Rollefson's curve for H_2S at 8.0μ placed there for com-

parison, while *C* represents the general appearance of Hettner's curve for water vapor in this region. We wish to call attention to the general agreement between that observed by us and Rollefson's curve and in addition to point out that nearly every maximum in Hettner's curve coincides with a minimum in our curve and vice versa.

Fig. 1.

We suggest therefore, as an explanation of the band reported by Rollefson and by Mischke at 8.0μ in hydrogen sulphide, that it is not due to hydrogen sulphide, but rather due to water vapor falsifications which may arise when a long cell is used. This evidence is further supported by the fact that the spacings between the lines as given by Rollefson are of the same magnitude as those given by Sleator and Phelps⁴ in their work on water vapor absorption rather than those observed in the bands of hydrogen sulphide.

Measurement of the Kerr Effect in the Infrared Spectrum

The work of Szivessy and Dierkesmann (*Ann. d. Physik* (5) **3**, 507 (1929)) in extending dispersion measurements of the Kerr elec-

tro-optic effect beyond the customary visible spectrum into the ultraviolet would seem to call for a similar extension into the infrared, if

possible. This I have recently succeeded in doing, in the case of carbon disulphide, with an accuracy apparently not far short of that attained in visual measurements.

The apparatus consists of a spectro-bolometer with very sensitive galvanometer, operated in connection with a Kerr cell. This has plates 5×37 cm and 1.3 cm apart. Light from a special tungsten strip filament lamp is concentrated in a narrow conical beam to an image in the center of the cell, from which it diverges to be focussed later on the slit of the spectrometer. A large aperture double-image prism (only one of the images is utilized) polarizes the entering light in the 45° azimuth and a similar prism crossed at 90° serves as "analyzer." The electrostatic stress converts the plane polarized light into elliptical and the minor axis of the ellipse is proportional to the square root of the resultant galvanometer deflection. The phase difference is readily computed upon comparing the deflection with

that produced by a known rotation of the polarizing prism. A high speed Wehrsen "Mercedes" static machine has so far served as a very satisfactory source of high potential.

The spectral range which can be explored in this way seems to be from about 0.5μ to 2μ or beyond, thus extending the previous wavelength range for this work some four-fold. Carbon disulphide, over this range, shows a dispersion of the Kerr double refraction in better agreement with the Havelock formula $B = C(n^2 - 1)^2 / \lambda n$ than might reasonably be expected. There are some discrepancies, however, to be investigated more carefully later—and explained if possible. The method is to be further developed and extended to such other materials as have sufficient infrared transparency.

Quantum Mechanics and the Chemical Bond

Three years ago I announced in a short note¹ the discovery of some new results regarding the chemical bond. It was pointed out that under certain conditions the formation of chemical bonds by an atom can destroy the distinction between s and p eigenfunctions, and a criterion determining whether this change in quantization of the single-electron eigenfunctions will or will not take place was given. It was also announced that this change in quantization permits the formation of four equivalent tetrahedral bonds by carbon.

Since then a number of further results bearing on the nature of the chemical bond have been obtained; it is the purpose of this letter to call the attention of physicists to a paper in the April, 1931, issue of the Journal of the American Chemical Society in which they are given in detail. It was first shown from the quantum mechanics that the main resonance integrals for an electron-pair bond between two atoms involve only one single-electron eigenfunction on each atom. In consequence many properties of electron-pair bonds can be derived from a consideration of single-electron eigenfunctions alone. Thus it is shown that if $s-p$ quantization is not changed, the bonds formed by the p eigenfunctions will tend to be at right angles to one another. A very simple but powerful approximate *quantitative* treatment of bond strengths is given. With its aid

it is shown that when $s-p$ quantization is broken through bond formation, the best bond eigenfunctions which can be formed from a combination of s and p eigenfunctions alone are tetrahedral eigenfunctions, so that the two, three, or four bonds formed will tend to make angles of $109^\circ 28'$ with one another. This explains the tetrahedral angles found experimentally not only for quadricovalent carbon, nitrogen, silicon, etc., but also for tricovalent nitrogen, oxygen, etc. The tetrahedral eigenfunctions also allow free rotation about single bonds, but not about double bonds.

When d eigenfunctions as well as s and p are available for bond-eigenfunction formation a number of bond configurations are possible. One d eigenfunction with s and p permits the construction of only four strong bonds, *and these are directed towards the corners of a square*. Such a configuration has been shown to exist for bivalent palladium and platinum, and this theory predicts it also for bivalent nickel in $K_2Ni(CN)_4$ and for trivalent gold. Two d eigenfunctions give six strong bonds directed towards the corners of an octahedron; this configuration is found in many complexes.

¹ Linus Pauling, Proc. Nat. Acad. Sci. **14**, 359 (1928).

It is also shown that in complex ions the orbital magnetic moments of electrons are extinguished through the interaction with surrounding atoms, so that the magnetic moment is due to the spin moments of unpaired electrons alone. Together with the results obtained regarding bond eigenfunctions, this leads to a complete theory of the magnetic moments of polyatomic molecules and complex ions. With its aid magnetic data have been shown to provide verification of many predictions regarding bond eigenfunctions; and in a number of doubtful cases magnetic data provide a basis for definite decision as to the type of bonds in a given complex.

These results have also permitted the formulation of a set of principles determining the structure of crystals containing electron-pair bonds, to be published in the *Zeitschrift für Kristallographie*.

Three of these results have been independ-

ently obtained by Slater and announced in a preliminary communication.² He points out the possibility of the formation of four equivalent tetrahedral bonds by a carbon atom (as I did in 1928), without giving the tetrahedral eigenfunctions and without recognizing that tetrahedral eigenfunctions are also important even when fewer than four bonds are formed; and mentions that this leads to restricted rotation about a double bond. Having apparently assumed the importance of one single-electron eigenfunction to bond formation, he also shows that p eigenfunctions should lead to 90° bond angles.

Time Lag in Changes of Electrical Properties of Rubber with Temperature and Pressure

An abstract of a paper by the author entitled "Time Lag in Changes of Electrical Properties of Rubber with Temperature and Pressure" appeared in the *Physical Review*, Vol. 35, page 1429, June 1, 1930. Data were presented which apparently showed that two or more hours might be required for the dielectric constant, power factor, and resistivity to become constant after the temperature had been changed. In attempting to check these results, an error in experimental technique was

discovered. Measurements with improved apparatus show that the dielectric constants and power factor follow the temperature changes with little if any time lag. No additional measurements on rubber under pressure have as yet been made.

Bureau of Standards,
Washington, D.C.,
April 6, 1931.

The Uncertainty Principle

Kennard has connected the uncertainty principle with radioactive disintegration by showing (*Phys. Zeits.* **30**, 495-497) how to derive Gamow's formula for radioactive disintegration from known quantum principles plus the uncertainty principle of Heisenberg without the additional postulate assumed by Gamow that a particle of energy W can pass through a potential wall of height $V > W$.

Here we have the pure chance phenomena of radioactive disintegration, independent of the disturbance produced by the act of measurement, and performed for us by nature at a rate that has remained constant since the solidification of the earth's crust, linked with the probability phenomena of the new quantum mechanics, the indeterminateness of which is assumed to be caused by an uncon-

trollable perturbation introduced of necessity in the process of measurement.

Is it not better to leave the indeterminateness in nature where we find it, rather than to attribute it to the inevitable perturbation introduced when making an observation, although we do not know how this perturbation introduces the indeterminacy?

If we can believe that the general laws of quantum mechanics are fundamental laws of nature, the various possibilities of natural behavior should be inherent in these laws, whether they be of a physical, chemical or biological character. I shall not expatiate here on the considerable progress that has already been made by the application of the quantum laws to chemistry, by the work of Heitler, London, and Slater. The generality

of these laws, which is responsible for their abstractness, and their flexibility, as evinced in a concrete manner by the uncertainty principle, make for their adaptability to other domains of thought. One might expect that this generality and plasticity would be characteristic of fundamental laws of nature. Viewed in this light one need not make apologies for nature by attributing the indeterminateness in its laws to the limitation of our knowledge imposed on us by the very act of observation.* Although if one feels that somehow our fallibility does play a part in our picture of the universe, one might view the objective laws of quantum mechanics as bringing before us the subjective aspect of definition and concept. As for the uncertainty principle, one can, following Darwin (Proc. Royal Soc. A130, 1931), regard it in the same role as the part played by the clocks and rods in the early formulation of the relativity theory when it was necessary to supplement the formal theory by concrete examples showing how the old classical ideas failed in specific cases. The general laws of the quantum mechanics, which are at the bottom of the uncertainty principle, are not conditioned by a theoretical clumsiness in our means of observation.

The intimate connection between the indeterminateness in quantum mechanics and the concept of observation may be due to the fact that "observation" implies structure. We could not plan our experiments but with the supposition that the elementary entities of nature have a structure. But the elementary entities of nature have neither a particle nor a wave basis. It is only after quantization—after observation—that one can legitimately introduce space and time. The Schroedinger equation may be looked upon as controlling,

in a statistical way, the space-time manifestations of the elementary entities of nature, although the equation itself is devoid of any geometrical interpretation. We make manifest the indeterminateness in nature by bringing over space-time concepts and space-time description to atomic theories that, in order to predict, must go beyond observation. If a scientific theory were humbled to be valid only as far as observation goes, what would happen to cosmogony and geophysics? Should one doubt the validity of scientific inference because it yields results that can not be expressed in terms of familiar things, that are beyond the range of our sensations? There are good reasons for believing that quantum laws are not laws which man's mind has imposed on nature but are laws which nature is having a rather difficult time imposing on man's mind.

Finally, if one does not try to elevate his preconceived ideas and intuitions about causality to a law of nature, but merely views causality as the assumption that nature can be comprehended, can be grasped in thought—though not in imagery—there is no failure of causality in quantum mechanics.

ALEXANDER W. STERN

Brooklyn, N. Y.,
April 11, 1931.

* Prof. J. E. Turner (Nature 126, pp. 995) views the indeterminism in quantum mechanics as having nothing to do with causation but interprets "not determined" to mean "not ascertained." Other physicists argue that the uncertainty principle does not exclude exact laws from physics but means merely that we have no way of verifying them.

On the Effect of Resonance in the Exchange of Excitation Energy

It is well known that exchange of excitation energy between atoms on collision takes place most readily if the "resonance" between the two atoms is good, i.e. if the quantum states of the two atoms are such that the excitation energy of one nearly matches the excitation energy of the other, so that only a small change in the relative kinetic energy of the two atoms is necessary in order to effect the energy balance before and after the collision.

This point has been discussed by Kallmann and London (Zeits. f. physik. Chem. 2B, 207 1929)) who came to the conclusion that the

cross-section would in general be larger the better the resonance. Their calculation is very interesting but not entirely free from objections. It may, therefore, not be out of place to look at the matter from another point of view, perhaps itself open to some objections, but which I believe brings out the nature of the problem very clearly.

The Franck-Condon principle, which says that those transitions are most probable which disturb the motion of the nuclei the least, has been very successful in accounting for the intensities in band spectra, and it has also

been applied recently to the case of predissociation (Franck and Sponer, *Göttingen Nach.*, 1928, 241; Herzberg, *Zeits. f. Physik* **61**, 604 (1930); Turner, *Bull. Am. Phys. Soc.* **6**, 16 (1931)). Now in the case under consideration we can treat the pair of atoms which exchange energy as an unstable molecule, draw potential energy curves for the electronic states of the "molecule," (similar to London, *Zeits. f. physik. Chem.* **11B**, 222 (1930)) and handle the transitions from one continuum to another in the same way that we treat, in the predissociation case, transitions which take place from a discrete state to a continuum. It may be well to point out, parenthetically, that the case of predissociation and the present case are really quite different from the case of adsorption or emission of radiation, and, natu-

a relatively large probability of transition provided, of course, the interaction between the atoms at this distance, r , is great enough. If the two atoms do not collide head on, this means that they have a relative angular momentum, and we can represent the situation by adding a term $(\hbar^2/8\pi^2 M) j(j+1)/r^2$ to the potential energy, where M is the reduced mass, and j the rotational quantum number; but as a more or less rigorous selection rule for j will hold, practically the same amount must be added to the curve for the final state: they will therefore continue to intersect at the same value of r . Thus all collisions with this distance of approach will be favored. Collisions with something near this distance of approach will be somewhat less favored, and there will be a spherical shell in which favorable collision

Fig. 1.

rally, the real justification of this use of the Franck-Condon rule will come when the matter has been given a more or less rigorous quantum mechanical investigation.

In Fig. 1 let curve 1 be the potential energy curve (potential energy = U , distance between atoms = r) with atom A excited, atom B unexcited, and let curve 2 be the curve with atom B excited, A unexcited. Suppose curve 1 represents the initial state of the pair of atoms. Then its intersection with a horizontal line gives the distance of closest approach of the atoms if they make a head-on collision with the energy indicated by the horizontal line. If curve 1, curve 2, and the horizontal line intersect at the same point, as shown, or somewhat near the same point, then, according to the Frank-Condon theory, we may expect a

take place. Now it is seen that the closer together the asymptotic values of U_1 and U_2 , in general the greater the distance r at which they will intersect, and hence, we may infer, the greater the size of the spherical shell in which collisions are favored by the particular factor under consideration. It may not be the only factor, and it certainly cannot stretch the region of favorable collisions out indefinitely, but all the indications from analogous cases are that it should be an important factor. The case where the asymptotic values of U_1 and U_2 coincide is just the case of exact resonance, and it is easy to see why transitions with exact resonance should be favored, but it is seen that the precise definition of good resonance is involved in complications which must be treated specially in any given case.

Of course, we cannot draw definite conclusions from such qualitative observations, but they at least provide a guide for future quantitative calculations. For the most part the applications of the Franck-Condon principle are just as qualitative as this one, but in the case of band spectra they have provided the stimulus for some successful quantitative work.

I have recently extended the quantitative work described in a preliminary note (*Proc. Nat. Acad. Sci.* **17**, 34 (1931)), where the force which acts between the two atoms is supposed to be due to their momentary dipole moments, by treating the two atoms as a molecule and using perturbations of the type introduced by Slater, (*Proc. Nat. Acad. Sci.* **13**, 423 (1927)). It appears, though with some assumptions I am trying to remove, that practically no transitions will take place unless the resonance is extremely good; the potential energy curves

in this case do not intersect. Yet, experimentally, cross-sections very much larger than normal, or cross-sections unusually large for the type of transition considered, occur for such great resonance differences as 40 to 60 millivolts. I am inclined to think that other forces than the interaction forces of dipoles come into play, even when the radius of action is very large. Kallmann and London, themselves, noted that large cross sections would be expected when electron orbits are large.

It may be well to mention here that Eq. (5) of my preliminary article mentioned above, is incorrect. This error, which was carried through, should not make much difference in the final results and will be corrected later.

The Formation of Striae in a Kundt's Tube

For the past seven years the author has been experimenting on striae formed in a Kundt's tube to determine, if possible, the cause of such striae. An article concerning the use of pith dust in a Kundt's tube was published by the author in *Nature* **118**, 157 (1926). In July 1929 he was able to show conclusively that a rotation of the dust particles on each side of a striation takes place; *Phys. Rev.* **36**, 1098 (1930); *Science* **72**, 442 (1930). January 14, 1931 the author made motion pictures of these rotations which take place on each side

the rotations taking place on each side of a single striation. Further details are given in the references above cited.

Fig. 2.

Fig. 1.

of each single striation. Fig. 1 shows an enlarged photograph of one such striation made from the motion picture negative. The black particles composing the striae were cork-charcoal. The striae were produced in a glass tube in which the air was compressed and rarefied by means of a metal piston attached to one prong of an electrically-driven tuning fork. Fig. 2 is a diagram showing the direction of

The striae in a Kundt's tube are formed by air vortices in the same manner as ripple-marks in sand are formed by water vortices. As shown by Darwin, *Proc. Royal Soc.* **36**, 18 (1883), these rotations are produced when an alternating fluid flow takes place about obstacles in its path. The clockwise and counter-clockwise rotations are maintained always in the same direction regardless of the fact that the fluid stream is alternating.

Also the author has shown that, when using cork particles of the same size, as the frequency of vibration of the air column in the tube increases, the average distance between striae becomes smaller. The photographs of Fig. 3 illustrate this fact. Also the author has shown that, with a constant frequency of vibration of the air in the tube, as the cork particle size is made smaller, the distance between adjacent striae becomes less. The photographs in Fig. 4 illustrate this fact.

The above mentioned observations will be discussed more in detail in a forthcoming publication. In this publication the author will discuss also the formation of striae which he

which have been made showing that the strain in a stroked glass rod clamped at its middle point increases in a direction from a point at the free end to a point at its center. The ex-

Fig. 3.

succeeded in producing on a glass rod wet with alcohol, during the summer of 1925; the absence of striae in a vacuum; the production of striae by an interrupted air stream when the frequency of interruption was too low to produce an audible tone; and some photographs

Fig. 4.

perimental work demonstrating all the above mentioned facts has been done by the author.

Zodiacal Light and Magnetic Disturbance

During a recent trip southward along the 75th meridian from Norfolk, Virginia, to Cape Maisi, Cuba, we observed the zodiacal light. In the evening of March 13, 1931, when the observations were begun, the zodiacal light was unusually bright, the zodiacal cone at 8 P.M. could be followed up to and beyond the Pleiades which were about 40° from the horizon. The zodiacal light was again strong during the evening of March 14. The following evening, March 15, the zodiacal light was distinctly weaker than on the preceding two evenings and for the next three evenings to March 18 it remained fairly weak, that is, it was of its normal brightness. We tried to make morning observations but had no success because Venus, which was in the morning sky, was bright enough to obscure the morning zodiacal light.

After our return from the voyage we found that the magnetic activity was zero from

March 1 to 10, a moderate disturbance began March 11 or 12 and died away on March 14, with magnetic calm from March 15 to 20. The magnetic data were obtained from the observatories at Cheltenham, Maryland, Tucson, Arizona, and Meudon, France, the data from Cheltenham being kindly furnished by the U. S. Coast and Geodetic Survey, and the data from Tucson and Meudon being taken from the Cosmic Data Broadcasts of Science Service. It is seen that the zodiacal light was unusually bright during the period of magnetic disturbance. This is in keeping with the atmospheric ion theory of the zodiacal light and the gegenschein (Phys. Rev. 35, 1098 (1930)).

BOOK REVIEWS

Handbuch der Spectroscopie, von H. KAYSER UND H. KONEN. Siebenter Band, Zweite Lieferung. Pp. 499-750. S. Herzel, Leipzig, 1930. Price RM28.

The second part of Volume 7 of the *Handbuch der Spectroscopie* is an eloquent testimonial to the industry of the authors. As they point out, such a compendium can only be a continuous affair, to be added to from time to time as observations on spectra multiply and their interpretations develop and crystallize into more comprehensive form. Even should our summaries of data and systems of notation become more condensed than at present, the "Handbuch" will never cease to be a mine of information for the laboratory spectroscopist.

This latest addition to the "Handbuch" contains bibliographies and tables of wave-lengths for gallium, gadolinium, germanium, hydrogen, helium, hafnium, mercury, holmium, indium, and iridium. For each element there is also a condensed summary of the literature. In cases where the classification of the lines into series has been made, the term designations of lines are included; modified notation following those of Fowler and Paschen being used for all simple cases, and the notation of the original authors being used where the spectral structure is complicated. The simple notation used is the same as in the first part of Volume 7, i.e., large Latin letters for singlets, large German letters for doublets, and small Latin letters for triplets.

For each element the bibliography is also completed to include all articles written since the issue of Volume 5 to the year 1927. Although none published later than 1927 are included, the number of references is enormous, reflecting the immense amount of spectroscopic research done during the years since the fifth and sixth volumes of the "Handbuch" were issued. For instance, in Volume 5 of Kayser's "Handbuch" there were 177 references to papers on hydrogen spectra, while the present volume contains 549. In spite of the fact that the spectral notation employed is not in accordance with modern usage, the collection of references in a few pages makes this latest addition to the "Handbuch" invaluable. There are very few misspellings and misprints. The print is clear, on good paper, and in the style so well known to those who have had occasion to use the "Handbuch." One looks forward to the volumes yet to appear, containing references and data for the remainder of the elements.

GEORGE MONK

Elektrophysik der Isolierstoffe. DR. ANDREAS GEMANT, Pp. 222+vi, figs. 76. Verlag von Julius Springer, Berlin, 1930. Price bound RM 21.50.

The causes of loss and absorption of energy in dielectrics are only very incompletely understood at the present time. But in recent years there has been a renewed interest in these problems and considerable progress has been made with them. It is therefore fitting that the present volume should appear. It is written by an able worker in this field and deals with both the scientific and engineering aspects of the subject. The book is evenly divided into two sections one in which the normal behavior of insulating materials is discussed, and the other in which breakdown phenomena are considered.

Under normal operating conditions losses in dielectrics result from the presence of either or both ions and dipole molecules. The theories which describe the various mechanisms are clearly and exactly given. On controversial points, of which there are many, the different view points are usually presented, after which the author gives his position and states why. A feature of this section is the discussion of the theories of P. Debye and of K. W. Wagner which, although they result from descriptions of entirely different mechanisms, are shown to lead to mathematical expressions of the same form for the power factor and dielectric constants as functions of temperature and frequency, indicating that only by means of the most exact measurements will a differentiation between them be possible.

The second section treats breakdown phenomena in gas, liquid and solid dielectrics, with particular reference to the work of Joffé, Peek, Rogoski, Slepian, Townsend and Wagner. As in the first section the experimental methods of measuring the various quantities involved are

but briefly given, if at all, while theoretical discussions are in some cases quite complete. Concluding paragraphs are devoted to general statements concerning the influence of the physical and chemical nature of a material on its dielectric strength. The physical characteristics are believed to be the much more important.

The book might perhaps have been improved in several respects.

1. Page 76. Since the effect of extremely high frequencies on the conductance of a very dilute ionic solution is mentioned it should have been treated more exactly. It leads to an increased conduction because the ionic atmosphere which is formed about the ion can not in this case become dissymmetrical, and not because the atmosphere can not form at all as in the case of the Wien effect.

2. Pages 85-90. The work of Phipps and his students on the conductivity of crystals is at least deserving of mention. The theory of Smekal which postulates an ionic conduction in lattice imperfections might also have been mentioned at this point since it apparently has found favor with many investigators.

3. In certain cases purely chemical facts concerning a particular insulating material have enabled the assignment of a mechanism to the conduction process taking place in it. Therefore there could have been included suggestions concerning the actual chemical composition of some of these materials. The colloid chemistry of insulating materials is also important.

4. The author list with journal citations might well have included page references to the text.

These suggestions are not intended to indicate an adverse judgement of the book. The arrangement content and manner of presentation are admirable. It can be recommended not only as a book which will make it easy to become acquainted with this important subject but also as one which will stimulate the interest of a research worker in this field.

J. W. WILLIAMS

THE PHYSICAL REVIEW

THEORY OF THE DIFFUSE SCATTERING OF X-RAYS BY SOLIDS

By G. E. M. JAUNCEY

WASHINGTON UNIVERSITY, ST. LOUIS, MISSOURI

(Received April 2, 1931)

ABSTRACT

The classical theory of x-ray scattering has been applied to the scattering of x-rays by the electrons in the atoms of a solid. The case in which the solid consists of atoms of one kind has been considered. The interactions of the waves scattered by each electron with those scattered by every other electron in the solid has been considered. The analysis is simplified by the fact that the orbital periods of the electrons in the atoms are very much shorter than the vibrational periods of the atoms due to thermal agitations. The final formula obtained is

$$S = 1 + (Z - 1) \frac{f'^2}{Z^2} + \frac{F^2}{ZN} X$$

where S is the scattered intensity per electron relative to the scattered intensity from a single isolated electron, Z is the atomic number, F the atomic structure factor including the effect of thermal agitation, f' is related to f the true atomic structure factor (without thermal agitation), N is the total number of atoms, and X is a certain double summation. The value of X has not been obtained for an amorphous substance but it has been evaluated for the case of a simple cubic crystal by Jauncey and Harvey in the following paper in this issue of the Physical Review.

I. INTRODUCTION

IN 1922, Jauncey¹ found that x-rays are diffusely scattered by crystals in a way which is similar to the scattering by amorphous solids. In particular, the spatial distribution of the scattered rays was found to be about the same for the crystals of rocksalt and calcite as for the amorphous substance glass. These experimental results were in distinct contrast to the results predicted by Debye's theory² of the intensity of x-rays regularly reflected by crystals. Debye's theory requires that diffuse scattering from crystals must occur, but that the spatial distribution and intensity of the rays scattered by crystals should be very different from the distribution and intensity of the rays scattered by amorphous substances. Furthermore, Debye's theory predicts that a rise of temperature will cause an increase in the intensity of the rays scattered

¹ G. E. M. Jauncey, Phys. Rev. 20, 405 (1922). Note: Figs. 2 and 6 in this reference should be interchanged.

² P. Debye, Ann. d. Physik 43, 49 (1914).

by crystals. Accordingly, Jauncey³ investigated the effect of temperature by measuring the intensities of the rays scattered by rocksalt and calcite at 568°K and at 290°K. It was found that neither rocksalt nor calcite showed as great an increase of temperature as was demanded by the theory. In 1924, Jauncey and May⁴ again investigated the scattering of x-rays by rocksalt and determined absolute values of the scattered intensity. The results agreed with the results previously found by Jauncey.¹

In 1917, A. H. Compton⁵ carried out a theoretical investigation of the effect of atomic structure on the intensity of x-rays regularly reflected by crystals. The unit in the diffraction or scattering of x-rays by matter is the electron. The intensity of the x-rays scattered per unit solid angle by a single isolated electron in a direction ϕ with the primary x-rays has been shown by J. J. Thomson⁶ to be

$$I = I_0(e^4/2m^2c^4)(1 + \cos^2 \phi) \quad (1)$$

where I_0 is the intensity of the primary x-rays. If Z electrons are closely packed together so that the charge of the aggregation is Ze and its mass is Zm , it is seen from Eq. (1) that the intensity of the rays scattered by the aggregation is Z^2 times the intensity scattered by a single isolated electron, or that the scattered intensity per electron in the aggregation is $Z^2/Z = Z$ times the intensity scattered by a single isolated electron. Hence, an atom which contains Z electrons closely packed at the center will give rise to scattered x-rays in a direction ϕ which have an intensity per electron of Z times the intensity scattered by a single isolated electron. If, however, the electrons are not massed close to the center of the atom, but are at distances from the center comparable with the wave-length of the x-rays, both constructive and destructive interference takes place between the x-rays scattered by the various electrons in the atom, with the result that the intensity per electron of the scattered rays is less than Z times the intensity scattered by a single isolated electron. The intensity of the x-rays scattered by a number of atoms depends upon the configuration of the electrons within each atom and upon the configuration of the atoms themselves. If the atoms are arranged in a crystal lattice, there are certain special directions in which the x-rays are scattered with great intensity, and thus we obtain Laue spots. However, if a Laue photograph is examined, it is found that in between the black spots on the developed photographic film there is general but less intense blackening. Part of this general blackening is due to the diffuse scattering found by Jauncey.¹ There are thus two effects in the scattering of x-rays by crystals, namely, special scattering, which produces Laue spots and which is caused by regular reflection from planes of atoms according to Bragg's law, and diffuse scattering.

The problem of the intensity of the special scattering by crystals has been

³ G. E. M. Jauncey, *Phys. Rev.* **20**, 421 (1922).

⁴ G. E. M. Jauncey and H. L. May, *Phys. Rev.* **23**, 128 (1924).

⁵ A. H. Compton, *Phys. Rev.* **9**, 49 (1917).

⁶ J. J. Thomson, "Conduction of Electricity through Gases," 2nd Edition, p. 325.

discussed at length by Compton.⁷ The configuration of the electrons in an atom is both rapidly and continually changing, and it becomes necessary to obtain a time average of the intensity of the x-rays scattered (the term "scatter" includes the ideas of both special and diffuse scattering) by the atoms of a crystal. However, the kind of average depends upon the particular effect in which we are interested. If we are studying the special scattering (i.e. Bragg reflection), we take one kind of average, whereas, if we are studying diffuse scattering, we take another kind of average. The first kind of average leads to the atomic structure factor as discussed by Compton.⁷ Recently Compton⁸ has developed the theory of diffuse scattering from the atoms of a monatomic gas. The scattering per electron in a direction ϕ with respect to the primary rays is determined only by the average configuration of the electrons within each atom, and not by the configuration of the atoms themselves. The atoms are so far apart that they can be treated as isolated systems of electrons. In the case of a gas there are no directions in which special scattering takes place.

The amplitude of the waves scattered in a direction ϕ by a single isolated electron is proportional to the square root of the right side of Eq. (1). For convenience, this amplitude is represented by unity. In the case of special scattering by a crystal (Bragg reflection), the intensity is proportional to the square of the time average of the amplitude per electron. In the case of diffuse scattering, the intensity of the scattered rays is proportional to the time average of the square of the amplitude per electron.

As example of the two kinds of average, let us consider the case of an atom with two electrons, both at a distance $r=a$ from the center, but with random orientations. If a crystal consists of atoms of this kind and if the center of each atom (the nucleus) is exactly at a lattice point and there is no thermal agitation, Compton⁷ has shown that the square of the average amplitude per electron is E^2 , where

$$E = (\sin ka)/ka \quad (2)$$

and

$$k = (4\pi \sin \theta)/\lambda. \quad (3)$$

In Eqs. (2) and (3), θ is the glancing angle of incidence when the crystal is set for the regular reflection of the wave-length λ . If, however, a monatomic gas consists of atoms of this kind, Compton⁸ has shown that the average square of the amplitude per electron is

$$S = 1 + (\sin^2 ka)/k^2 a^2 \quad (4)$$

where k is given by Eq. (3) and θ is half the angle of scattering.

When E , the average amplitude per electron in a crystal, is multiplied by Z , the atomic structure factor F is obtained. In 1921, Bragg, James and Bosanquet⁹ showed how experimental values of the atomic structure factor,

⁷ A. H. Compton, "X-Rays and Electrons," Chap. V.

⁸ A. H. Compton, Phys. Rev. 35, 925 (1930).

⁹ Bragg, James and Bosanquet, Phil. Mag. 41, 309 (1921); 42, 1 (1921).

or F values as they are called, can be obtained from the experimental values of the intensity of x-rays reflected in different orders from the different sets of planes in a crystal. In an actual crystal, however, the atomic nuclei are subject to thermal agitation and the atomic structure factor F which is obtained from crystal reflection is not referred to the center of the atom but to a lattice point about which the center of the atom vibrates. We shall call the atomic structure factor which is referred to the center of the atom or nucleus the true atomic factor, and we shall represent this by f .

For several years it has seemed to the writer that in order to unravel the structure of atoms by means of x-rays it would not only be necessary to make observations on the x-rays regularly reflected, but also on the x-rays diffusely scattered by crystals. The one effect must in some way be complementary to the other. It is the purpose of this and the following paper to show how the two effects are interrelated.

II. GENERAL THEORY

We shall first consider the intensity of the x-rays scattered by a large number, n , of electrons. Take a point O as shown in Fig. 1. Let AO represent the direction of the primary x-rays and OB the direction of the scattered rays. The plane containing AO and OB is then the plane of scattering. Let OV

Fig. 1.

bisect the angle AOB . Now draw a plane perpendicular to the line OV , and let OU be the line where this plane cuts the plane of scattering. We shall call the plane whose trace is OU the reference plane. The waves which are scattered by all electrons in the reference plane are in phase with each other. We shall assume the phase angle of all such waves to be zero. Consider an electron at P . The path retardation of the rays scattered by the electron at P relative to the rays scattered by an electron in the plane OU is $CP + PD$. This retardation can be shown to be $2z \sin \theta$, where z is the length of PE and PE is perpendicular to the plane OU . The angle θ is one-half the scattering angle ϕ . The retardation depends only upon the distance of P from the reference plane and is not affected by moving P in any direction parallel to the ref-

erence plane. The phase angle of the waves scattered by an electron at P is then

$$(2\pi/\lambda)2z \sin \theta = (4\pi z \sin \theta)/\lambda \quad (5)$$

For brevity we shall call this phase angle kz where k is given by Eq. (3) and θ of that equation is $\phi/2$.

Let the r th electron be at a distance z_r from the reference plane, so that the phase angle associated with this electron is kz_r . The amplitude of the waves scattered by a single isolated electron is unity, so that the resultant amplitude of the waves scattered by n electrons is the vector sum of the amplitudes associated with each electron. The resultant intensity I is the square of this vector sum, so that

$$I = \left(\sum_{r=1}^{r=n} \cos kz_r \right)^2 + \left(\sum_{r=1}^{r=n} \sin kz_r \right)^2. \quad (6)$$

Since $\cos^2 kz_r + \sin^2 kz_r = 1$, this reduces to

$$I = n + \sum_{r=1}^{r=n} \sum_{s=1}^{s=n} \cos k(z_r - z_s). \quad (7)$$

The symbol $\sum \sum'$ implies that in the double summation r is never taken equal to s . The value of I given by Eq. (7) is that due to a particular configuration of the n electrons. If the electrons are moving about, we must consider the probability of the configuration which gives rise to the intensity I . Let the probability that the r th electron is between z_r and $z_r + dz_r$ be $p_r(z_r)dz_r$. For brevity we shall write this $p_r dz_r$. The probability of a given configuration is then $\prod_{r=1}^n p_r dz_r$. The average intensity is therefore given by the n -tuple integral

$$I_{\text{ave}} = \int \cdots n \cdots \int \{n + \sum' \sum' \cos k(z_r - z_s)\} \prod_{r=1}^{r=n} p_r dz_r. \quad (8)$$

It should be remembered that n is the total number of electrons in, say, a 0.1 mm cube of a substance, and is therefore a number perhaps of the order 10^{17} . The limits of each integral are such that each

$$\int p_r dz_r = 1 \quad (9)$$

In consequence of Eq. (9),

$$\int \cdots n \cdots \int n \prod_{r=1}^{r=n} p_r dz_r = n \quad (10)$$

immediately. To evaluate the integral of the double summation, let us fix our attention on one of the terms of the summation, say, $\cos k(z_u - z_v)$, which refers to the two particular electrons, the u th and the v th electrons. In carry-

ing out the n -tuple integration, each integral with respect to z_r will equal unity unless $r=u$ or v . Hence we can perform $(n-2)$ integrations, so that

$$\int \cdots n \cdots \int \cos k(z_u - z_v) \prod_{r=1}^{r=n} p_r dz_r = \iint p_u p_v \cos k(z_u - z_v) dz_u dz_v \quad (11)$$

Hence

$$I_{\text{ave}} = n + \sum' \sum' \iint p_r p_s \cos k(z_r - z_s) dz_r dz_s. \quad (12)$$

Dividing Eq. (12) by n , we obtain the scattered intensity per electron, thus

$$S = 1 + (1/n) \sum' \sum' \iint p_r p_s \cos k(z_r - z_s) dz_r dz_s. \quad (13)$$

III. SCATTERING FROM A SOLID

Actually, of course, electrons are aggregated into atoms. We shall now consider the scattering of x-rays by the electrons in the atoms in a solid consisting of one kind of atom each of which contains Z electrons. We shall assume that the motions of the electrons within an atom are very much more rapid than the heat motion of the atom. This enables us to obtain a time average of the configuration of the electrons within an atom over a time interval which is long compared to the orbital period of an electron within the atom, but which is still so short that the configuration of the atoms themselves has practically remained unchanged during the interval.

The r th and s th electrons of Eq. (13) may or may not be in the same atom. Let us consider the case where they are in the same atom. In this case we may take the reference plane of Fig. 1 through the nucleus of the atom. If we assume that the probability function for each electron is symmetrical about the reference plane through the nucleus, then each

$$\int p_r \sin kz_r dz_r = 0 \quad (14)$$

so that

$$\begin{aligned} \iint p_r p_s \cos k(z_r - z_s) dz_r dz_s \\ = \left(\int p_r \cos kz_r dz_r \right) \times \left(\int p_s \cos kz_s dz_s \right) \end{aligned} \quad (15)$$

By referring to Compton,⁷ it will be seen that

$$\int p_r \cos kz_r dz_r = E_r \quad (16)$$

where E_r is the average amplitude associated with the r th electron. Hence

$$\iint p_r p_s \cos k(z_r - z_s) dz_r dz_s = E_r E_s. \quad (17)$$

In each atom there are $Z(Z-1)/2$ pairs of electrons and this is the number of the products $2E_r E_s$ for each atom. Let us now introduce an average quantity E' , defined by

$$Z(Z-1)E'^2 = \sum_{r=1}^{r=Z} \sum_{s=1}^{s=Z} E_r E_s \quad (18)$$

where in the summation r is not taken equal to s . Also let us introduce a quantity f' defined by

$$f' = ZE' \quad (19)$$

In the theory of crystal reflection,⁷ the true atomic structure factor f is defined by

$$f = \sum_{r=1}^{r=Z} E_r \quad (20)$$

The double summation for each atom is therefore $Z(Z-1)f'^2/Z^2$, and, since there are n/Z atoms, we obtain on summing for all the atoms

$$(n/Z) \times Z(Z-1)f'^2/Z^2 = n(Z-1)f'^2/Z^2. \quad (21)$$

Multiplying by $1/n$, Eq. (13) reduces to

$$S = 1 + (Z-1)f'^2/Z^2 + (1/n) \sum'' \sum'' \iint p_r p_s \cos k(z_r - z_s) dz_r dz_s \quad (22)$$

where the symbol $\sum'' \sum''$ denotes summation when the r th and s th electrons are always in different atoms.

Fig. 2.

IV. ORBITAL MOTIONS OF THE ELECTRONS IN THE ATOMS

In Fig. 2, let OU be the reference plane and let the center of the t th atom be at Q and let the r th electron which is in the t th atom be at S . Let $AQ = x$;

and $CS = y_{tv}$, so that the distance of the electron at S from the reference plane is

$$z_{tv} = x_t + y_{tv}. \quad (23)$$

Similarly, let the center of the u th atom be at R , and the w th electron in this atom be T . Let $ER = x_u$ and $FT = y_{uw}$, so that

$$z_{uw} = x_u + y_{uw}. \quad (24)$$

Taking two particular atoms, together with a particular electron in the first atom and a particular electron in the second, we may average for the positions of the two electrons by taking an interval of time which is long compared with the orbital period of the electrons, but so short that the centers of the atoms have practically remained stationary during this interval. Hence we can treat the x 's as constant when we integrate and dz may be replaced by dy . In this case

$$\begin{aligned} & \iint p_r p_s \cos k(z_r - z_s) dz_r dz_s \\ &= \iint p_1 p_2 \cos k(x_t - x_u + y_1 - y_2) dy_1 dy_2 \\ &= \cos k(x_t - x_u) \iint p_1 p_2 \cos k(y_1 - y_2) dy_1 dy_2 \\ &\quad - \sin k(x_t - x_u) \iint p_1 p_2 \sin k(y_1 - y_2) dy_1 dy_2 \end{aligned} \quad (25)$$

where the subscripts 1 and 2 have been written for the subscripts tv and uw . The p 's are now probability functions referred to the center of each respective atom. If the atom is symmetrical the integral containing $\sin k(y_1 - y_2)$ vanishes and we are left with the integral containing $\cos k(y_1 - y_2)$. The term containing this integral then reduces to

$$\begin{aligned} & \left(\int p_1 \cos k y_1 dy_1 \right) \times \left(\int p_2 \cos k y_2 dy_2 \right) \cos k(x_t - x_u) \\ &= E_1 E_2 \cos k(x_t - x_u) \end{aligned} \quad (26)$$

where the E 's are given by Eq. (16). If the atoms are of the same kind and we sum for the Z electrons in each of the two particular atoms, we obtain

$$\left(\sum_{r=1}^{r=Z} E_r \right)^2 \cos k(x_t - x_u).$$

Then, summing for all the atoms, we obtain

$$\sum_r'' \sum_s'' \iint p_r p_s \cos k(z_r - z_s) dz_r dz_s = f^2 \sum_t' \sum_u' \cos k(x_t - x_u) \quad (27)$$

V. HEAT MOTIONS OF THE ATOM

We now remember that although the electrons in the atoms are moving much more rapidly than the centers of the atoms, yet the atoms are themselves moving with their thermal velocities. If we are dealing with a solid, the centers of the atoms are vibrating about their mean positions. We therefore introduce a probability function P for the center of the atom. Taking an average over a time long compared with the period of thermal oscillation of the atoms but short compared with the time during which scattering measurements are made, we see that Eq. (22) becomes

$$S = 1 + (Z - 1)f'^2/Z^2 + (f^2/ZN) \sum_{t=1}^{t=N} \sum_{u=1}^{u=N} \iint P_t P_u \cos k(x_t - x_u) dx_t dx_u \quad (28)$$

where $N = n/Z$, the number of atoms involved.

Let us replace the x 's in Eq. (28) by z 's, and let z_r now refer to the distance of the center of the r th atom from the reference plane. Next, let the r th atom oscillate about a mean position whose distance from the reference plane is x_r . Also let the displacement of the center of the atom from its mean position be y_r , so that $z_r = x_r + y_r$. The problem thus becomes similar to that in section IV of this paper and the analysis is similar, excepting that in the case of an amorphous solid it does not seem reasonable to assume that the probability function for the displacement of the center of the atom from its mean position is symmetrical about the mean position. However, if we do make this assumption in order to simplify the analysis, the double integral of Eq. (28) becomes

$$\iint P_t P_u \cos k(z_t - z_u) dz_t dz_u = H_r H_s \cos k(x_r - x_s) \quad (29)$$

where

$$H_r = \int P_r \cos ky_r dy_r \quad (30)$$

H_r may be called the temperature factor for the r th atom. If, in addition, we make a second simplifying assumption that H is the same for all the atoms of the solid, and if we write F for fH ,

$$S = 1 + (Z - 1)f'^2/Z^2 + (F^2/ZN) \sum_{r=1}^{r=N} \sum_{s=1}^{s=N} \cos k(x_r - x_s) \quad (31)$$

where x_r is now the fixed mean position about which the center of the atom oscillates. The quantity F is the atomic structure factor which includes the effect due to thermal agitation, while f' in virtue of Eqs. (18), (19) and (20) is related to the true atomic structure factor f according to

$$f'^2 = f^2 + \left(f^2 - Z \sum_{r=1}^{r=Z} E_r^2 \right) / (Z - 1). \quad (32)$$

Hence except when the probability function E_r is the same for each electron in the atom $f' < f$. It is unlikely that the probability function for a K electron is the same as that for an L electron and therefore f' should be greater than the true atomic structure factor.

The double summation in Eq. (31) has not been determined for an amorphous solid, but can be evaluated for a simple cubic crystal consisting of atoms of one kind. This evaluation has been effected by Jauncey and Harvey in the following paper in this issue of the Physical Review.

THEORY OF THE DIFFUSE SCATTERING OF X-RAYS BY SIMPLE CUBIC CRYSTALS

BY G. E. M. JAUNCEY AND G. G. HARVEY
WASHINGTON UNIVERSITY, ST. LOUIS, MISSOURI

(Received April 2, 1931)

ABSTRACT

The value of X in the previous paper by Jauncey has been determined for the case of a simple cubic crystal consisting of atoms of one kind and the formula obtained by Jauncey reduces to:

$$S = 1 + (Z - 1) \frac{f'^2}{Z^2} - \frac{F^2}{Z}$$

There are no experimental results for a crystal consisting of atoms of one kind but Jauncey and May have obtained values for the diffuse scattering of x-rays from a crystal of rocksalt. Assuming rocksalt to consist of atoms of atomic number $(11+17)/2$ or 14, we have calculated values of f' using values of F given by James and Firth. These calculated values of f' are found to be only slightly greater than the values of F at absolute zero. Also Jauncey has measured the effect of temperature on the diffuse scattering from crystals. From the above formula calculations of the ratio of the scattering at temperatures of 568° and 290°K have been made using F values given by James and Firth. The theoretical and experimental values of this ratio in one case are 1.29 and 1.33 respectively, and in another case are 1.13 and 1.18, thus showing good agreement between theory and experiment.

I. INTRODUCTION

IN THE preceding paper in this issue of the Physical Review Jauncey¹ has shown that the scattering of x-rays by a solid consisting of atoms all of the same kind is given by

$$S = 1 + (Z - 1)f'^2/Z^2 + (F^2/ZN) \sum_{r=1}^N \sum_{s=1}^N \cos k(x_r - x_s) \quad (1)$$

where the various quantities are defined in Jauncey's paper. As explained in Section 5 of that paper, the right side of Eq. (1) depends on the two simplifying assumptions: (1) the probability function for the displacement of the center of the atom from its mean position is symmetrical about the mean position, and (2) the temperature factor H is the same for all atoms. These two assumptions are probably not quite valid for an amorphous solid, but are valid for a simple cubic crystal of atoms of one kind. We shall therefore take Eq. (1) to be exactly true for this kind of crystal. The quantity x_r in Eq. (1) is the distance of the mean center, about which the r th atom is oscillating due to its thermal motion, from the reference plane defined in the previous paper.¹ In a simple cubic crystal x_r is the distance of a lattice point from the reference plane.

¹ G. E. M. Jauncey, Phys. Rev. this issue p. 1193.

II. EVALUATION OF THE DOUBLE SUMMATION

In order to avoid confusion, we shall replace x_r and x_s by w_r and w_s . It is our object to evaluate

$$\sum_{r=1}^N \sum_{s=1}^N \cos k(w_r - w_s).$$

Let us take a crystal parallelepiped whose sides contain $P+1$, $Q+1$, and $R+1$ atoms so that $N = (P+1)(Q+1)(R+1)$ or PQR since P , Q , and R are large numbers. Let the size of the parallelepiped be such that the absorption of x-rays in the crystal is negligible so that every atom in the crystal is bathed in x-rays of the same intensity. On the other hand, we suppose that the length of each side of the parallelepiped is many times the wave-length of x-rays. A crystal with the length of each side about 0.1 mm is what we have in mind. Let the crystal axes be parallel to the axes of rectangular cartesian coordinates with the origin at a corner of the crystal. A lattice point of the crystal will then have the coordinates

$$x = pD, \quad y = qD, \quad z = rD \quad (2)$$

where p , q , and r are integers and D is the lattice constant. Let the reference plane¹ pass through the origin of coordinates and let the direction cosines of the normal to this plane be l , m , n . The distance of a lattice point from this plane is then

$$w_{pqr} = lpD + mqD + nrD \quad (3)$$

If we imagine Z electrons massed at each lattice point of an ideal crystal, we shall have as in Eq. (6) of the previous paper¹

$$I = \left\{ Z \sum_{p=0}^P \sum_{q=0}^Q \sum_{r=0}^R \cos kw_{pqr} \right\}^2 + \left\{ Z \sum_{p=0}^P \sum_{q=0}^Q \sum_{r=0}^R \sin kw_{pqr} \right\}^2 \quad (4)$$

In the triple summations in Eq. (4) p , q , and r may be equal. Let us first sum with respect to r , so that we obtain

$$\sum_{r=0}^R \cos kw_{pqr} = \sum_{r=0}^R \cos k(A_{pq} + rnD) \quad (5)$$

where

$$A_{pq} = plD + qmD \quad (6)$$

and is a constant during this summation. Now it can be shown that²

$$\sum_{r=0}^R \cos k(A_{pq} + rnD) = \cos k \left(A_{pq} + \frac{R-1}{2} nD \right) \sin \frac{kRnD}{2} \csc \frac{knD}{2} \quad (7)$$

² See, e.g. Hobson—Plane Trigonometry, 4th Edition, p. 90.

and that

$$\sum_{r=0}^R \sin k(A_{pq} + rnD) = \sin k\left(A_{pq} + \frac{R-1}{2}nD\right) \sin \frac{kRnD}{2} \csc \frac{knD}{2} \quad (8)$$

Summation with respect to q and then p thus yields

$$\begin{aligned} \sum_{p=0}^P \sum_{q=0}^Q \sum_{r=0}^R \cos kw_{pqr} \\ = \cos kD\left(\frac{P-1}{2}l + \frac{Q-1}{2}m + \frac{R-1}{2}n\right) \sin \frac{kPlD}{2} \sin \frac{kQmD}{2} \\ \sin \frac{kRnD}{2} \csc \frac{kD}{2} \csc \frac{kmD}{2} \csc \frac{knD}{2} \quad (9) \end{aligned}$$

and

$$\begin{aligned} \sum_{p=0}^P \sum_{q=0}^Q \sum_{r=0}^R \sin kw_{pqr} \\ = \sin kD\left(\frac{P-1}{2}l + \frac{Q-1}{2}m + \frac{R-1}{2}n\right) \sin \frac{kPlD}{2} \sin \frac{kQmD}{2} \\ \sin \frac{kRnD}{2} \csc \frac{kD}{2} \csc \frac{kmD}{2} \csc \frac{knD}{2} \quad (10) \end{aligned}$$

so that Eq. (4) becomes

$$I = Z^3 \cdot \sin^2 \frac{kPlD}{2} \sin^2 \frac{kQmD}{2} \sin^2 \frac{kRnD}{2} \csc^2 \frac{kD}{2} \csc^2 \frac{kmD}{2} \csc^2 \frac{knD}{2} \quad (11)$$

The angle of scattering enters the problem through the relation¹

$$k = (4\pi \sin \phi/2)/\lambda. \quad (12)$$

If we have chosen values of ϕ , the scattering angle, and l, m, n the direction cosines of the normal to the reference plane, in such a way that

$$kD \neq 2\pi a, \text{ or } kmD \neq 2\pi b, \text{ or } knD \neq 2\pi c \quad (13)$$

where a, b, c are any integers, the value of the trigonometric function on the right side of Eq. (11) is of the order unity. Now, dividing the right side of Eq. (11) by the total number of electrons, $PQRZ$, we find the scattered intensity per electron to be

$$S = \frac{ZO(1)}{PQR} \quad (14)$$

where $O(1)$ is a quantity whose magnitude is of the order unity. For a crystal of KCl, $Z=20$ and, if we are dealing with a crystal in the form of a cube the length of whose edge is 0.1 mm, the value of PQR is about 10^{17} , so that the

right side of Eq. (14) is of the order 10^{-16} which may be taken as zero. Therefore there is no diffuse scattering from an ideal simple cubic crystal whose atom centers are held exactly at lattice points with the electrons massed at the center of each atom.

If Eq. (1) is applied to this ideal crystal, the same result must be obtained as in the previous paragraph. In this case $f' = F = Z$, so that we have

$$0 = 1 + (Z - 1) + (Z/N) \sum_{r=1}^N \sum_{s=1}^N \cos k(w_r - w_s) \quad (15)$$

Solving Eq. (15) for the double summation we obtain

$$\sum_{r=1}^N \sum_{s=1}^N \cos k(w_r - w_s) = -N. \quad (16)$$

Substituting this in (1), we obtain

$$S = 1 + (Z - 1)f'^2/Z^2 - F^2/Z \quad (17)$$

for the scattering per electron from a crystal of simple cubic form whose atoms are all of the same kind and each of which contains Z electrons. In Eq. (17), it will be seen by reference to the preceding paper¹ that F is the atomic structure factor which includes the effect due to thermal agitation, while f' is related to the true atomic structure factor f , which does not include the effect of thermal agitation, according to

$$f'^2 = f^2 + \left[f^2 - Z \sum_{r=1}^Z E_r^2 \right] / (Z - 1) \quad (18)$$

where E_r is the average amplitude associated with the r th electron in the atom. If the average amplitude associated with one electron is the same as that associated with any other electron $f' = f$ and f' is then the true atomic structure factor.

III. COMPARISON WITH EXPERIMENT

Unfortunately, results on the diffuse scattering by a crystal consisting of atoms all of the same kind are not available. However, in 1924 Jauncey and May³ measured the absolute intensity of x-rays diffusely scattered by a crystal of rocksalt. They obtained the curve shown in Fig. 1. The curve XYZ represents the Thomson value of the scattering. Referring to their paper, it is seen that they used x-rays containing two wave-lengths, 0.71Å and 0.40Å. The peaks A and B are due to the wave-lengths 0.40Å and 0.71Å respectively. The point C was obtained when sufficient aluminum was inserted in the primary beam to remove the longer wave-length constituent of the x-rays. We have therefore drawn the broken curve $DAFG$ of Fig. 1, and this is then due to the scattering of x-rays of wave-length 0.40Å. It seems preferable to use the curve for this wave-length, since it is known from the diagram at which

³ G. E. M. Jauncey and H. L. May, Phys. Rev. **23**, 128 (1924).

value of ϕ the scattering approaches zero. Using this curve and dividing each ordinate by the Thomson value of the scattering at the same angle we obtain the S curve shown in Fig. 2 in which the abscissa is $(\sin \phi/2)/\lambda$. This S curve is for x-rays scattered by rocksalt at 290°K.

In 1928 James and Firth⁴ obtained F values from the regular reflection of x-rays by rocksalt at various temperatures. Their F values are for Na+Cl. In order to compare the present theory with experimental values, we shall

Fig. 1.

assume rocksalt to be made up of atoms of the same kind whose atomic number is $(11+17)/2 = 14$. We therefore take as F values to be substituted in Eq. (17) one half the values given for Na+Cl in the paper by James and Firth. These average F values are shown in the second column of Table I. Values of S found from Fig. 2 are shown in the third column of this table. From Eq. (17), values of f' can thus be determined and these are shown in the fourth column. James and Firth give F values extrapolated to absolute zero and the averages of these for Na and Cl are shown in the fifth column. The values in

⁴ R. W. James and E. M. Firth, Proc. Roy. Soc. A117, 62 (1928).

the fourth and fifth columns should be nearly but not quite equal. The true atomic structure factor f is somewhat greater than the value of F at absolute zero, if there is zero point energy.

Fig. 2.

TABLE I.

$(\sin \phi/2)/\lambda$	$F_{290^\circ K}$	$S_{290^\circ K}$	f'	$F_0^\circ K$
0.1	12.3		12.8*	12.8
0.2	9.4	1.24	10.1	9.9
0.3	6.9	1.82	8.0	7.6
0.4	5.2	1.93	6.6	6.1
0.5	3.9	1.94	5.4	4.8
0.6	2.8	1.88	4.6	4.0
0.7	2.1	1.77	3.8	3.3
0.8	1.6	1.56	3.2	2.8
0.9	1.2	1.38	2.6	2.4
1.0	0.8	1.26	2.1	2.0
1.1	0.5	1.17	1.7	1.6
1.2	0.3	1.10	1.6	1.4

* By extrapolation.

As zero angle of scattering is approached, f' and F each approach Z and S approaches zero. This agrees with the experimental curves shown in Figs. 1 and 2.

In 1922, Jauncey⁵ found a temperature effect for the diffuse scattering by rocksalt. The temperatures used by Jauncey were 290°K and 568°K. From

the values given by James and Firth,⁴ F values at 568°K can be interpolated. The wave-lengths used by Jauncey were 0.28Å and 0.36Å at 15° and 30° scattering angle respectively. The ratios of the values of S found are shown in the fifth column of Table II. F values obtained from James and Firth are shown in the second and third columns. Values of f' obtained from Fig. 2 and Eq. (17) are shown in the fourth column. Now putting the values of $F_{290^\circ K}$ and $F_{568^\circ K}$ in Eq. (17) and using the appropriate f' values, we obtain theoretical values for $S_{290^\circ K}$ and $S_{568^\circ K}$. The ratios of these values are shown in the sixth column.

TABLE II.

$(\sin \phi/2)/\lambda$	$F_{290^\circ K}$	$F_{568^\circ K}$	f'	$S_{568^\circ K}/S_{290^\circ K}$	
				Exp.	Theory
0.467	4.25	3.20	5.8	1.33	1.29
0.720	1.95	0.90	3.7	1.18	1.13

It is seen that there is good agreement between the experimental and theoretical values of the ratios.

For a monatomic gas Compton⁶ has shown that

$$S = 1 + (Z - 1)f'^2/Z^2 \quad (19)$$

so that from the experimental values of S values of f' can be obtained. If x-rays are scattered by a simple cubic crystal of the same chemical element as the gas, values of f' can be obtained from the experimental values of S and F for the crystal. The values of f' for the gas should nearly agree with those for the crystal, the slight difference being due to the structure of an atom in a crystal being affected by the proximity of other atoms.

ABSOLUTE WAVE-LENGTHS OF THE COPPER AND CHROMIUM K-SERIES

By J. A. BEARDEN

DEPARTMENT OF PHYSICS, THE JOHNS HOPKINS UNIVERSITY

(Received April 6, 1931)

ABSTRACT

In the measurement of x-ray wave-lengths by ruled gratings two principal difficulties have been discussed which may account for the difference observed between the wave-lengths determined by this method and those determined by using crystal gratings. They are, the periodic error in the grating, and the geometrical divergence of the x-ray beam. It is now shown that the effect of the periodic error can be determined by a study of the intensities of the optical ghost lines. For a good quality optical grating it has been found that the error in x-ray wave-lengths due to the periodic error in the grating is thus of no importance. By using a suitable disposition of apparatus the effect of the geometrical divergence of the x-ray beam can be made as small as desired. Thus it is concluded that ruled gratings can be used for precise wave-length measurements of x-ray spectra.

In the present experiment the two parallel plate method has been used for determining the angles of incidence and diffraction. Five glass gratings of different grating spaces and ruled on two ruling engines have been used. The results from the various gratings on the same wave-length have agreed satisfactorily. No consistent variations of any type were observed. The final results from 172 sets of plates are given in the following tables.

Spectral line	Crystal λ	Grating λ	Limiting error	Grating λ - Crystal λ
Cu $K\beta$	1.38914A	1.39225A	$\pm 0.00014A$	$+0.224\%$
Cu $K\alpha$	1.53838	1.54172	± 0.00015	$+0.217\%$
Cr $K\beta$	2.08017	2.08478	± 0.00021	$+0.222\%$
Cr $K\alpha$	2.28590	2.29097	± 0.00023	$+0.222\%$

From these results the true grating space of a calcite crystal is $d = 3.0359 \pm 0.0003A$. Using this value of the grating constant, Planck's constant as determined by Duane, Palmer and Yeh is, $h = 6.573 \pm 0.007 \times 10^{-27}$ erg · sec. e/m can be determined from the dispersion of x-rays by using the absolute wave-length of an x-ray spectrum line. The mean of the values of the dispersion as given by Stauss and Larsson gives $e/m = 1.769 \times 10^7$ e.m.u.g⁻¹. The values of these constants are independent of any imperfection in the crystal. If the crystal lattice is assumed to be perfect we then have Avogadro's number, $N = 6.019 \times 10^{23}$ mol. per mole, and the charge on the electron $e = 4.806 \times 10^{-10}$ e.s.u. Using this value of e , and d as above, we find Planck's constant $h = 6.623 \times 10^{-27}$ erg · sec.

MEASUREMENTS of the wave-length of x-ray lines using ruled gratings have been made by a number of investigators.¹⁻⁷ The results obtained

¹ A. H. Compton and R. L. Doan, Proc. Acad. Sci. 11, 598 (1925).

³ F. L. Hunt, Phys. Rev. 30, 227 (1927).

by this method have been in general higher than the corresponding wave-lengths measured by means of a crystal grating. Unfortunately the differences observed between the grating values and the crystal values by different experimenters have not been the same. In the best of the experiments, differences exist which appear to be greater than the probable errors in the experiments. It has been pointed out by the writer⁸ that these differences are most likely due to the quality of the gratings used and consistent errors of observation. The present experiment was undertaken in an effort to eliminate as far as possible the uncertainty which exists concerning the absolute wave-length of x-rays.

THEORY OF RULED GRATINGS FOR X-RAY MEASUREMENT

Since ruled gratings must be used at tangential incidence for x-rays, the usual grating formula $n\lambda = d(\sin i - \sin r)$ may be written in terms of the small angles θ and α of Fig. 1 as

$$n\lambda = 2d \left(\sin \frac{2\theta + \alpha}{2} \sin \frac{\alpha}{2} \right) \quad (1)$$

where θ is the angle between the surface of the grating and the direct beam, and α the angle between the reflected beam and the diffracted beam.

The angles θ and α for x-rays are very small so that the problem of accurately measuring x-ray wave-lengths is principally a problem of measuring very small angles with a high degree of precision. Assuming that these angles can be precisely measured, it will be of interest to investigate the possible error in the wave-length due to other causes.

The geometrical divergence of the x-ray beam perpendicular to the plane of the grating will shift the position of the spectrum line as was first pointed out by Porter.⁹ Porter's result was for the special case where the distance from the source to the center of the grating, and the distance from center of the grating to the position of the image were equal. Stauss¹⁰ has considered in a similar manner the more general case where the distances are not equal. The complete diffraction equation then becomes:

$$n\lambda = d(\cos \phi_1 - \cos \phi_2) \left[1 + \frac{3x^2}{20(\phi_2^2 - \phi_1^2)} \left(\frac{\phi_2^2}{l_2^2} - \frac{\phi_1^2}{l_1^2} \right) \right] \quad (2)$$

where $\phi_1 = \theta$, $\phi_2 = (\alpha + \theta)$, x is the length of grating used, l_1 the distance from the source to the grating, and l_2 the distance from the grating to the image. It will be seen that the correction term will be either + or - depending on the

¹⁰ H. E. Stauss, Phys. Rev. **34**, 1601 (1929).

values of l_1 and l_2 . It will also be noticed that the position of the 0 order will be displaced if $l_1 \neq l_2$ thus

$$\phi_2 = \phi_1 \left[1 + \frac{3x^2}{20} \left(\frac{1}{l_1^2} - \frac{1}{l_2^2} \right) \right]. \quad (3)$$

The magnitude of this correction depends on the method used in measuring ϕ_1 and ϕ_2 .

The geometrical center of the slits is not the center of the reflecting surface of the grating. If β represents the angle between the central slit ray and a line from the source to the effective center of the grating, it has been shown¹¹ that

$$\beta = \frac{s^2}{4\phi_1 l_1^2} \quad (4)$$

where s is the slit width and ϕ_1 and l_1 are the same as in Eq. (2).

The divergence of the x-ray beam in the plane of the grating leads to a correction in the wave-length of the form

$$n\delta\lambda = \frac{d}{2} \left(\frac{\phi_1^2 l_1}{2l_1^2} - \frac{\phi_2^2 l_2^2}{2l_2^2} \right) \quad (5)$$

where $2(h_1 + h_2)$ is the length of spectrum line, and $2h_1$ the effective height of grating.

Prins¹¹ has criticized the writer's published results⁶ believing that a correction of the type shown in Eq. (2) would account for the difference in wave-length observed between the grating and crystal methods. Correspondence with Prins has shown that he had misinterpreted the writer's disposition of apparatus. This correction, as will be shown later, is of negligible importance.

There are three types of errors which are usually present in the ruling of a grating, either of which would lead to erroneous absolute wave-lengths. These errors, the erratic, the error of run, and the periodic error have been discussed by Michelson and Rowland in connection with the absolute wave-lengths of optical spectra. The erratic error is not susceptible to analytical correction but its importance can best be determined by using gratings ruled on different ruling engines and comparing the results.

The error of run can be determined in a number of ways. Probably one of the most precise methods of determining this error is the focusing property exhibited by such gratings. Assuming parallel incident light, Fagerberg¹² has derived an equation of the form

$$\frac{d_1}{d_2} = 1 + \frac{x \cos^2 \psi_2}{r(\sin \psi_1 - \sin \psi_2)} \quad (6)$$

where d_1 and d_2 are the grating spaces at the extremes of the grating, ψ_1 is the angle of incidence, ψ_2 the angle of diffraction, x the length of the grating, and r

¹¹ J. A. Prins, *Nature* **124**, 370 (1929).

¹² Sven Fagerberg, *Zeits. f. Physik* **62**, 457 (1930).

the distance from the grating to the focus. With this method it is possible to detect an error in the grating space of 10^{-8} cm. Another method which has been used by the writer in connection with the above is to rule every 4th or 7th line on the grating longer than the other lines. The distance between these lines can then be measured directly by a comparator. Also the average grating space can be accurately measured by determining the number of spaces on a grating and the distance between the extreme lines.

The periodic error of the grating will produce an asymmetrical spectrum line which always makes the angle of diffraction appear larger than it should be. This effect is of no importance in ordinary optical gratings for the error is inversely proportional to the length of the grating used. In the x-ray application, however, the length of the grating used is only a few mm so the error may be important. Fagerberg has calculated the error for x-rays and obtained

$$\delta\lambda = \frac{2m}{x} \lambda \quad (7)$$

where m is the maximum displacement of any line on the grating from an ideal grating with the average grating space m_0 , x is the length of the grating used, and λ the wave-length. He assumed m to be from 0.0005 to 0.001 mm, $x = 1$ mm and found $\delta\lambda = 0.001$ to 0.002λ which is the order of magnitude of the observed difference between grating measurements and crystal measurements. It should be pointed out, however, that the values of m assumed were, for good quality gratings, too high. m can be determined from the intensity of the Rowland ghost lines in a grating. The relation between the intensity of the ghost lines and the intensity of the main line may be written approximately

$$\frac{I}{I_0} = \left(\pi N \frac{m}{m_0} \right)^2 \quad (8)$$

where I is the intensity of the first order ghost, I_0 the intensity of the main line, N the spectral order, m the maximum displacement of a line from the ideal grating, m_0 the average grating space.

It is true that for gratings of large grating space (e.g. 50 lines/mm) one might be able to have $m = 0.001$ mm and the intensity of the ghost lines be very weak in the low orders. However if one examines the very high spectral orders the ghost lines would be very intense. One can usually observe 30 or more orders with a grating of 50 lines per mm. If we observe the 30th order of such a grating and have $m = 0.001$, the intensity of the ghost lines would be more than 20 times the intensity of the main line. In any case one can determine the importance of this error by carefully examining the intensity of the ghost lines of the grating. If one wished to get an accurate estimate of m for a coarse ruled grating, I believe it would be permissible to rule a small spaced grating (e.g. 600 lines/mm) and determine m from such a grating; thence rule the coarse grating using the same part of the ruling engine screw. There seems little reason to believe that the ruling engine would misplace the lines on a coarse grating any more than on a finely spaced grating.

Compton¹³ has considered the question of the refraction of the x-rays at the surface of the grating, and concludes that refraction could not cause any displacement of the spectral lines. It has been shown by Siegbahn,¹⁴ and has also been observed by the writer, that the type of surface influences greatly the intensity of the x-ray spectra. It is difficult to believe, however, that this could in any way displace the spectral lines. The writer has also been able to improve the intensity of the x-ray spectra many times on a lightly ruled grating by etching it. In order to test the effect of etching on the position of the spectral lines, one half of a grating was etched and the other half left unetched. The grating was mounted in such a manner that either etched or unetched part could be used. The results were the same within experimental error from both parts.

Thus, it seems from the above considerations that the measurement of x-ray wave-lengths by the use of ruled gratings can be made reliable. By a suitable disposition of the apparatus the error in the wave-length should be just the error of measuring the grating constant d and the two angles θ and α .

Fig. 1. Diagram of apparatus.

METHOD OF EXPERIMENT

In the present experiment the K -series of copper and chromium were chosen as a source of K-rays. The intensities of these lines can be made very great and they are the longest wave-lengths that can be worked with successfully without using a vacuum spectrograph. These wave-lengths can also be used to determine directly the grating space of such crystals as calcite and rock salt. Even though the angles of diffraction and reflection for these lines are small, it is believed that greater precision can be secured by using these wave-lengths than could be obtained by use of longer wave-lengths with a vacuum spectrograph.

There are several methods by which the angles θ and α could be measured. However, from a consideration of the error involved in each method it appears that the modification of the Uhler and Cooksey¹⁵ parallel plate method,

¹³ A. H. Compton, Jour. of the Franklin Inst. Oct. (1929).

¹⁵ H. S. Uhler and C. D. Cooksey, Phys. Rev. **10**, 645 (1917).

used by the writer,⁶ is preferable. Fig. 1 shows the arrangement of the apparatus. This method avoids error due to any variation in the width of the slits, or non-uniformity of illumination over the slit. It will also be seen that it is not necessary that the grating be accurately on the axis of rotation as is essential in other methods. The measurements are all linear measurements and no angular motion of the grating is needed for a determination of the angles.

In order to determine the errors to be expected from this arrangement Eq. (1) may be written in terms of the measured quantities as

$$n\lambda = \frac{d}{2b^2} \left[\frac{(Y-Z)^2}{y^2} \right] (y \pm z)z \quad (9)$$

where b , x , y , and z , are as indicated in Fig. 1. In Eq. (9) the angles were used instead of the sine of the angle, and the angle was put equal to the tangent of the angle. This equation is in error by approximately 1 part in 3000 for the angles involved. It can be shown that for a given distance from the grating to the second plate that the minimum error in wave-length for a given error in measuring x occurs when b is made a maximum. This neglects the geometrical divergence of the x-ray beam and from Eq. (3) it will be seen that this must also be considered in choosing b . The distances y and z must be made large enough to be conveniently measured. A good comparator cannot be depended upon to better than about 0.001 mm. Thus, in order to obtain the desired precision y and z must be greater than 10 mm. This makes the distance from the grating to the second plate about 2 meters. An error in measuring the distance x produces an error in the wave-length of about 3 times as much as the same error in y or z . Fortunately the lines determining x are very narrow and are never more than 1 mm apart so x can be measured to a much higher precision than y or z . By assuming an error of 0.001 mm in x , y or z one is lead to expect an error in λ of approximately 1 part in 10,000.

In the present experiment the distance l_1 from the first slit to the grating was 45 cm, from the grating to the second plate 191 cm, and from the grating to the first plate 7 cm. A typical plate gives $\phi_1 = 3 \times 10^{-3}$, $\phi_2 = 7 \times 10^{-3}$ for the first order, and $\phi_2 = 16 \times 10^{-3}$ for the sixth order. Thus Eq. (2) becomes

$$n\lambda = d(\cos \phi_1 - \cos \phi_2)(1 - 1.93 \times 10^{-6}) \quad \text{1st order}$$

$$n\lambda = d(\cos \phi_1 - \cos \phi_2)(1 + 0.054 \times 10^{-6}) \quad \text{6th order}$$

Eq. (3) becomes

$$\phi_2 = \phi_1(1.0000087)$$

for the 2nd plate, and

$$\phi_2 = \phi_1(0.99964)$$

for the first plate.

On the first plate this corresponds to 0.0002 mm. From Eq. (4) $\beta = +4.15 \times 10^{-3}$ or 0.00008 mm on the 2nd plate, and Eq. (5) gives for the 6th order

$\delta\lambda = -1.64 \times 10^{-13}$ cm. Thus there are no corrections of any importance. In any case some are + and some are -, so the total correction is probably much less than any individual correction.

APPARATUS

The apparatus was mounted on a reinforced concrete block $6.5'' \times 30'' \times 96''$. The top of the block was a smooth stone. Iron blocks $1'' \times 4'' \times 4''$ were inserted about $3''$ from the top and at various positions in the block when it was cast. Threaded holes in the center of the iron blocks permitted iron rods to be rigidly attached to the base. The apparatus was held in position by these rods. This base was supported by 3 concrete blocks under each end. Between the blocks, rubber, felt and wood strips were inserted to damp out the vibrations from the building.

The plate holders were made from a solid brass plate $1/2'' \times 4'' \times 6''$. The surface against which the photographic plates rested was scraped to a plane surface. The photographic plates were held against this surface by a plane brass plate against which pressed two strong springs. A piece of blotting paper was inserted between this brass plate and the back of the photographic plate to equalize the pressure on the photographic plate. The plate holders were attached to a $2''$ square iron rod which was held rigidly to the base by two $1.25''$ iron rods. The photographic plates were inserted and removed without disturbing the adjustment of the plate holders.

The grating was mounted on a three point support which was attached to a slide capable of being moved through several mm. The position of the slide was determined by a scale and dial, reading to 0.001 mm. This slide rested on a table which rotated on accurately made centers. The table could only be rotated through 200° , but this was sufficient for making adjustments. It was found that such a table was far more satisfactory in rotating about an axis than the ordinary spectrometer.

The slits were made of steel with gold faces 1 mm thick. One jaw was clamped rigidly and the other jaw held against it by small springs. Thin spacers were used to obtain the desired slit widths. The two slits were attached to a brass tube which was capable of being rotated by a long arm and a tangent screw. Thus after the slits had once been made accurately parallel they could be clamped in position, and any further adjustment of tilt could easily be made by the tangent screw.

The x-ray tube was a water-cooled Coolidge type, with a side arm and a thin window of aluminum (0.01 mm thick) to reduce the absorption of the copper and chromium x-rays. The focal spot was usually about 1 to 2 mm in diameter and the tube was operated about 10 m.a. and 40 K.V. The x-rays were taken off at about 10° from the face of the target. The chromium targets were prepared by electroplating a layer of chromium on the regular copper targets. The x-ray tube was mounted on a slide in order that the source of greatest x-ray intensity could be placed in line with the slits. The tube could also be raised and lowered to bring the focal spot in line with the center of the slits, grating and plates. Evacuated tubes with thin celluloid windows were

placed between the slits and between the plate holders to reduce the absorption of the x-rays.

The experiment was carried out in a small room in which the temperature could be accurately controlled. A recording mechanism kept a continuous record of the temperature and the temperature never varied by more than 0.1°C . During a single exposure the temperature usually remained constant to within 0.02°C .

ALIGNMENT AND CALIBRATION OF APPARATUS

The alignment of the plate holders, center of grating, and center of slits in a horizontal line was accomplished by adjusting each to a given height above the top of the stone base. The height of the focal spot of the x-ray tube was adjusted by placing a horizontal slit on this line midway between the tube and second plate, thence adjusting the height of the tube until the image of the focal spot fell on the center of the second plate P_2 . This adjustment was made to within 0.5 mm.

The adjustment of the grating surface parallel to, and on the axis of rotation was very conveniently and accurately made by using the modified Michelson interferometer shown in Fig. 1. The grating which was ruled on a plane parallel plate was spluttered with gold or silver to obtain a good optical reflection. The grating was mounted with the reflecting surface against a rigid three point support on the slide of the rotating table.

If one places plane parallel plates in positions G' and G'' (Fig. 1) of the same thickness as the plate on which the grating G is ruled, it will be seen that the optical path is the same whether the rotating table is in the position shown, or after it has been rotated through 180° . The grating slide and the slide which supported the second interferometer mirror were adjusted until the central white light fringe remained in the same position when the rotating table was turned through 180° . Thus the grating surface was accurately set on the axis of rotation to within 0.1 of a fringe. The grating surface was made parallel to the axis of rotation by observing the number of fringes in the field of the two 180° positions. Care was taken to make sure that the same number of fringes represented zero angle between the grating surface and the axis, and not an angle of twice as many fringes. This angle was made 0° to within 1 fringe/20 mm which is about $2''$ of arc. It will be noticed that after the adjustments are once made the grating can be taken out and replaced very easily by the use of the interferometer. It was not necessary that the grating surface be spluttered, as the fringes were always visible even with the cleanest glass surface. The interferometer was also used to check the position of the grating during an exposure.

The axis of rotation was then made approximately perpendicular to the horizontal line, which passed through the center of the slits and the center of the plate holders. This was accomplished by allowing a beam of light to pass through a slit in the center of the second plate holder P_2 and thence reflected by the grating surface back on to the slit.

The slits were then moved horizontally until the x-ray beam passed over

the axis of rotation. In order to do this, the slit S_2 nearest the grating (about 30 mm away) was made very narrow (approximately 0.003 mm). The grating was adjusted parallel to the x-ray beam by x-ray reflection, and the slits moved until the narrow beam was partially cut off.

The grating was then rotated through 90° . The grating surface was then perpendicular to the direction of the x-ray beam. A telescope fitted with a Gauss eye piece was placed about 5 meters away and adjusted until the image of the cross-hairs was reflected back by the grating on to the cross hairs. A plane parallel mirror was inserted in place of the photographic plate, and the plate holder P_1 adjusted until the image of the cross hairs was returned as above. The mirror was then placed in the second plate holder P_2 which was likewise adjusted. Thus the two plate holders were made parallel and also perpendicular to the x-ray beam to within $5''$ of arc.

The grating was rotated to a position parallel to the x-ray beam and moved completely out of the path of the x-rays. The slit S_2 was made 0.01 mm wide and the slit S_1 near the x-ray tube was made 0.015 mm. A photographic plate was then placed on a slide between the grating and the first plate holder P_1 . A short exposure of about 10 seconds was sufficient to record a sharp line on the plate. The plate was then moved about 1 mm and the grating was moved 0.001 mm into the x-ray beam. Another exposure of 10 seconds was made. This was repeated until the grating cut off the entire x-ray beam. If the slit S_2 was not parallel to the grating, the lines on the developed plate were not cut off uniformly by the grating at the top and bottom. In this way the slit S_2 could be made parallel to the grating to within $10''$ of arc. The parallelism of the slit S_1 was tested in the following manner. A photographic plate was placed in the plate holder P_1 . The direct x-ray beam was recorded. The grating was rotated through an angle of about $5'$ of arc and then put in position to reflect the x-ray beam. The reflected beam was thus recorded. If the slits were parallel to each other and parallel to the axis of rotation of the grating, the two lines on the developed plate would be parallel. Thus by accurately measuring the separation of the lines at the top and bottom of the plate, the perfection of the adjustment was determined. If the lines were not parallel, S_1 was readjusted, and the above process repeated. In this way the slits were made parallel to each other and parallel to the axis of rotation of the grating within $10''$ of arc.

The lines on the grating were aligned parallel to the axis of rotation of the grating in the following manner. A vertical slit about 50 cm from the grating was illuminated by a mercury arc. A double cross hair in the viewing telescope was rotated until the spectral lines formed by the grating were parallel to the cross hairs. The grating was rotated 180° and the spectral lines observed again. When the lines of the grating were parallel to the axis of rotation, the spectral lines formed in this position were parallel to the cross hairs. Since the grating space varies as the cosine of the angle of tilt this adjustment was only made to within 0.5° .

The distance between the plate holders was measured by placing an iron rod $3/4''$ square between the two plate holders, and then measuring with

inside micrometers the distance between the parallel ends of the iron rod and the plate holders. The length of the rod was determined by comparison with the laboratory standard, which had been calibrated by the Bureau of Standards, Washington, D. C. Independent measurements by different observers agreed to within 0.02 mm, so that the error in the final value was probably less than this. The comparator on which the separations of the lines on the plates were measured was carefully adjusted and calibrated. Six gratings have been used in the present work. Four of these gratings (1-4) were ruled by Professor Wood in this laboratory, and the other two were ruled by Mr. Pearson under the direction of Professor Michelson of the University of Chicago.* All the gratings were ruled on glass. Larger angles could have been used by using a heavier material for the ruled surface, but glass gratings give sharper and more intense spectra than the metallic surfaces. Also, the glass gratings can be spluttered with gold and used at large angles. In this case the intensity of the spectra is greatly increased as compared to the unspluttered glass surface and the sharpness of the spectral lines remains unchanged. The characteristics of the gratings are as follows.

Number 1 was ruled with 287 lines per mm on a plane optical glass surface with a very light ruling. The ruling was uniform and no lines were missing. The surface ruled was approximately 25 mm square. In order to examine the grating with optical light the top and bottom of the grating was etched, and then spluttered with gold. The intensity of the Rowland ghost lines in the 11th order was about $1/3$ the intensity of the main line, thus m [from Eq. (8)] would be 0.00006 mm, and for $x=4$ mm, Eq. (7) gives $\delta\lambda = 0.00003\lambda$. It was found that the intensities of the first and second orders of the x-ray spectra, from the etched portion of the grating, were increased 5 or 10 times as compared to the unetched part. The higher orders were not improved. Spluttering the grating with gold improved the intensity of the unetched portion but did not improve the etched part. The error of run was estimated by the focusing effect in various orders and was less than $10^{-5}d$.

Number 2 was ruled with 143 lines per mm on a plane parallel plate made from good quality plate glass. The ruling was heavier than on number 1 and it was not necessary to etch part of the grating for observation of the optical spectra. The ghost lines were weaker in this grating in the 22nd order than in the 11th order of number 1. Etching did not improve the intensity of the x-ray spectra even though the intensity of the optical spectra was increased several times. Spluttering with gold increased the x-ray spectra from the whole grating by a factor of three or four. The error of run was estimated as above and found to be of no importance. This grating had some missing lines near the middle of the ruling, so it was only used for testing the effect of etching and no results are listed from it.

* The results from these two gratings were obtained at the University of Chicago. The apparatus was essentially the same as described above. Through the courtesy of Professor Michelson the experiment was carried out in one of the constant temperature ruling engine vaults. The writer also wishes to express his appreciation to the members of the Physics Department for placing at his disposal the facilities for carrying out this part of the experiment.

Number 3 was ruled with 287 lines/mm on a plane parallel plate similar to number 2. This grating was not etched and was very similar to number 1. On this grating every 7th line was made longer than the others so that direct measurement of the distance between these 7th lines could be made. Also the number of lines on the whole grating could be easily determined, and by measuring accurately the distance between the extreme lines the grating space d was obtained. The error of run was less than $10^{-5}d$, and the intensity of the ghost lines was about the same as in grating 1.

Number 4 was a duplication of number 2 except the 4th lines were ruled longer as in number 3. This grating was not etched and possessed characteristics very similar to number 2 and 3.

Number 5 was a glass grating ruled with 50 lines per mm on the ruling engines at the University of Chicago. This grating seemed to be very free of ghost lines, as no ghost lines could be observed even in the very high orders. The first $1/4$ of the ruled surface, however, possessed a very bad error of run, probably due to not allowing the ruling engine to run a sufficient length of time before the ruling was started. The grating space of this grating was obtained by carefully determining the pitch of the ruling engine screw. This grating was not carefully examined by the writer until after the x-ray spectra had been taken. The erratic results obtained were completely explained by this error of run in the grating. By eliminating all exposures, which were taken on the bad part of the grating the results were consistent with the results from the other gratings.

Number 6 was a grating with 600 lines per mm, ruled on the same engine as number 5. One part of this grating, which was lightly ruled and gave faint optical spectra, gave x-ray spectra about twice as intense as the more heavily ruled portion. The resulting wave-lengths were the same, within experimental error, from both parts of the grating.

Two types of photographic plates were used. The results with gratings 5 and 6 were obtained with selected plate glass plates coated with Eastman x-ray emulsion. These plates were developed, washed, and dried in the ordinary manner. It has been stated¹⁰ that certain precautions used in the manufacture of commercial plates are omitted in preparing special plates. Thus the plates used in the experiments with gratings 1-4 were the regular commercial x-ray plates. About one half of the plates were "treated" as described by D. Cooksey and C. D. Cooksey,¹⁶ and the remaining plates were not previously treated, but were dried in alcohol and allowed to attain equilibrium in a humid atmosphere. No difference in the consistency of the results was noted between the last two methods. A considerable difference was noted however between these latter methods and the regular developing methods used with the special plates. A test was also made using a standard which was made by silvering a piece of glass the size of the plates used, then making four diamond scratches at equal intervals on the silvered surface. This surface was put in contact with the emulsion and a flash of light from above the plate recorded four very

¹⁶ D. Cooksey and C. D. Cooksey, Phys. Rev. 36, 80 (1930).

fine lines on the photographic plate. The plate was then developed, and by comparing the distance between these lines with those on the standard, a test could be made for contraction or expansion of the plate due to the different methods of developing. The results obtained were essentially in agreement with those of D. Cooksey and C. D. Cooksey¹⁶ except the variations were not quite as great.

METHOD OF TAKING EXPOSURES

In exposing a series of plates, the grating was first withdrawn from the path of the x-ray beam and a short exposure given to record the direct beam on the second plate P_2 at the position 1 in Fig. 1. A plate was put in the first plate holder P_1 , and the direct beam recorded at 2. The grating was next moved into position for reflection of the x-ray beam, and after allowing 15 to 30 minutes for the slide to attain an equilibrium position, the reflected beam was registered at 3. This plate was then removed and a short exposure given to record the reflected beam at 4. The plate P_2 was then covered with a lead screen almost to the position where the first order would appear, and a long exposure (6 to 24 hours) given to record the various orders of diffraction. At the end of the long exposure another set of plates was taken to make sure that nothing had moved during the exposure. A new plate was put in P_2 , and the reflected beam recorded at 4. Likewise a plate was put in P_1 and the reflected beam recorded at 3. The grating was then removed from the path of the x-ray beam and the two positions, 2 and 1 recorded. Since the wave-length depends so much on the position of the reflected beam, another method of taking the exposures was used on about 40 sets of plates. Exposures 1, 2, 3 and 4 were taken as above. A new plate (or the same plate with ends reversed) was placed in P_2 . The position of the reflected beam was covered with a screen. After about half the long exposure had been given the screen was removed for a short time to record the reflected beam. At the end of the exposure the grating was removed from the path of the x-rays and the direct beam recorded. Thus if there was any slow change in the position of the apparatus, the reflected beam was recorded in the mean position. The results were in good agreement with the above method. At first it was difficult to get the initial and final exposures to agree as closely as desired. In the latter exposures, however, when the temperature was constant and the vibration from the building damped out, the plates checked as accurately as comparator measurements could be made, which was to about 1 part in 10,000.

The separations of the lines on the plates were measured with an accurately calibrated comparator. In making the measurements 5 or 10 settings were made on each line on the plate. The plate was then reversed and a similar set of measurements made. If a difference of more than 0.004 mm existed between the distances as measured in the two positions, the plate was remeasured. Several sets of plates were arbitrarily remeasured after several weeks, but no appreciable differences were detected. The wave-lengths were calculated from Eq. (1) using Andoyer's 15 place trigonometric tables.

RESULTS

Typical results are shown in Fig. 2. It will be seen that the two α lines are not resolved on any of the plates, but this is not to be expected, as a calculation shows that the separation would only be a few hundredths of a mm. In order to compare these lines with the crystal measurements, one must take a weighted mean of the α_1 and α_2 lines as given by the crystal measurements. If we assume a form of the lines of the type $y = e^{-x^2}$ it can be shown that the maximum intensity of the unresolved doublet should occur very near the "center of gravity" of the two lines. Siegbahn's value of the copper $K\alpha$ line

Fig. 2. I copper target, grating 50 lines per mm. II copper target, grating 287 lines per mm. III copper target, gold sputtered grating 143 lines per mm. IV chromium target, grating 143 lines per mm. V copper target, grating 600 lines per mm.

thus weighted is 1.5386Å, and for the chromium $K\alpha$ line is 2.2862Å. The measurements on the β lines do not involve this difficulty of weighing as the separation of the doublet is so small that it is of no significance in the present work. These crystal values must be corrected for the index of refraction of the x-rays in the crystal. The corrected crystal wave-lengths which are compared with the grating measurements are shown in Table IV.

The average results obtained from each grating are given in Table I. The column headed "gratings" gives the number of the grating as listed in the section on "alignment and calibration of apparatus." The prime numbers are the same as the unprimed numbers except the grating was spluttered with gold. In the experiment 172 sets of plates were taken under various condi-

tions, such as different angles of reflection θ , different slit widths and length of exposure. The measurements from 107 plates have been retained and the other discarded because the initial and final exposures failed to check or on account of other experimental difficulties.

In order to show the type of variation obtained with each grating Table II gives the copper series results for grating 4'. The lowest value recorded for any wave-length was +0.13 percent and the highest +0.31 percent greater than the corresponding crystal values. In obtaining the average for each grating each order was given equal weight. This method was used because in the low orders the lines were intense and easily measured, while in the higher orders the lines were more difficult to measure but the errors were of less importance.

In any case it was found that almost any consistent method of weighing gave practically the same result. The probable error has not been given for each set

of measurements as in almost every case it was much less than the probable consistent errors in the experiment. It is believed that the differences between the results for various gratings form the best method of determining the probable error in the experiment. This may be seen more easily from Table III

6	0.211 (11)	0.218 (16)	0.216 (3)	0.213 (4)
Weighted Average	0.224 (161)	0.217 (277)	0.222 (113)	0.222 (182)

where the percent difference is given between wave-lengths as measured by grating and crystal methods. The number in parenthesis is the number of orders of each wave-length which were measured for each grating. Thus line 5', means that grating number 5 was spluttered with gold, 49 orders of the copper $K\beta$ line and 82 orders of the copper $K\alpha$ line were measured, and with the chromium target 44 orders of the $K\beta$ line and 67 orders of the $K\alpha$ line were measured. The weighted average was obtained by multiplying each value by the number of measurements (in parenthesis) and dividing the sum by the total number of measurements.

The final results are given in Table IV. The crystal wave-lengths are those given by Siegbahn¹⁷ which have been corrected for the index of refraction of the x-rays in the crystal. The limiting error has been estimated by the following method.

TABLE IV.

Spectral Line	Crystal λ	Grating λ	Limiting Error	Grating λ - Crystal λ
Cu $K\alpha$	1.38914A	1.39225A	± 0.00014	+0.224%
Cu $K\alpha$	1.53838	1.54172	± 0.00015	+0.217%
Cr $K\beta$	2.08017	2.08478	± 0.00021	+0.222%
Cr $K\alpha$	2.28590	2.29097	± 0.00023	+0.222%

In addition to the probable error calculated from the variation of the results, there are three possible sources of consistent error that have to be taken into consideration. They are: the measurement of the grating constant, the distance between the plate holders, and the precision of the comparator on which the plates were measured.

The grating spaces of gratings 1 to 4 were measured directly as described above. This method essentially determines the pitch of the ruling engine screw. The pitch of the screw as determined from these gratings differed by less than 1 part in 20,000. The grating space of gratings 5 and 6 was deter-

¹⁷ M. Siegbahn, "The Spectroscopy of x-rays" (1925).

mined by measuring directly the pitch of the ruling engine screw. It appears to the writer that the maximum error in the grating space of the gratings should not exceed 0.005 percent.

The distance between the plate holders (184.280 cm) was measured by two observers and the results agreed to within 0.002 cm. The iron bar was compared with the laboratory standard and also measured on the comparator on which the plates were measured. Thus the maximum error in the distance between the two plate holders must have been less than 0.004 percent.

In addition to the calibration of the comparator as already described, it was further checked for erratic or periodic error by measuring the distance between the lines on a coarsely ruled grating. From these results it is concluded that the absolute error in the comparator was not greater than 0.001 mm over the range used. Since the distances on the plates varied from 4 mm to 50 mm, the average error must have been less than 0.008 percent.

It will be seen from Table III that the differences between the results from different gratings and different wave-lengths are of negligible importance as compared to the possible consistent errors. Thus the limiting error has been taken as 0.01 percent.

TABLE V.

Investigator	Spectra line	λ	Grating λ — Crystal λ	Probable error	Date
Compton-Doan	Mo $K\alpha$	0.7078A	-0.1%	$\pm 0.4\%$	1925
Thibaud	Cu $K\alpha$	1.540	+0.1	$\pm 1.$	1926
Hunt	Pt $M\alpha$	6.1	+1.6		1927
	Al $K\alpha$	8.5	+2.0		
Bäcklin	Mo $L\alpha$	5.402	+0.11	± 0.2	1928
	Mo $L\beta$	5.174	+0.14	± 0.2	
	Al $K\alpha$	8.333	+0.12	± 0.1	
	Mg $K\alpha$	9.883	+0.09	± 0.2	
	Fe $L\alpha$	17.61	+0.17	± 0.2	
Wadlund	Mo $K\alpha_1$.708	+0.1	± 0.1	1928
	Cu $K\alpha_1$	1.537	0.	± 0.08	
	Fe $K\alpha_1$	1.938	+0.3	± 0.2	
Howe	Cu $L\alpha$	13.37	+0.6	± 0.3	1929
	Fe $L\alpha$	17.66	+0.5	± 0.3	
Bearden*	Cu $K\alpha$	1.5418	+0.22	± 0.02	1929
	Cu $K\beta$	1.3922	+0.22	± 0.02	
Cork	Mo $L\alpha_1$	5.4116	+0.29		1930
	Mo $L\beta_1$	5.1832	+0.30		
Bearden	Cu $K\alpha$	1.54172	+0.217	± 0.01	1931
	Cu $K\beta$	1.39225	+0.224	± 0.01	
	Cr $K\alpha$	2.29097	+0.222	± 0.01	
	Cr $K\beta$	2.08478	+0.222	± 0.01	

* These results are not the same as those published but they have been corrected for the difference between Eq. (9) which was used for calculating the wave-lengths and the correct Eq. (1). Also the index of refraction of the x-rays in the crystal was neglected in this preliminary report.

DISCUSSION

It is interesting to compare the absolute measurements of the x-ray wavelengths obtained by various investigators using ruled gratings. Table V gives a summary of these results, where the probable errors are approximately those given by the authors. It will be noticed that all the results are high except the pioneering results of Compton and Doan and the copper $K\alpha_1$ result of Wadlund.

The copper $K\alpha_1$ line was recorded by Wadlund on only three plates, and on the plate showing the most measurable orders a difference of 0.75 percent in wave-length was observed in different orders. Measurements made by the writer using the same grating gave results about 0.2 percent higher than the crystal values. The results obtained by Backlin and Cork on the molybdenum $L\alpha$ and $L\beta$ lines differ by almost 0.2 percent. Howe and Backlin differ by more than 0.3 percent on the iron $L\alpha$ line. These differences observed by the various investigators are rather difficult to understand. However, it has been observed by the writer that an error of 0.2 percent can easily be made unless all adjustments are precisely made. It is very essential that the angle θ be checked at the beginning and end of an exposure as this forms a satisfactory criterion for accepting or rejecting a given set of plates. The satisfactory agreement between the present results for different gratings and also those obtained by the writer in 1929 seem to support this criterion.

In Table III it will be noted that the results with the gold spluttered gratings 4' and 5' are higher than the results obtained with the unspluttered gratings. The difference appears to be greater than the experimental error but probably is not of sufficient magnitude to indicate a fundamental difficulty with the grating method. The spluttered layers were very thin (absorbed about 95 percent of optical light) and it is conceivable that there might have been some interaction between the top of the gold surface and the glass surface. However, the difference was so small that it was not thought worth while to plan a detailed experiment to test the question.

The great difference between the wave-lengths thus measured and those obtained from crystal measurements indicates some fundamental difficulty in the two methods. As was seen in the earlier part of this paper no suggestion has been supported which would influence the grating results. It is known, however, that crystals such as rocksalt are much less perfect than crystals of calcite, but even calcite cannot be considered a perfect crystal. In order to account for the mechanical properties of crystals, Zwicky¹⁸ has developed a theory which strongly suggests that even in crystals of calcite there might be a concentration of atoms at rather regularly spaced intervals. This would make the average density of the crystal greater than the density of the small elements of the crystal which are effective in diffracting x-rays. Such an imperfection in the crystal would account for the observed difference in wave-length as measured by ruled gratings and crystals. In any case it appears that the difficulty must be either in the crystal or in the constants used to calculate the grating space of the crystal from chemical data.

¹⁸ F. Zwicky, *Helvetica Physica Acta* **3**, 269 (1930).

DETERMINATION OF THE FUNDAMENTAL CONSTANTS

The absolute wave-length measurements obtained above allow us to determine directly the fundamental grating constant of crystal gratings. The complete Bragg law of diffraction may be written

$$n\lambda = 2d \sin \theta \left(1 - \frac{1 - \mu}{\sin^2 \theta} \right) \quad (10)$$

where n is the order of diffraction, λ the wave-length, d the grating space of the crystal, θ the angle of diffraction, and μ the index of refraction of the x-rays in the crystal. Sine θ and μ have been precisely measured by many investigators. It is thus possible to determine the distance d between the layers of atoms in the crystal almost as accurately as the wave-length λ of the x-rays is known. Siegbahn and Dolejek¹⁹ have found for the copper $K\beta$ line $\sin \theta = 0.229334$. Larsson²⁰ has found $(1 - \mu)/\lambda^2 = 3.72 \times 10^{10}$ or $(1 - \mu)/\sin^2 \theta = 1.36 \times 10^{-4}$. Substituting these values and the wave-length of the copper $K\beta$ line from Table IV in Eq. (10) one finds

$$d = 3.0359 \pm 0.0003 \text{ \AA}$$

One of the most precise methods of measuring Planck's constant h is by determining the high frequency limit of the continuous x-ray spectrum. The quantum relation

$$Ve = h\nu$$

may be written in the form

$$h = Ve \left(\frac{2d \sin \theta}{c^2} \right) \quad (11)$$

where v is the potential applied to the x-ray tube, d is the grating space of the crystal used and θ the minimum angle of diffraction. The experiment of Duane, Palmer and Yeh²¹ gives directly the value of $v \sin \theta$ as 2039.9 ± 0.9 volts. Using the value of d obtained from Eq. (10), $e = 4.77 \times 10^{-10}$ e.s.u. and $c = 2.99796 \times 10^{10}$ cm/sec we obtain

$$h = 6.573 \pm 0.007 \times 10^{-27} \text{ erg} \cdot \text{sec.}$$

All different theories of the dispersion of x-rays agree in the limiting case when the frequency of the radiation is much greater than the natural frequency of the electrons in the dispersing medium. The relation is

$$1 - \mu = \frac{ne^2}{2\pi m\nu^2} \quad (12)$$

where μ is the index of refraction, n the number of electrons per cm³ in the

¹⁹ M. Siegbahn and V. Dolejek, *Zeits. f. Physik* 10, 160 (1922).

²⁰ Alex. Larsson, *Inaugural Dissertation*, Uppsala, 1929.

²¹ Duane, Plamer and Yeh, *Opt. Soc. Amer.* 5, 376 (1921).

dispersing medium, e the charge on the electron, m the electronic mass, and ν the frequency of the radiation. This equation can be rewritten in the form

$$\frac{e}{m} = \frac{2\pi Mc^2}{F\rho Z} \times \frac{(1-\mu)}{\lambda^2} \quad (13)$$

where M is the molecular weight, F the Faraday constant, ρ the density, z the molecular number, λ the wave-length of the x-rays and c the velocity of light. Stauss²² has recently measured $(1-\mu)$ for the molybdenum $K\alpha_1$ and $K\beta$ lines using quartz as the refracting medium. His value of $(1-\mu)$ is

$$(1-\mu)_{K\alpha_1} \times 10^6 = 1.804 \pm 0.001.$$

If we increase the crystal value of the molybdenum wave-length by 0.221 percent, which seem justifiable from the agreement of the writer's measurements of the copper and chromium K -series, we obtain for the molybdenum line the wave-length

$$\text{Mo}K\alpha_1 = 0.7094\text{\AA}$$

Substituting this wave-length in Eq. (13) and the other constants from Birge's²³ tables one obtains

$$\left(\frac{e}{m}\right)_{K\alpha_1} = 1.765 \pm 0.001 \times 10^7 \text{ e.s.u.}$$

This value of e/m is very unsatisfactory because it does not agree with either the usual spectroscopic value or the deflection method value. However, it should be pointed out that Larsson's²⁰ value of $(1-\mu)$ is much higher than this value from Stauss's experiment. If one uses an average of the values obtained by Larsson and Stauss we have

$$\frac{e}{m} = 1.769 \times 10^7 \text{ e.s.u.}$$

Thus it appears that further experiments on the dispersion of x-rays will have to be made before confidence can be placed in the value of e/m obtained in this manner.

The above constants as determined from the grating measurements of x-ray wave-lengths are unaffected by the possible imperfections of the crystal. It may be interesting, however, to calculate other fundamental constants assuming that the crystal grating is perfect.

From fundamental considerations of crystal structure it can be shown that the grating space d of a rhombohedral crystal is given by

$$d = \left(\frac{nM}{N\rho\phi}\right)^{1/3} \quad (14)$$

²² H. E. Stauss, Phys. Rev. **36**, 1101 (1930).

²³ R. T. Birge, Phys. Rev. Sup. **1**, 1 (1929).

where n is the number of molecules in each elementary rhombohedron, M the molecular weight of the crystal, N is Avogadro's number, ρ the density of the crystal, and ϕ is the volume of a rhombohedron, the perpendicular distance between whose opposite faces is unity. It can also be shown that

$$\phi = \frac{(1 + \cos \beta)^2}{(1 + 2 \cos \beta) \sin \beta} \quad (15)$$

where β is the angle between the axis of the crystal. All the quantities in Eq. (14) can be precisely measured except N . Thus if the crystal is perfect, an independent determination of d should make possible a precise measurement of Avogadro's number N . Using the value of d found from Eq. (14) and the other constants from Birge's²⁴ tables one finds

$$N = 6.019 \pm 0.003 \times 10^{23} \text{ mol. per mole}$$

If Avogadro's number N can be accurately determined in this manner the charge on the electron e can be obtained from the relation

$$F = Ne \quad (16)$$

where F is the Faraday constant. Thus

$$e = 4.806 \pm 0.003 \times 10^{-10} \text{ e.s.u.}$$

Planck's constant h determined from Eq. (11) using $e = 4.806 \times 10^{-10}$ and the other constants the same as above, gives

$$h = 6.623 \pm 0.004 \times 10^{-27} \text{ erg}\cdot\text{sec.}$$

The values of N and e obtained from Eqs. (14) and (16), and the value of h using e from Eq. (16) appear to be entirely too high. The numerous ways in which these constants enter into theoretical calculations make the acceptance of these high values almost impossible. This may be interpreted as a support of the theory of mosaic structure of crystals. If the entire difference, observed in the x-ray wave-lengths as measured by the two methods, be attributed to the mosaic structure, then we now have a precise method for determining quantitatively the magnitude of this effect in any crystal. An independent experimental determination of the mosaic structure would of course allow us to calculate N and e as above, with higher precision than has been attained by other methods.

THE TRANSPARENCY OF SODIUM FLUORIDE AND LITHIUM FLUORIDE IN THE EXTREME ULTRAVIOLET

By EUGENE H. MELVIN

CHEMICAL LABORATORY, UNIVERSITY OF CALIFORNIA

(Received April 8, 1931)

ABSTRACT

Artificially prepared single crystals of sodium and lithium fluorides were tested for transparency to extreme ultraviolet light by means of a one meter concave grating vacuum spectrograph. The source used was a highly condensed spark discharge through a Pyrex capillary. These crystals were expected to be more transparent than calcium fluoride (fluorite) due to their lower indices of refraction. Lithium fluoride was transparent to 1083Å (132Å below the limit of fluorite) which is the practical limit to be expected. Sodium fluoride was transparent to 1320Å, which is not thought to be the limit of the pure material. Crystals of these salts have been made as much as 5 cm in diameter, and they are rather insoluble and easily cut and polished being very similar to fluorite.

RESEARCH work in the extreme ultraviolet part of the spectrum has been handicapped by a lack of transparent materials. The most transparent material known was calcium fluoride (fluorite) which Liefson¹ found transparent to 1215Å (this is exceptional and fluorite that transmits to 1400Å is very scarce). Lyman² has tested a great number of naturally occurring crystals; he found none as good as fluorite and that fluorite varied greatly in its transparency. Therefore research work has been directed towards the preparation of large single crystals from pure salts.

Crystals have several advantages in spectrographic work. A prism spectrograph gives a much brighter spectrum than a grating spectrograph. Crystals have greater dispersion than glasses near the transmission limit; so if prisms of various crystals were available one could obtain high dispersion in any desired part of the spectrum. Achromatic lenses can be made when crystals are obtainable that have about the same transmission limits. Crystals that transmit far into the extreme ultraviolet have high dispersion in the near infrared.

There were several reasons for the choice of sodium and lithium fluorides. They are cubic crystals, which make the preparation of lenses and prisms simpler than from other classes of crystals. Calcium fluoride was the most transparent solid known, and since the fluoride ion was the chief determining factor the fluorides were given the most consideration. Lithium fluoride was first prepared because the lithium ion is smaller and has fewer electrons than the calcium ion. Since the index of refraction is closely related to the absorption or transmission of light, a plot of the dispersion curves of cubic crystals was thought worthwhile; all that had been measured were those of calcium

¹ S. W. Liefson, *Astrophys. J.* 63, 73 (1926).

² T. Lyman, *Astrophys. J.* 25, 45 (1907).

fluoride, sodium chloride, and potassium chloride. Since then Gyulai³ has measured the dispersion curves for five alkali halides. All the measurements are shown in Fig. 1. The fact that the curves do not cross and are of the same general shape was used to limit the research to crystals which showed the most promise, since a single measurement of the index of refraction fixed its relative position in the plot and indicated how transparent the pure crystal would be in the extreme ultraviolet. Sodium fluoride has the lowest index of refraction (1.328 for N_D) for any cubic crystal and therefore should be the most transparent in the extreme ultraviolet. The only other cubic crystal that might have as low a value for N_D is potassium fluoride which is very deliques-

Fig. 1.

cent and consequently for practical use out of the question. Lithium fluoride has a value for N_D of 1.384, while calcium fluoride has a value of 1.434. Therefore pure sodium fluoride and lithium fluoride should be more transparent than calcium fluoride.

The single crystals, made by a method previously published,⁴ were prepared from repurified C.P. chemicals. The transparency was the best test of the purity. Crystals of sodium and lithium fluorides cleave easier and better than fluorite. They were tested by placing a thin cleavage plate of about 1 mm thickness between the light source and the slit of a one meter concave grating

³ Z. Gyulai, *Zeits. f. Physik* **46**, 809 (1927).

⁴ H. C. Ramsperger and E. H. Melvin, *J.O.S.A. and R.S.I.* **15**, 359 (1927).

vacuum spectrograph. The light source used was a condensed spark discharge through a Pyrex capillary at a residual air pressure of about 0.002 mm of Hg; this gave a line spectrum extending to 500A. The crystal window was protected by glass tubes from metal sputtered from the aluminum electrodes.

RESULTS

Spectrograms showing the transparency of the crystals are not published due to the fact that faint lines near the transmission limit are not visible in reproduction. The percentage of light transmitted is difficult to judge due to the type of source used. A description of the results follow.

Lithium fluoride. Four crystals of lithium fluoride were tested. The transmission limits varied between 1083A and 1350A. All the crystals were very transparent to within 200A of their limit. The salts used in preparing the crystals were from different sources which may explain the variations, since the treatment given them was the same in all cases.

Sodium fluoride. Two crystals of sodium fluoride were tested. One crystal transmitted to 1740A with almost no absorption of light, then absorption was complete; the other crystal transmitted to 1320A where absorption set in completely.

DISCUSSION

The limits of transparency varied considerably for both salts. The limit of 1083A obtained for lithium fluoride appears to be the practical limit of transmission for the pure salt based on the curves shown in Fig. 1. This limit is 130A beyond that obtained for the best fluorite. The limit of 1215A for fluorite would seem to be the limit for pure calcium fluoride. As indicated in Fig. 1, sodium fluoride should be more transparent than lithium fluoride, but this was not found to be the case, slight traces of impurities are thought to be the explanation of this. The great absorption that traces of impurities may have is shown in a recent paper by Hilsh and Pohl⁵ who measured the dispersion frequencies above 1600A of many alkali halides. They distilled the salts onto a quartz plate to measure their absorption, and found that the layer of salt had to be of the order of 0.001 mm thick to get appreciable amounts of light through the salt below the first absorption wave-length. Thus we see that extremely small amounts of such salts as these would effect the transmission of extreme ultraviolet light very markedly.

Sodium fluoride and lithium fluoride are better than fluorite also in that they do not become colored and opaque with use—some crystal windows were tested many times. These crystals are about as hard as fluorite so that anyone familiar with fluorite can cut and polish them. Single crystals up to 5 cm in diameter have been prepared and there seems no reason why much larger ones could not be prepared. Plates are very easy to cleave and have very good surfaces. Lithium fluoride is rather insoluble—0.27 g per 100 g of water at 10°C—and can be ground and polished in water. Sodium fluoride is more soluble—4.3 g per 100 g of water at 18°C—and so cannot be allowed to stand in water.

THE ANGULAR DISTRIBUTION OF PHOTOELECTRONS EJECTED BY POLARIZED ULTRAVIOLET LIGHT IN POTASSIUM VAPOR

BY MILTON A. CHAFFEE
UNIVERSITY OF CALIFORNIA

(Received April 10, 1931)

ABSTRACT

Light of wave-lengths in the region of 2400Å selected by a monochromator and polarized by a pile of quartz plates illuminated a jet of potassium vapor. The lateral directions of emission of the photoelectrons relative to the electric vector were studied. Though the electrons were ejected with energies less than one equivalent volt, the experiments were definite in establishing that the most probable direction of ejection is that of the electric vector and that the angular distribution varies as the square of the cosine of the angle between the electric vector and the direction in question. This result is in accord with predictions of the wave mechanics for a spherically symmetrical atom and incidentally therefore constitutes additional evidence that molecules do not play an appreciable part in the observed photo-ionization of potassium vapor.

INTRODUCTION

THE wave mechanics predicts that the most probable direction of emission of photoelectrons by polarized radiation is forward of the electric vector. The forward component of the ejected electrons is furnished by the momentum of the absorbed quantum and therefore is only appreciable when the momentum of the absorbed quantum is comparable with that of the photoelectron. Apart from this forward component the distribution in angle about the electric vector decreases with the square of the cosine of the angle between the direction in question and the electric vector.

A great amount of experimental work on the angular distribution of photoelectrons ejected by x-rays has verified the above predictions of theory.¹ The present work has sought to examine experimentally the phenomena in the optical region. Here the momenta of the absorbed quanta are so small that no forward component should be observed and therefore the angular distribution should follow a cosine squared law for the longitudinal as well as the lateral distribution. The experiments reported in this paper have shown that for the lateral distribution of the electrons ejected by ultraviolet light in potassium vapor such is the case.

EXPERIMENTAL METHOD

Rather troublesome difficulties were encountered in the present work because the problem was that of measuring the velocity directions of electrons

¹ C. D. Anderson, Phys. Rev. 35, 1139 (1930). This paper contains references to other work in the field.

having less than one equivalent volt of energy. Making sure that the photoelectrons observed were really from the vapor was itself an elusive and difficult task.

The main requirements of the experiment were as follows. First, light had to pass through the tube ionizing the vapor without striking the electrodes or walls of the tube which, in the presence of the vapor, were extremely photoactive. Second, the electrodes and tube had to be maintained at room temperature to avoid thermionic emission, while a sufficient and constant vapor density of potassium to obtain a measurable number of photoelectrons was necessary. Third, an intense and constant source of ultraviolet light was necessary in order to give a good photo-effect at the lowest possible vapor density. The upper limit to the allowed vapor density was set by the requirement that the mean free path of the electrons had to be comparable with the dimensions of the ionizing chamber.

Fig. 1. Diagram of apparatus.

These requirements were satisfied by an apparatus which incorporated many features similar to that used by Lawrence² in his measurement of the photo-ionization probability of potassium and that of Williamson³ who studied as well the distribution of velocities of the photoelectrons produced in potassium. A jet of vapor was ionized by plane polarized radiation inside a cylindrical grid, which was practically field free, so that electrons traveled in their original directions of ejection. Those that were ejected in the direction of a slit (a solid angle of 11.5 degrees) were accelerated into a faraday cylinder and measured by a Compton electrometer (sensitivity 10,000 mm/volt).

Figure 1a, b shows a detailed description of the apparatus. The light source consisted of a cobalt spark (which has many strong lines in the region 2300–2700Å) quenched by a blast of air which served both to steady the spark at one position and to increase greatly the intensity of the ultraviolet light. The light was focused by lens L_1 into the slit of a Bausch and Lomb quartz monochromator which resolved the light into a band of about 500Å

² E. O. Lawrence, *Phil. Mag.* **1**, 345 (1925).

³ R. C. Williamson, *Phys. Rev.* **21**, 107 (1923).

around 2400Å, thus eliminating the visible spectrum which would only produce photoelectric emission from the potassium surfaces. Lens L_2 , a quartz-fluorite achromatic combination, focused the light to infinity. The light was polarized by two piles of quartz plates P set at the polarizing angle, which gave a measured polarization of 86.6 percent, the second pile of plates serving to refract the beam back to its original axis so that rotation of the polarizer did not throw the beam out of alignment with the collimating diaphragms D . The tube was constructed of Pyrex glass with the quartz window W_1 sealed on by a quartz-Pyrex graded seal. The polarized beam passed through a system of collimating diaphragms D , the last diaphragm being slightly larger than the others to avoid scattering of the main beam. It was at a small positive potential with respect to the grid and slit, so that photoelectrons ejected from the diaphragm did not enter the faraday cylinder. The light after passing through the grid passed through a long tube and out through a quartz window W_2 which was set at an angle so that the reflected beam was multiply reflected a sufficient number of times to prevent it again reaching the grid. The fluorescence of this quartz window showed the beam to be in good focus through the tube.

Figure 1b shows the arrangement of the potassium boiler and vapor jet. The heating coil around the potassium reservoir F_2 controlled the density of the vapor stream, while the furnace F_1 was kept at a slightly higher temperature to avoid condensation of the vapor. J_1 indicates the copper jet in which the vapor entered the tube, and this was at a positive potential V_a with respect to the grid in order to eliminate the emission of electrons. The potassium after passing through the grid condensed on the walls of the tube and after each run the tube was warmed enough to allow the potassium to run back into the reservoir. The tube was cooled by several air blasts, and the electrodes were kept cool by conduction through short heavy leads which were cooled on the outside of the tube by the air blast. A copper gauze cylinder concentric with the grid and at the potential of the slit was placed inside along the walls of the tube for electrostatic shielding. Denoting the potential of the grid as zero, slit A was 1.5 volts positive, denoted by V_a . V_b was 4.5 volts positive (to draw the electrons into the faraday cylinder) and V_c , the potential of the faraday cylinder, was 6 volts positive. V_d was 3 volts positive thereby preventing thermionic emission from the jet reaching the collector.

RESULTS

Figure 2 is a plot of the relative number of electrons as ordinates ejected at angles with the electric vector given by the abscissas. The curve shows the cosine square distribution law, and the crosses represent averages of about twelve observations of each setting of the polarizer. The parallel plate polarizer was rotated over a 180° range, taking observations at 30° intervals. The abscissa 0° denotes the direction parallel to the electric vector. Assuming the validity of the cosine squared law, these observations were corrected for the lack of complete polarization of the light, due to the inefficiency of the polarizer and the depolarization of the quartz window, leading to the circles. It is seen that the corrected points fall fairly well along the cosine-squared curve.

The photoelectric currents for the 0° setting of the polarizer were of the order of magnitude of 10^{-14} amperes.

ERRORS

There remains after correction of the observations a small residual recorded emission of electrons at right angles to the electric vector. This is of importance for if it is real it means that the cosine-squared law does not hold. There are four paramount sources of experimental error which could be responsible for the observed effect at 90° .

First there is the possibility of a small photoelectric emission by scattered light from the electrodes. The diaphragming of the light was, however, so carefully arranged that no emission at all was observed before vapor entered the tube or after the jet of vapor was cut off. The routine preliminary procedure before each run was to make certain that there was no photo-emission before the potassium reservoir was heated, then the vapor pressure was raised

Fig. 2. The relative numbers of photoelectrons ejected at various angles relative to the electric vector. The crosses represent experimental data. The circles represent data corrected for lack of complete polarization of the light. The curve represents the cosine squared distribution.

to a point where there was a measurable photo-effect, and next it was established that the photo-effect fell to zero when the jet was cut off. These control observations practically eliminated this source of spurious effects from consideration. Secondary electrons such as photoelectrons reflected from the grid and slits, however, remain as an unknown factor which might have been great enough to contribute appreciably to the observations.

The error introduced by the finite width of the slit and the accelerating potential of 1.5 volts between the grid and slit was quite inappreciable. The earth's magnetic field was not balanced out for the curvature of the paths of the photoelectrons produced by this field was of the order of magnitude of 10 cm and therefore not a serious source of systematic error. Because of the continuous distillation of potassium on the electrodes contact electromotive force fields undoubtedly were very small.

Perhaps the greatest source of error was introduced by the scattering of the electrons in the vapor. From the temperature of the molten potassium and the geometry of the jet orifice and electrodes an estimate of the vapor pressure of the jet in the region of ionization gave the value of 0.002 mm of mercury pressure. Using Brode's⁴ data on the mean free paths of 0.7 volt electrons in potassium vapor it was accordingly calculated that in the present experiments the probability of a scattering collision of a photoelectron formed in the jet on passing to the slit was of the order of magnitude of one-half. Because small angle scattering⁵ is greater than scattering at large angles it therefore appears that this is a quite appreciable source of systematic error and indeed is very probably responsible for the observed emission at right angles to the electric vector.

DISCUSSION

The wave-length dependence of the photo-ionization of potassium vapor is anomalous in the respect that it does not decrease monotonically to shorter wave-lengths beyond the series limit as is the case in caesium and rubidium.^{6,7} The possibility has been suggested¹ that this anomalous behavior is ascribable to a large amount of molecular ionization, and indeed some rather good arguments have been adduced in favor of this hypothesis.⁸ It appears, however, that a general consideration of all the evidence, particularly that obtained in most recent work,⁹ indicates that the observed photo-ionization of potassium vapor is really that of the potassium atom.

The present experiments have a bearing on this question for it is to be expected that the cosine-squared angular distribution of the photoelectrons about the electric vector will hold only for a spherically symmetrical atomic system. Professor J. R. Oppenheimer has kindly informed the writer that he has estimated that the emission perpendicular to the electric vector would be of the order of magnitude of one-third that in direction of the electric vector if the emission were from potassium molecules. The fact that the present experiments have yielded much less than this amount therefore may be regarded as further evidence that the potassium atom is responsible for the observed effects.

The writer is indebted to the General Electric Company for a photoelectric cell used in calibrating the polarizer and to the Committee-on-Grants-in-Aid of the National Research Council for the quartz-fluorite lens used in the present work.

In conclusion the writer wishes to acknowledge a great indebtedness to Professor E. O. Lawrence who suggested the problem and gave many suggestions which made possible the success of this work.

THE ABSORPTION OF THE $K\alpha$ LINE OF CARBON IN VARIOUS GASES AND ITS DEPENDENCE UPON ATOMIC NUMBER

BY ELMER DERSHEM AND MARCEL SCHEIN*

UNIVERSITY OF CHICAGO

(Received March 27, 1931)

ABSTRACT

A description is given of the apparatus and methods used in a photographic investigation of absorption coefficients for the $K\alpha$ line of the carbon ($\lambda=44.6\text{\AA}$) in different gases and in gold leaf. The mass absorption coefficients, μ/ρ , found were as follows: He, 3600; CO_2 , 4780; N_2 , 3850; O_2 , 5765; Ne, 13100; A, 45700; Kr, 31800; Xe, 6740; Au, 12500. Some of the atomic absorption coefficients (μ_a) derived from these values on the assumption that the absorption is independent of chemical combination are as follows: C, 0.44×10^{-19} ; N, 0.89×10^{-19} ; O, 1.52×10^{-19} ; Ne, 4.36×10^{-19} . The wave-length of the $K\alpha$ line of carbon lies between the K and L_I absorption limits of these elements. The values of $\log \mu_a$ when plotted against $\log Z$ fall upon a straight line whose slope is 4.4. Hence in this wave-length region this should be the value of p in the equation $\tau_a = C\lambda^n Z^p$, provided that $\lambda_K < \lambda < \lambda_L$. The results of extrapolating current x-ray formulas to this wave-length are given and the values of μ_a so obtained are, in general, considerably too large. Since the exponent of Z in the above equation is found experimentally to be as large or larger than in the case of ordinary x-rays it appears that the proper exponent of λ may be considerably less than 3.

INTRODUCTION

THIS investigation was undertaken to determine absorption coefficients for soft x-rays over as great a range of wave-lengths and absorbing elements as might be possible with the use of ruled gratings to isolate single wave-lengths and a photographic method to measure intensities. The present report deals only with data obtained with the use of one wave-length, that of the $K\alpha$ line of carbon (44.6 \AA). As will be shown in a following paper the reflecting power of a mirror for these rays is intimately related to the absorption of the radiation by the mirror. Hence it was necessary first to investigate the laws of absorption applicable to such soft x-rays in order to determine the exact role played by absorption in modifying the intensity of reflection of x-rays from mirrors and gratings.

The x-ray absorption coefficient of an atom of any element is usually considered to consist of two terms as may be expressed in the following equation, $\mu_a = \tau_a + \sigma_a$ in which μ_a is the total atomic absorption coefficient and τ_a and σ_a are the atomic fluorescence and scattering absorption coefficients respectively. For radiations longer than 1 \AA , σ_a becomes quite small in comparison to τ_a .

In the case of ordinary x-rays the atomic fluorescence absorption coefficient was early found to be very well represented by the formula $\tau_a = C\lambda^n Z^p$ in which C is a constant depending upon the absorption region considered, λ the

wave-length and Z the atomic number. For wave-lengths less than 1A the values of the exponents n and p are very nearly 3 and 4 respectively. For longer wave-lengths there is considerable evidence that n decreases and p increases with increasing wave-length. A number of methods have been proposed for theoretically evaluating the above constants. These will not be discussed here. From a consideration of experimental data, Richtmyer and Warburton¹ found empirically the values, $C = 2.24 \times 10^{-26}$ for wave-lengths shorter than the K limit and $C = 0.33 \times 10^{-26}$ for those between the K and L_I limits, n and p being taken as 3 and 4 respectively and λ expressed in Angstrom units. Allen² with data extending in some instances to 4A found the corresponding values of C to be 2.18×10^{-26} and 0.299×10^{-26} respectively while reducing the value of n to 2.92. Gray³ summarized the existing data and proposed a more complicated formula for the K region, namely:

$$\tau_a = 1.92(1 + 0.008Z)(1 - \lambda/4\lambda_K - \lambda/50\lambda_{K^2})Z^4\lambda^3 \times 10^{-26}.$$

The factors in parenthesis are introduced empirically to compensate for the reduction found in n with increasing wave-length. Between the K and L_I absorption limits Gray finds the simpler formula $\tau_a = 0.255Z^4\lambda^{2.7} \times 10^{-26}$.

An important investigation by Jönsson⁴ extended absorption measurements for some metals to nearly 12A. He concluded that the absorption per K electron, for all elements, could be represented by the same function, $f(Z\lambda)$ of the product of the atomic number and the wave-length. This is made applicable to the case of wave-lengths longer than that of the K limit by multiplying $f(Z\lambda)$ by the ratio of the wave-length of the K limit to that of the nearest absorption limit having a wave-length greater than that of the absorbed radiation. This latter step depends for its justification upon the experimental fact as shown by Richtmyer⁵ that the magnitude of the absorption discontinuity at the K limit is very nearly equal to the ratio of the wave-length of the L_I limit to that of the K limit. Jönsson tabulates values of $f(Z\lambda)$ obtained from experiment for values of $Z\lambda$ between 8 and 790. With the aid of these tables one may compute absorption coefficients by Jönsson's method for various elements and wave-lengths provided $8 < Z\lambda < 790$.

Woernle⁶ has investigated the absorption of certain gases for wave-lengths ranging from 2.3A to 9.9A and found some variation from the law proposed by Jönsson. His results indicate that the exponent of Z is greater in the L than in the K absorption region.

All of the above formulas were deduced from a consideration of data relating to wave-lengths less than 12A and one should not expect them to hold for wave-lengths as long as that of the carbon $K\alpha$ line. Nevertheless, since they furnished previous to this investigation about the only means of estimat-

ing the order of magnitude of the absorption to be expected, it is of some interest to calculate absorption coefficients by the use of these formulas and to compare the results with those obtained experimentally. These results are given in Table II.

APPARATUS AND METHODS

A sketch of the apparatus is shown in Fig. 1. A beam of x-rays passed upward from the water-cooled x-ray tube *X*, through the slit *S*₁ which was covered with a thin film of celluloid, then through the slit *S*₂ onto the grating *G*. This was a plane glass grating having 600 lines per mm and gave a very intense first "inside order" of the *K*α line of carbon when the glancing angle of incidence was about 4°40'. The shield *S*₃ was so placed as to cut out all

Fig. 1. Diagram of apparatus.

other wave-lengths while letting the *K*α line of carbon pass through a narrow slit and fall upon the photographic plate *P* which was carried by the sliding plate holder *H*. The latter could be given a step-by-step motion across the path of the x-ray beam by means of an electromagnet which is not shown in the sketch but which could be operated at will by pressing a button outside the spectrograph. The apparatus could be opened for adjustments or the changing of plates by raising the cylinder *C* with the aid of the rope and pulley *R*. When closed the bottom flange of this cylinder rested on the sulphur-free gasket *K* which made a vacuum tight seal between the cylinder and the base plate *B*. The x-ray tube and spectrograph were evacuated by mercury diffusion pumps connected to the outlets *O*₁ and *O*₂. The valve *V* could be

either opened or closed by a ratchet device actuated by another electromagnet controlled from outside.

When in operation the apparatus was used as follows: With the valve V open the spectrograph was evacuated to a pressure of about 2×10^{-5} mm Hg. Several photographs of the $K\alpha$ line were then taken with different times of exposure. The valve V was then closed and such an amount of gas admitted from the gas reservoir GR as was estimated to absorb one half or more of the radiation. Several exposures were then made with varying time of exposure. These times of exposure were so chosen as to produce blackenings intermediate between the lightest and darkest lines obtained in the vacuum. Pressures were measured with the calibrated McLeod gauge M , which was provided with two compression chambers in order to measure a large range of pressures. Readings were taken repeatedly during a run to check against pressure changes. Finally the valve V was opened, the gas swept out and another series of exposures similar to the first were made.

The power input to the tube was kept constant during a run. Ordinarily a current of 22 milliamperes and an effective voltage of 2.7 kv were used. Lines of the desired density were usually secured in one to three minutes when the chamber was evacuated. This varied somewhat from time to time due to variations in the amount of carbon adhering to the target of the x-ray tube, but no sudden changes in the intensity of the carbon line were ever noted. However, continuous variations of five or ten percent per hour were common. It was found that by rubbing a small quantity of stopcock grease on the stem supporting the filament of the x-ray tube that some portion of the stem would remain at just the right temperature to cause a slow evaporation of carbon compounds which would maintain a quite constant amount of carbon deposit on the target provided the energy input to the tube did not exceed that noted above.

Eastman x-ray plates and x-ray developer were used, care being taken to avoid over-development and to keep the plates rotating while in the developer. The densities of the lines were then compared with the aid of a photoelectric photometer recently constructed in this laboratory. In this instrument, which will be described in more detail elsewhere, a beam of light from a small bulb was directed upon a fine slit so placed that the light passing through the slit fell upon a potassium hydride photoelectric cell connected to a string electrometer. The photographic plate was then placed with the film side very close to the slit and moved across the beam of light by means of a graduated screw. The time for a given reflection of the string of the electrometer was noted when the various lines and intervening clear spaces were in front of the slit. Repeated measures of the same lines gave variations in electrometer readings of much less than one percent. The time required for the electrometer string to move a certain number of divisions with a line before the slit minus the time for the same deflection with the adjacent clear portion of the plate in front of the slit was taken as a measure of the relative density of the line.

The noble gases used were obtained from the Air Reduction Sales Company and were guaranteed to be spectroscopically pure. This was verified by

tests with a small direct vision spectroscope which gave no evidence of lines other than those belonging to the gas in question. Carbon dioxide was obtained by heating magnesium carbonate, nitrogen by heating sodium azide and oxygen by the electrolysis of barium hydroxide. These gases were dried by phosphorus pentoxide. Such gases as would not be condensed were further purified by passing through a liquid air trap. For those of higher boiling points carbon dioxide snow in acetone was used to cool the trap. The data for gold were obtained with the use of gold leaf. The thickness of the latter was determined by weighing.

RESULTS AND CALCULATIONS

The mass absorption coefficients were determined from the equation $I/I_0 = e^{-(\mu/\rho)\rho x}$ in which x is the length of path through the gas from the celluloid window on the slit S_1 to the photographic plate. This distance was 57.7 cm. The density ρ , was computed from the density at standard conditions and the experimental values of temperature and pressure.

The ratio I/I_0 was obtained from the photographic density measurements and the times of exposure of the lines with and without gas in the chamber. Several methods of determining this ratio from density measurements were tried. In one method four lines having different exposure-times were photographed near one end of the plate with the chamber evacuated, followed by seven lines through the gas, the latter exposure-times being lengthened to give densities intermediate between the extremes of those obtained without gas in the chamber. The chamber was then again evacuated and the first four lines repeated on the other end of the plate. Curves were drawn with the photometer densities of the lines in vacuum plotted against exposure-time. In case the curves obtained at the beginning and end of the run were not identical, the densities of the lines through the gas were corrected on the assumption that the radiation from the tube had varied uniformly in intensity throughout the time of the complete operation. The time which would have been required in vacuum to produce a blackening equal to that of any line through the gas could be read from these curves. The ratio of this time to the actual exposure time of the line through the gas is, from the reciprocity law, the desired ratio of intensities, I/I_0 . Each line taken through the gas thus gave a measure of this ratio.

In some cases in which a sufficient number of lines in vacuum had not been secured to give a suitable curve of blackening against time, auxiliary plates with variable time of exposure were taken and curves of blackening against exposure-time were drawn for each of these. Let T_v be the exposure time of a line in vacuum and T_{va} the time to produce the same blackening on the auxiliary plate. Also let T_g be the exposure time of a line in gas and T_{ga} the time to produce the same blackening on the auxiliary plate. Then

$$\frac{I}{I_0} = \frac{T_v}{T_g} \times \frac{T_{ga}}{T_{va}}.$$

Experience showed that the two methods led to identically the same result when the average of a considerable number of comparisons were taken.

The results of these measurements are summarized in Table I. The large number of observations taken in some cases reduced the mathematical probable error but the actual error is perhaps considerably larger. This comes from

the fact that not all of the variations are due to chance errors. The absorption coefficient for carbon is derived from that of carbon dioxide on the assumption that absorption is independent of chemical combination. This assumption appears justified when we consider the relatively enormous effect of atomic

Fig. 2.

number as contrasted with the number of electrons in a molecule. For example, the absorption by an atom of neon with 10 electrons is considerably greater than that of a molecule of carbon dioxide with 22 electrons. Fig. 2 shows the logarithm of atomic absorption coefficient plotted against loga-

rithm of atomic number for the elements carbon, nitrogen, oxygen and neon. The straight line thus obtained indicates that μ_a is a function of the atomic number only, or that its dependence upon any other factor is relatively small, since the atomic absorption coefficients derived from measurements on molecules of CO_2 , N_2 , O_2 and atoms of Ne are thus shown to be proportional to the atomic number raised to the same power. Some measures of the absorption of sulphur dioxide were made. When corrected for the probable impurity the gas was found later to contain, the value of μ_a so obtained for sulphur agreed fairly well with a continuation of the straight line of Fig. 2 and strengthened our conviction that this line represents the true law of absorption for this wave-length in the elements from carbon to sulphur. However it was thought best to repeat these measures with other samples of gas before publication of final values for the absorption of sulphur.

From the slope and intercepts of the line of Fig. 2 the following formula for the atomic absorption coefficient of an element in which $\lambda_K < 44.6\text{\AA} < \lambda_{L,I}$ is easily deduced.

$$\mu_a = 1.65Z^{4.4} \times 10^{-23}.$$

This equation may then be used to determine the absorption coefficients of the other elements in this region of atomic number.

The experimental values of the absorption coefficients for the elements investigated are given in Table I. Except for the elements represented in Fig. 2 these all fall in different absorption regions. It may be noted that the mass absorption coefficient of argon is greater than that of krypton, xenon or gold while the absorption by an atom of krypton is greater than that of any other atom in the list. This is readily explained by the fact that with increasing atomic number of the absorber the K , L , M and N absorption limits pass in turn to the high frequency side of the incident radiation and the electrons belonging to these levels cease to absorb. Nevertheless this decrease is, perhaps, more than might be expected. For example, in the case of an atom of xenon there remain 26 electrons with natural frequencies less than that of the incident radiation yet these absorb only about one half as much as the 14 electrons in an argon atom whose natural frequencies are such as to permit absorption.

CONCLUSIONS

The experimental results indicate a probable value of 4.4 for p in the equation $\tau_a = C\lambda^n Z^p$ when it is applied to the L absorption region of the absorbing element and to wave-lengths in the neighborhood of the $K\alpha$ line of carbon. A value of n cannot be deduced directly, since only one wave-length was investigated. Nevertheless there is indirect evidence that n for this region may be considerably less than 3. It may be noted that the values of τ_a listed in Table II which are computed from the formulas of Richtmyer and Warburton, Allen, and Gray are considerably too large. This indicates that either C or n or both have smaller values in this soft x-ray region than is the case for ordinary x-rays. The numerical value of $C\lambda^n$ for some of these elements has

TABLE II. *Experimental and calculated values of atomic absorption coefficients for the $K\alpha$ line of carbon. τ_a should equal μ_a at this wave-length.*

Absorber	$\mu_a \times 10^{19}$ Experimental	$\tau_a \times 10^{19}$ Richtmyer and Warburton	$\tau_a \times 10^{19}$ Allen	$\tau_a \times 10^{19}$ Gray	$\tau_a \times 10^{19}$ Jönsson
He	0.238	3.2	2.28	2.7	0.19

been shown experimentally to be 1.65×10^{-23} . If we assume a value of C equal to that of the Richtmyer and Warburton formula we obtain $n = 2.24$. With the values of C taken from the formulas of Allen and Gray we find $n = 2.27$ and $n = 2.31$ respectively. This does not yield a trustworthy value of n since the value of C is quite uncertain. In fact we do not know that an equation of the assumed form can represent absorption coefficients in this region. On the other hand the method of Jönsson is shown to lead to values of the right order of magnitude. This appears at first somewhat difficult to understand, since his assumption that the absorption is a function of λZ is equivalent to assuming that the exponents of λ and Z are the same. If, however, the exponent of Z increases and the exponent of λ decreases with increase of λ at such rates that the changes in one approximately compensate for the changes in the other, it would be possible to secure an apparent but quite fortuitous agreement with experiment by assuming the absorption to be a function of λZ raised to some intermediate power. In view of the fact that all investigations indicate that the exponent of Z is always greater than the exponent of λ and also that this difference probably increases with increase of wave-length, it seems probable that the results achieved by Jönsson's method are to be explained in this way.

It is planned to continue this investigation with the use of other wave-lengths in an endeavor to find the law relating absorption to wave-length in this region and to test further the dependence of absorption upon atomic number.

NOTE ADDED IN PROOF:

It has been called to the author's attention that Kurtz⁷ used the entire beam of x-radiation from a carbon target and measured its absorption in several of these gases. Substituting his values of the constants in the equation $\tau_a = C\lambda^n z^p$ we obtain $\tau_a = 1.7 z^{4.4} \times 10^{-23}$. Considering the uncertainty regarding the homogeneity of his radiation the results are in remarkable agreement with those obtained in the present investigations.

THE REFLECTION OF THE $K\alpha$ LINE OF CARBON FROM QUARTZ AND ITS RELATION TO INDEX OF REFRACTION AND ABSORPTION COEFFICIENT

BY ELMER DERSHEM AND MARCEL SCHEIN*

RYERSON PHYSICAL LABORATORY, UNIVERSITY OF CHICAGO

(Received March 27, 1931)

ABSTRACT

Measurements were made of the ratio of the intensity of the reflected ray to that of the incident ray in the case of the $K\alpha$ line of carbon reflected from a mirror of fused quartz for glancing angles of incidence between $1^\circ 30'$ and 8° . The atomic absorption coefficients of carbon, nitrogen, oxygen, and neon were experimentally determined by the writers as described in the preceding article. This gave the value of the oxygen coefficients directly and data from which the atomic absorption coefficient of silicon could be calculated. The linear absorption coefficient, μ , of quartz was then computed from its density, percentage composition, and the atomic absorption coefficients of its constituents. Then from the relation $\kappa = \mu\lambda/4\pi$, the absorption index κ , was found to be 1.68×10^{-3} . The value of $\delta = 1 - n$ was computed from the Drude-Lorentz formula and found to be 4.8×10^{-3} . Convenient methods for the calculation of the intensity of either the parallel or perpendicular components of the reflected ray are derived from the Fresnel equations relating to absorbing media. A curve computed with the above values of δ and κ predicts somewhat higher reflectivity than found experimentally. Use of the value $\kappa = 2.5 \times 10^{-3}$ yields a computed curve agreeing well with the experimental one. On the other hand, assuming values of δ other than that given above leads to less satisfactory agreement.

INTRODUCTION

THIS investigation was undertaken with the view of measuring the intensity of soft x-rays reflected at various angles from a mirror and at the same time determining, either theoretically or experimentally, the magnitude of the index of refraction and the absorption coefficient of the mirror. Knowing the latter two quantities and the curve of reflected intensity plotted against glancing angle of incidence it should be possible to learn something regarding the precise validity of the extrapolations of classical dispersion formulas from the optical to the soft x-ray region.

Quartz appeared to be one of the most promising materials for investigation since it could be highly polished and particularly because the $K\alpha$ line of carbon ($\lambda = 44.6\text{\AA}$), which is one of the most intense and easily obtained lines in this region, was so far removed from a critical frequency of either silicon or oxygen that the index of refraction could be computed from classical dispersion theories with a great deal of confidence. Hence measurements of the intensity of reflection of this line from quartz were made and the results briefly noted in a paper read before the American Physical Society.¹ However

* Fellow of International Education Board.

¹ Dershem and Schein, Phys. Rev. 35, 292 (1930).

it was not found possible to secure a film of quartz sufficiently thin to transmit a measurable amount of this radiation and permit a direct measure of its absorption coefficient. Hence attention was turned to the possibility of measuring the absorption of this line in gases and determining the law of absorption for elements of low atomic number. A description of this work is given in the preceding paper. In this way a value of the absorption coefficient of oxygen was obtained directly and that of silicon was determined from the formula $\mu_a = 1.65 Z^{4.4} \times 10^{-23}$ which had been derived from the experimental data pertaining to other elements.

THEORY

The critical glancing angle of total reflection for hard x-rays is quite sharply defined and furnishes a convenient method of measuring indices of refraction in this case. However, with increase of wave-length the discontinuity in reflected intensity at the critical angle becomes less abrupt and finally for very soft x-rays entirely disappears. This is due partly to a more gradual change in reflected intensity at the critical glancing angle as this angle becomes larger, even in the case of substances entirely transparent to the radiation. However it is mainly due to an increase of absorption. Hence if the index of refraction is to be deduced from an experimental curve of reflected intensity plotted against glancing angle it is necessary to know the absorption coefficient and to find, if possible, the value of the index of refraction which must be assumed in order to secure agreement between calculated and experimental curves.

A formula for computing the ratio of reflected to incident intensity at various angles may be derived in the following manner. In using this formula the index of refraction and the index of absorption may be either known or assumed.

Considering first the component with the electric vector perpendicular to the plane of polarization, the ratio of the reflected to the incident amplitude is given in the following formula of Fresnel,² in which ϕ and r are the angles of incidence and refraction measured from the normal.

$$\frac{R_s}{E_s} = \frac{\cos \phi - n \cos r}{\cos \phi + n \cos r} \quad (1)$$

By Snell's law $\cos r = (1 - \sin^2 \phi / n^2)^{1/2}$. Hence

$$\frac{R_s}{E_s} = \frac{\cos \phi - (n^2 - \sin^2 \phi)^{1/2}}{\cos \phi + (n^2 - \sin^2 \phi)^{1/2}}$$

Changing to the glancing angle of incidence θ , since $\cos \phi = \sin \theta$

$$\frac{R_s}{E_s} = \frac{\sin \theta - [n^2 - (1 - \sin^2 \theta)]^{1/2}}{\sin \theta + [n^2 - (1 - \sin^2 \theta)]^{1/2}}$$

In order to take account of absorption it is necessary to substitute a complex expression³ for n , namely $(1 - \delta - i\kappa)$ in which $1 - \delta$ is the index of refraction

² Cf. Drude, "Theory of Optics" English translation, 282 (1902).

³ Drude, loc. cit. p. 360 et seq.

tion and κ the index of absorption. Since δ and κ are small compared to unity the squares and products of these quantities may be neglected. Also θ may be substituted for $\sin \theta$. Making these substitutions and simplifications⁴

$$\frac{R_s}{E_s} = \frac{\theta - (\theta^2 - 2\delta - 2i\kappa)^{1/2}}{\theta + (\theta^2 - 2\delta - 2i\kappa)^{1/2}} \quad (2)$$

Setting

$$a - ib = (\theta^2 - 2\delta - 2i\kappa)^{1/2} \quad (3)$$

$$\frac{R_s}{E_s} = \frac{\theta - a + ib}{\theta + a - ib}$$

Multiplying by the complex conjugate to secure the square of the absolute value which is the desired ratio of intensities

$$\left(\frac{R_s}{E_s}\right)^2 = \frac{(\theta - a)^2 + b^2}{(\theta + a)^2 + b^2} \quad (4)$$

Squaring Eq. (3) and separately equating the real and imaginary terms

$$a^2 - b^2 = \theta^2 - 2\delta \quad (5)$$

$$b = \kappa/a \quad (6)$$

Whence

$$a^2 = \frac{1}{2} \{ \theta^2 - 2\delta + [(2\delta - \theta)^2 + 4\kappa^2]^{1/2} \} \quad (7)$$

The numerical value of a may now be readily determined by substituting the known or assumed values of θ , δ and κ in (7). The positive value should be chosen for all square roots in the preceding discussion. Equation (6) then yields the value of b . The ratio of reflected to incident intensity is then given by substituting these values in (4).

For the case of the parallel component we have

$$\frac{R_p}{E_p} = \frac{n \cos \phi - \cos r}{n \cos \phi + \cos r}$$

Handling this in a similar manner we obtain in place of Eq. (4) the following

$$\left(\frac{R_p}{E_p}\right)^2 = \frac{(\theta - 2\delta\theta - a)^2 + (b - 2\kappa\theta)^2}{(\theta - 2\delta\theta + a)^2 + (b + 2\kappa\theta)^2}$$

a and b have the same values as in the case of the perpendicular component.

The reflected intensity of the parallel component is slightly less than that of the perpendicular component. In the case of the $K\alpha$ line of carbon reflected from quartz this is negligible for small angles, becoming about 5 per cent at 8° .

⁴ An equation of this form has been given by Prinz, *Zeits. f. Physik* 47, 479 (1928) but this is not a final form for numerical calculations.

Schön⁵ has developed a more complicated formula for the parallel component yielding results equivalent to that above. Thibaud⁶ has also published a formula of essentially the same form as that of Schön.

APPARATUS

The principal parts of the apparatus were the same as previously used and described by one of the writers⁷ in an investigation of the reflection of the carbon line from glass. However certain mechanical features were added to permit direct comparisons of the incident and reflected beams.

Referring to Fig. 1, X is a water-cooled x-ray tube, the rays from which pass through the slits S_1 and S_2 and falling upon the grating G , become spread out into a spectrum of which only the inside order of the $K\alpha$ line may pass

Fig. 1. Diagram of apparatus.

through the shield S_3 and strike the quartz mirror M . This mirror could be turned through small known angles by means of the lever L and the screw T . This screw could be turned in small steps by an electromagnetically operated ratchet controlled from outside. Another ratchet, operated by an electromagnet, was used to turn the eccentric cone bearing B on which the mirror was mounted. The mirror could thus be moved alternately into or out of the beam by a one-half turn of the bearing B . In this way a series of exposures of the direct and reflected beams could be taken alternately upon the plate P . The latter was carried on the plate holder H which could be given a step by

⁵ Schön, *Zeits. f. Physik* **53**, 165 (1929).

⁶ Thibaud, *Jour. de Physique* **7**, 37 (1930).

⁷ Dershem, *Phys. Rev.* **34**, 1015 (1929).

step transverse motion by means of another electromagnetically operated ratchet not shown in the sketch. In this way from 12 to 20 separate exposures could be made on one plate.

The apparatus could be opened or closed by raising or lowering the cylinder *C* by means of a rope and pulley. A vacuum seal between the cylinder and the base plate *B*₁ was secured by means of the sulphur free rubber gasket *K*. During operation a vacuum higher than 10^{-4} mm Hg was maintained by means of mercury diffusion pumps connected to the outlets *O*₁ and *O*₂.

RESULTS

The densities of the lines produced by the reflected and the direct rays were compared by photometric measurements and the ratio of their intensities determined in the same manner as described in the preceding article on absorption coefficients. The experimental points thus obtained are marked with circles in Fig. 2. The curves shown in this figure are, however, plotted

Fig. 2.

from values of the ratio of reflected to incident intensity computed from Eq. (4). The values of δ and κ to be used were determined in the following way.

Since the *K* absorption frequencies of oxygen and silicon are much higher and their *L* absorption frequencies much lower than that of the *K* α line of carbon, δ may be computed from the simplified Drude-Lorentz formula, $\delta = e^2 n / 2\pi m \nu^2$ in which *n* is the number of electrons per cc having lower natural frequencies than that of the incident radiation. In this case the *K* electrons are not considered. One may also use the more extended formula, $\delta = e^2 N / 2\pi m \sum n_e / \nu^2 - \nu_e^2$ in which *N* is the number of molecules per cc, *n*_e the number of

electrons per molecule belonging to the characteristic energy level c and ν_c the frequency pertaining to this level. The values of δ obtained from these formulas do not differ by so much as one percent owing to the fact that the incident frequency lies approximately midway between the characteristic K and L frequencies of oxygen and silicon. For quartz and the carbon line the value thus obtained for δ is 4.8×10^{-3} .

The value of κ was found from the experimental equation deduced in the preceding article on absorption coefficients namely, $\mu_a = 1.65 Z^{4.4} \times 10^{-23}$ whence μ_a for silicon is found to be 18.2×10^{-19} . This in conjunction with the experimental value of μ_a for oxygen, 1.52×10^{-19} , and the density of fused quartz, 2.206 gm. cc, yields the value, $\mu = 47200$ for the linear absorption coefficient of quartz. Then the absorption index κ , can be found from the equation $\kappa = \mu\lambda/4\pi = 1.68 \times 10^{-3}$.

Curve I of Fig. 2 was computed with the use of the above values of δ and κ . This curve lies somewhat above the experimental points. This might be taken to indicate that the real value of the absorption coefficient was greater than that determined from the work on the absorption of gases. Edwards⁸ finds a similar result when using ordinary x-rays. He suggests that the absorption of the surface layer may be greater than that of the mirror as a whole.

Other values of δ and κ were tried in an endeavor to find the best fit with experiment. Curve II in which $\kappa = 2.5 \times 10^{-3}$ and δ has the same value as in curve I, gives a very good approximation to the experimental results. In computing for curve III the values, $\kappa = 1.68 \times 10^{-3}$ and $\delta = 4.0 \times 10^{-3}$ were used. This curve is distinctly less in accord with the experimental points. These curves and many others that were computed but not shown in the figure indicate that the value of δ computed from the dispersion formula is very nearly the correct one but that the effective value of the absorption index is about fifty percent higher than that determined from absorption measurements in gases. There is also the possibility that surface films or a lack of perfect smoothness have reduced the reflected intensity in much the same manner as would be the case if the absorption were really greater than the value deduced from experiment. The question might also be raised as to whether, or not, the true value of the absorption index may be thus obtained from the absorption coefficient. It is perhaps rather, to be considered remarkable that theories and formulas developed for the optical region before anything was known of x-rays or quantum absorption phenomena should yield results so nearly in accord with experiment when extended to this region where the wave-lengths are one hundred times smaller and the requirement of surface smoothness presumably so much more exacting. This work is to be continued with some changes in technique which it is hoped will somewhat increase the accuracy of measurement. Also other wave-lengths and other mirrors will be employed.

In conclusion we wish to express our appreciation to Professor A. H. Compton for his cordial interest and support throughout this investigation and the preceding one on the absorption of gases, and to thank the International Education Board for the award of a fellowship which made it possible for one of us (M.S.) to engage in the study of these problems.

A DIRECT MEASUREMENT OF THE INTENSITY VARIATIONS
OF THE HELIUM LINES WITH VOLTAGE

BY JOSEPH RAZEK

RANDAL MORGAN LABORATORY OF PHYSICS, UNIVERSITY OF PENNSYLVANIA

(Received April 6, 1931)

ABSTRACT

The intensity variations with voltage of some of the brighter lines of the low voltage helium arc spectrum were determined by means of a recently developed photoelectric spectrophotometer. The radiation was developed in a copper ball, 20 cm in diameter. The equipotential cathode and grid from a commercial three-electrode tube formed the internal structure, the sphere itself being the anode. This arrangement gave an extremely bright spectrum, even at the striking voltage, with a relatively low current density in the space. The results on 5016 (1^1S-2^1P) and on 6678 (1^1P-2^1D) were generally smooth curves. Lines 4026 (1^3P-4^3D), 4471 (1^3P-3^3D), and 5876 (1^3P-2^3D), show a region of constant intensity with arc voltages from 27 to 35 volts, thereafter increasing smoothly. Line 4713 (1^3P-3^3S) shows definite maxima near the critical exciting potentials. The accurate linear relationship between the intensity of the light admitted to the photoelectric cell and the amplified output of the photoelectric cell was established by a separate experiment. For the measurements on the spectrum lines, every intensity measurement was referred to a standard lamp operated at a constant resistance. The absence of oscillations in the arc current was shown by a vacuum tube voltmeter.

INTRODUCTION

KNOWLEDGE of the intensity variations of spectrum lines as a function of the excitation voltage is of considerable importance in certain theoretical discussions in spectroscopy. It has been customary to obtain this knowledge by photographing the spectrum repeatedly, each exposure being made at a definite voltage, and all other variables kept as nearly constant as possible. The intensity of the lines was then determined by means of some form of densitometer.^{1,2,3,4} Although this method has yielded valuable results nevertheless many difficulties and sources of error are involved. The photographic method is very time-consuming and many exposures must be made to get a sufficient number of points to plot a curve. Since the exposures are frequently very long, it is difficult to keep all the arc conditions constant. Furthermore, the relation between the actual light intensity and the resultant blackening of the plate is always subject to uncertainty, since it is influenced by many factors difficult to control. The various densitometers at present available are quite satisfactory, and so they introduce no source of error as important as the others mentioned.

For reasons above mentioned, a direct method for determining line intensities is desirable. The property of a photoelectric cell of translating light values into electrical quantities is at once suggested. However, when a photoelectric cell is used, it is found that the currents resulting from the very small amount of energy in a given line, are so feeble that they must be read with an electrometer,⁵ or amplified by means of some form of vacuum tube amplifier. The electrometer has the disadvantage of being slow and somewhat difficult

Fig. 1. Diagram of spherical low voltage arc discharge tube.

to keep in constant adjustment. The vacuum tube amplifiers used heretofore have employed the usual type of a.c. amplification.⁶ The research to be described employed a resistance coupled d.c. bridge grid resistor amplifier.^{7,8}

DESCRIPTION OF THE SPECTRUM TUBE

The spectrum tube in which the arc was formed is shown in Fig. 1. The tube differs from conventional designs in that the volume in which the dis-

charge takes place is quite large. The body of the tube was made of spun copper hemispheres, heavily silvered and polished. The two hemispheres were soldered together on an equatorial flange. The vacuum connection was made on the pole of one of the hemispheres, while the cathode and grid structures were admitted through a tube in the other hemisphere. The arc was observed through a slit in the upper hemisphere, over which a tube and glass plate were attached.

The cathode and grid structure were taken from a commercial three electrode tube, Arcturus type 247. This consists of a heating filament within a

Fig. 2. Wiring diagram for low voltage arc discharge tube.

tube on which the active material is placed. A coarse grid is concentric with the cathode tube. The usual plate structure was removed, and the metal of the hemispheres used instead.

The tube was wired as shown in Fig. 2. The fact that the filament was entirely insulated from the cathode made it possible to put all structures within the tube, except the cathode, at nearly the potential of the anode. In this way, the potential of the entire space within the hemispheres, with the exception of the small volume between the cathode and grid, was nearly uniform. The filament was heated by means of a storage battery in the usual manner. A

center tapped resistance was connected across the filament with the center tap connected to the anode through a milliammeter. The anode to cathode voltage was applied from a potential divider across a bank of batteries, and a milliammeter indicated total cathode to anode current. The voltmeter across the potential divider indicated the voltage applied to the anode, with the slight and constant potential drop in the milliammeter and leads.

DESCRIPTION OF LABORATORY SET-UP

The tube described was connected to a vacuum system, and after a short preliminary treatment to condition the active deposit on the cathode, helium gas was admitted to the tube by means of the conventional arrangement of bulb and stop-cocks. Due to the presence of the waxed joints, no effort was

Fig. 3. Diagram of optical arrangement for determining intensities of spectrum lines by means of a photoelectric cell and standard lamp.

made to degas the metal sphere. Since the actual runs were only of a few hours duration at the most, the amount of impurities was very slight. The majority of the data for the curves shown was obtained with no trace of mercury or hydrogen observable in a direct vision spectroscop.

The spectroscop, photoelectric cell and amplifier were those of the Razek-Mulder color analyzer described elsewhere.⁹ A diagrammatic sketch of the optical arrangement is shown in Fig. 3. Light from the arc is reflected and brought to a focus on the slit of the spectroscop by means of a mirror and cylindrical lens. After dispersion by means of a prism, the spectrum is reflected by a mirror through the lens of the exit tube on to the slit at the end

⁹ Mulder and Razek, *J.O.S.A. and R.S.I.* 20, 155 (1930).

of the tube. A slight tilting motion of the mirror moves the spectrum across this slit, admitting the selected line to the photoelectric cell. The current resulting in the photoelectric cell is amplified in a bridge grid resistor amplifier, and the amplified current noted on a galvanometer.^{7,8}

To provide a standard of intensity, and to correct the readings for the slowly changing sensitivity of the amplifier, a calibrating lamp was employed. A 6-8 volt automobile headlight bulb was mounted over the 45° mirror. A small scratch through the silvered back of the mirror admitted light from this bulb into the spectrometer. The light from this bulb could be cut off from the spectrometer by means of a bulb-operated camera shutter. In this way it was possible to calibrate the sensitivity of the system at a given wave-length against the standard lamp. In order to keep the current through the lamp constant to a high degree of precision, an arrangement due to Richardson was used. This is shown in Fig. 4. The lamp is made one arm of a Wheatstone

Fig. 4. Wiring diagram for Richardson bridge for holding standard lamp at constant operating resistance.

bridge, while the arm R_2 consists of a standard ohm, of a capacity sufficient to carry the lamp current without overheating. The arm R_1 was fixed at 1000 ohms, and the arm R_3 was variable. The current through the lamp, and hence the resistance at which it was operating was regulated by a bank of rheostats. When set up in this manner, the lamp was actually operated at constant resistance. During the short runs which were necessary to get data on a given line, it is safe to assume that the deterioration of the lamp was negligible, especially since the lamp currents which gave light intensities of the same order of magnitude as the arc, were well below the rated current values. The temperature at which the lamp was operated in a given set of readings was determined so that the deflection for the standard lamp was approximately equal to the maximum deflection due to the line under study. The value of R_3 was then set so that the bridge was balanced when the lamp operated at the selected temperature. After this setting was made, the bridge was kept balanced by adjusting the rheostats controlling the current through the lamp.

The procedure in actual operation was as follows: The tilting mirror in the spectrometer is set so that the desired line is admitted to the photoelectric cell. The light from the arc is cut off from the spectrometer by interposing a shutter in front of the window in the sphere, and the vacuum tube bridge balanced to give a zero galvanometer deflection. On opening a shutter in front of the sphere, a galvanometer deflection is obtained, which is proportional to the light intensity of the line admitted to the cell. The light of the arc is then cut off and the shutter in front of the adjusted calibrating lamp opened, giving a galvanometer deflection proportional to the light of the standard lamp. In this way, every reading for the arc intensity can be referred to the

Fig. 5. Intensity variation with arc voltage, helium line 4026 (1^3P-4^3D).

standard with a minimum of delay. This procedure was repeated for various arc voltages.

In this work, the arc current was kept constant by adjusting the temperature of the filament as the anode to cathode voltage was raised. Arc currents of 30 and 50 milliamperes were used. Currents as high as 300 milliamperes could be passed through the arc, with only 25 volts across the anode to cathode. The pressure of the helium was about 0.25 mm of mercury.

Direct light from the filament and cathode was eliminated entirely by blanking out the central portion of the glass observation window with a diaphragm, and viewing the arc from a slight angle. The effectiveness of this procedure was shown by the fact that when the filament was operated at a temperature considerably above that used during a run, no deflection of the

galvanometer could be observed, even in the red end of the spectrum, with no anode voltage on the hemisphere.

The dispersion of the prism used was small, but since the lines of the helium spectrum are spaced rather far apart, no difficulty was experienced in making certain that only the desired line was admitted to the photoelectric cell. Previous to every group of tests, the wave-length scale was calibrated against a mercury arc, and the corrections which must be applied to the wave-length scale on the color analyzer were determined. In cases where a bright line has a companion, this companion line is so faint in comparison to the

Fig. 6. Intensity variation with arc voltage, helium line 5016 (1^1S-2^1P).

brighter line that its influence on the photoelectric cell current is entirely negligible, or, in any case, the combined effect is obtained.

The question as to the propriety of taking the deflection of the galvanometer as proportional to the light intensity, is of fundamental importance in this work. The linear relationship between the intensity of the light and the galvanometer current was determined by using a point source at varying distances from a diffusing screen in front of the cell. The relative intensity was determined by employing the inverse square law. The galvanometer response was shown to be linear with the light falling on the photoelectric cell at least to one tenth of one percent—far above the precision of these tests.

DISCUSSION OF RESULTS

In order to determine whether the direction of the changing arc voltage influenced the intensity of the line, the intensity was determined for both increasing and decreasing voltage. It was found that in every case, the intensity at a given voltage was somewhat higher for increasing voltage than for decreasing voltage. This is shown in Figs. 5 and 6, which are the intensity-voltage curves for the 4026 and 5016 lines. This effect is independent of the time in that the same effect is obtained even when a given operating point is approached as rapidly as possible, the intensity being determined by the direction of approach. No explanation is offered at this time, but the existence of this phenomenon indicates the necessity of controlling the experimental procedure so that the voltage always changes in the same direction.

Fig. 7. Intensity variation with arc voltage, helium lines 4471 (1^3P-3^3D), 5876 (1^3P-2^3D).

The remaining curves were all made with the voltage increasing. Since it is at times difficult to approach a given operating point without overshooting, especially at the higher voltages, the accidental variations in the curves at these points may be due to this cause.

Lines 5026, 4471 and 5876 show a region of nearly constant intensity in the region from 27 to 35 volts. This is probably related to the fact that the lines have a series relationship, line 4471 being (1^3P-3^3D) and 5876, (1^3P-2^3D) and line 4026 (1^3P-4^3D). These are shown plotted in Figs. 5 and 7.

Line 4713 shown in Fig. 8, shows a most unusual behavior. The intensity of the line is a maximum, very near to the striking voltage, around 25 volts, dropping to almost half value at about 40 volts. From this point the intensity rapidly increases to about 53 volts, in the vicinity of the second ionization

potential, and thereafter remaining nearly constant. This is consistent with the observations of Bazzoni and Lay² and with those of Cornog.³ All observations made on this line were generally consistent with these results.

Fig. 8. Intensity variation with arc voltage, helium line 4713 (1^3P-3^3S).

Line 6678, shown in Fig. 9, increases regularly with increasing voltage, generally similar to line 5016.

The results obtained on all these lines were in general agreement with those of Bazzoni and Lay,² but inconsistent with those of Hughes and Lowe.¹ The latter used a non-equipotential cathode and a rather long tube of gas. The falling off in intensity which they show may be caused by the absorption of the radiation by the gas itself.

Fig. 9. Intensity variation with arc voltage, helium line 6678 (1^1P-2^1D).

The arc currents used in this work were quite low. On account of the unusually large volume of the discharge tube, these low currents resulted in

extremely low values of current per unit volume. However, since the cathode and grid structures were approximately of the same dimensions as those used by Bazzoni and Lay² and Cornog,³ the current densities in the vicinity of the cathode were comparable. It is desirable that the current densities be kept as low as possible to minimize space charge effects, which might have an important influence on the effective potential of the arc.¹⁰

The voltage exciting the arc can differ from that indicated by the voltmeter due to several causes. Since the voltage could not be read any closer than 0.2 volt, the various differences were negligible if they did not amount to that quantity. The voltage drop across the plate milliammeter was only about 0.05 volts and hence could be neglected. The first ionizing potential for helium is 24.48 volts, and since the arc struck at 24.5 volts, the contact difference of potential at the cathode was negligible. No error was introduced by the voltage equivalent to the initial velocity of the electrons leaving the cathode since this was operated at a relatively low temperature. Furthermore, an equipotential cathode was used, and hence there was no voltage drop for this element.

The absence of peak voltages in the arc, due to oscillations was verified by an appropriately connected vacuum tube voltmeter. No oscillatory voltages as great as 0.2 volt were detected, although the vacuum tube voltmeter could readily show these.

By changing the potential of the center tapped filament return, it was possible to change the distribution of the current between the grid plate structure and the filament. Under ordinary conditions, about ten percent of the current returned through the filament structure. No change in the intensity of the lines could be observed, even if half of the current returned through the filament structure. This probably showed that the internally silvered sphere was quite effective in integrating the light output, and completely avoided the difficulties caused by "wandering" of the discharge.

CONCLUSION

These results show that the photoelectric spectrophotometer can be used to study intensity variations in spectra with a speed and ease of operation which tends to minimize many of the difficulties inherent in work of this kind. This is especially apparent when it is noted that all the data for a given curve can be obtained in about fifteen minutes. The greater light intensity possible with the use of a large spherical radiation space overcomes the difficulties caused by the feeble light output of the conventional designs of low voltage arcs.¹¹

In conclusion, the writer desires to express his appreciation to Dr. C. B. Bazzoni, who suggested this problem, and under whose direction and supervision this work was done. The writer is further indebted to his colleague, Mr.

¹⁰ Mott-Smith and Langmuir, *Phys. Rev.* **28**, 727 (1926).

¹¹ Eckart and Compton, *Phys. Rev.* **24**, 97 (1924).

Peter J. Mulder, for his collaboration in developing the automatic spectrophotometer, and in taking the data here presented.¹²

Note added in proof:

Obviously, the intensity relationships existing between the lines relative to one another cannot be deduced from the curves shown. The absolute value of the intensity scale unit is different for every line and is determined by the wave-length energy curve of the standard lamp, the color response curve of the photoelectric cell, and other factors.

CERTAIN PHOTOELECTRIC PROPERTIES OF GOLD

BY LLOYD W. MORRIS

LABORATORY OF PHYSICS, UNIVERSITY OF WISCONSIN

(Received April 10, 1931)

ABSTRACT

Variations in the photoelectric behavior of a gold filament were studied both during an extended outgassing, and later upon reaching a stable condition.

Changes in photoelectric properties as outgassing proceeded.—Full arc sensitivity rose quickly in the initial period, then decreased slowly to a stable value. Fatigue curves showed a systematic change from a negative fatigue (i.e. a decrease in sensitivity with time of standing) at the beginning to a gradually increasing positive fatigue which slowly decreased to zero. A shift in long wave limit constant with the change in full arc sensitivity was observed.

Changes in photoelectric properties produced by increasing temperature.—Full arc sensitivity decreased slightly. Individual line sensitivity was studied by use of a quartz double monochromator. Lines close to the long wave limit increased enormously in sensitivity with temperature, for those more removed this was less marked, while below 2350A there was a slight decrease. A shift in long wave limit toward the red was observed during the outgassing period and the final fatigueless state. During this latter period photo-current per unit light intensity curves established a shift in long wave limit from 2560A to 2610A between temperatures of 20°C and 740°C.

SEVERAL studies have been made in this laboratory of the photoelectric behavior of thoroughly outgassed metals. This report covers an investigation of the photoelectric properties of gold with particular reference to:

1. Variation of full arc sensitivity of the gold filament together with the associated change in long wave limit as outgassing proceeds.
2. A systematic change in fatigue curves with continued outgassing.
3. Variation of full arc and line sensitivity together with long wave-length limit as a function of temperature when the filament is in a "fatigueless" condition.

APPARATUS

The gold samples in the form of U-shaped filaments some 0.03 mm thick by 4 mm wide were hung within a molybdenum cylinder which served as the collecting electrode. Potential and current leads passed out through a pressed seal at the top of the tube. The cylinder was supported from the bottom of the Pyrex tube by a double re-entrant seal through which the collector lead passed. This insured the longest possible glass path between filament and cylinder. As an additional precaution, grounded interior and exterior guard rings were placed at the top of the tube between the filament and collector. Photo-currents were read upon a Compton quadrant electrometer by using

either the rate of charge method or by maintaining a steady deflection by means of cupric oxide and glass high resistances.

The exciting light entered through a quartz window attached to the tube by a graded quartz to Pyrex seal. A hole in the side of the cylinder crossed by molybdenum wires allowed the light to fall upon the filament. The source of light was a vertical type Cooper-Hewitt quartz mercury arc operated at 80 volts. This was used either directly in front of the window or in connection with a Leiss quartz double-monochromator with lens by which the slit image was thrown upon the filament.

In the latter portion of the work this monochromator and arc were mounted upon a heavy cast iron base provided with levelling screws, two horizontal motions, and one of rotation about a vertical axis. Adjustable stops were provided on this latter motion so the monochromator slit image could be thrown quickly from the filament to a linear thermopile deep within an evacuated brass chamber, the double walls of which were filled with water. The beam entered through a quartz window of the same thickness as that on the photoelectric tube, thus giving the same optical path in the two cases. The dimensions of the slit and pile were such that it was unnecessary to re-focus the image when changing from one wave-length to another, further assuring exact equivalence throughout a run of the light incident on filament and pile. Thermopile readings were taken by means of a Kipp type ZC galvanometer with a scale distance of 6 meters.

Pressures were measured by either a McLeod gauge or an ionization manometer of the Dushman-Found¹ type which read to 1×10^{-8} mm of mercury. Usual precautions were taken to avoid waxed joints and the only stop-cocks were on the low pressure side of the system separated by two liquid air traps from the tube. The second trap, nearest the tube, was immersed in liquid air, only after the major portion of the outgassing process was complete.

The gold from which the filaments were rolled was obtained from the Bureau of Standards. Although no analysis was given it was stated to be the purest obtainable at any of the government mints.

PROCEDURE

The ionization gauge was outgassed and the rest of the vacuum system thoroughly torched for a week before the tube was sealed on. During this time the molybdenum cylinder was bombarded at a cherry red for 40 hours in a separate system. The filament was carefully cleaned with absolute alcohol and the tube was then assembled and sealed on to the system with the cylinder at atmospheric pressure for only a short time.

After initial photoelectric readings were taken the filament was heated by gradually increasing currents, with frequent stops to check variations in sensitivity and associated long wave-length limit. Then the tube was baked for 100 hours at 470°C, the filament being maintained at a slightly higher tem-

¹ Dushman and Found, *Phys. Rev.* 23, 734 (1924).

perature by a small heating current. During this period the vacuum system and mercury columns received frequent and vigorous torchings. The filament was then glowed at 600°C to 700°C for many hundreds of hours. Temperatures were based on the measured variation of resistance of the gold filament in combination with data given by Northrup² on the temperature variation of the resistivity of gold. With the placing of liquid air on the second trap pressures of 1×10^{-8} were reached and maintained throughout the experiment.

Long wave-length limits were measured in the initial stages by glass filters and various organic solutions indicated by Dahm,³ their transmission being checked on a quartz spectrograph. Later the monochromator was used, while for the last run the monochromator and thermopile arrangement described above was employed. In these determinations the electrometer was used with rate of charge at from 20,000 to 40,000 mm per volt.

Fig. 1. Curve 1. Variation of full-arc sensitivity in arbitrary units as a function of outgassing time.

Curve 2. Variation of photo-sensitivity with time of standing after heating current is stopped expressed in percent of initial sensitivity.

RESULTS

The results obtained during the outgassing process are summarized in Fig. 1. Curve 1 portrays the change in photoelectric full-arc sensitivity with increasing time of outgassing. The initial period is pictured on an enlarged scale to show better the rapid variation which takes place at first heating. The term "outgassing" is used to cover both glowing of the filament at 650°C and also baking. In the early stages low filament currents were used and the

² Northrup, Jour. Frank. Inst. 177, 287 (1914).

³ Dahm, Jour. Opt. Soc. 15, 266 (1927).

time scale is adjusted to equalize roughly their unequal heating effects. That is, 5 hours with 2 amperes heating current is plotted as one hour for the first reading, 20 hours at 3 amperes as 9 hours, etc.

In the initial stages of outgassing the sensitivity changes gradually after the heating current is stopped. This phenomenon, frequently called fatigue, is believed to be due to the gas layer being reformed on the surface of the metal. Curve 2 shows the behavior of these fatigue curves during outgassing. There is a rapid change in sensitivity when the heating current is stopped due to the filament cooling. At the end of five minutes this change is negligible, however, and the curves shown here are plotted as percent of the deflection five minutes after the heating ceases. The Roman numerals on the fatigue curves correspond to the time as shown by corresponding numerals on curve 1.

Fig. 2. Variation of line sensitivity with temperature expressed in percent of sensitivity at room temperature.

Two things are of interest here. Fatigue curve I which was taken on the upward slope of curve 1 shows negative fatigue as would be reasonable to expect. The others show a systematic change, rising to a maximum positive fatigue in IV and returning to practically zero fatigue in VII. Fatigue curves taken with monochromator on individual lines at same time as VII also show small fatigue. The pressure at this time was 1×10^{-8} mm and the ionization gauge showed no difference in pressure with the filament hot or cold, although in the earlier stages large changes resulted upon starting the heating currents.

The change in long wave-length limit observed during the run was consistent with the variation in the full-arc sensitivity. The long wave limit rose rapidly upon outgassing from a value in the neighborhood of 2000Å at the start to 3200Å at the point of greatest sensitivity. From then on it moved towards shorter wave-lengths as the full-arc sensitivity decreased.

Tests made throughout the outgassing process demonstrated a shift in long wave limit towards longer wave-lengths with increasing temperature. During intermediate stages determinations made with both absorption cells and monochromator were in good agreement and showed a shift of 200A approximately linear with temperature between 20°C and 640°C.

The full-arc deflections were at all times temperature sensitive and showed a marked decrease between 550°C and 740°C to a value well below that at room temperature. This, of course, represented the integrated result of the change in wave-length sensitivity throughout the effective spectrum. The results of a study of the variation of the individual line sensitivity with temperature are given in Fig. 2.

Fig. 3. Ratio of photo-current to incident light intensity and its logarithm as a function of the wave-length of incident light.

The double monochromator was used at slit widths of 0.6 mm, comparison tests made with a spectrograph showing the purity obtained to be equivalent to that of a single monochromator using slit widths of 0.2 mm or less. Coincident measurement of the line intensities by means of the thermopile arrangement mentioned earlier, in connection with the curves in Fig. 2, form the basis for the long wave-length determinations shown in Fig. 3. Due to difficulty of plotting the points for intermediate temperatures only the curves for room temperature and 740° are shown. The omitted points fall in order between these extremes and would have yielded a family of curves lying within those shown. More recent research in these laboratories on tantalum and silver by Cardwell⁴ and Winch,⁵ respectively, have yielded curves of

⁴ Not yet published.

⁵ Winch, Phys. Rev. 37, 1269 (1931). Next paper in this issue.

the same general character. In fact, this type of behavior was presaged by earlier work of Ives⁶ and Hornbeck⁷ on potassium.

The marked increase in sensitivity for the longer wave-length lines (eight-fold for 2537 between room temperature and 740°) is to be expected from their proximity to the long wave limit which changes with increase in temperature. That this increase is not due to a change in reflecting power appears probable from the results obtained by Winch, mentioned above. He observed similar curves for silver and found no change in reflecting power with temperature for any of the wave-lengths used. It is planned to investigate this for gold in future work.

As for Fig. 3, the observed shift in the long wave-length limit and the extended toe of the high temperature curve may be the direct result of the increased kinetic energy of the conduction electrons. The shape of the curve renders an exact determination of the long wave limit difficult. The log-curves would yield 2560A cold and 2610A at 740° as probable values. Present experiments with an arc of extremely high intensity promise to allow the use of much smaller slit-widths that may more accurately define these threshold values.

In conclusion, the author wishes to express his indebtedness to Dr. C. E. Mendenhall under whose direction the work was done.

THE PHOTOELECTRIC PROPERTIES OF SILVER

BY RALPH P. WINCH

LABORATORY OF PHYSICS, UNIVERSITY OF WISCONSIN

(Received April 10, 1931)

ABSTRACT

Silver is carefully outgassed and its photoelectric properties studied during outgassing and after stable conditions are reached. An outgassing curve is plotted for the 1200 hours of heat treatment given the silver before final readings were taken. For thoroughly outgassed silver curves are plotted showing photoemission as a function of temperature for fixed wave-lengths of incident light. These curves show that for wave-lengths near the long wave limit there is a marked increase in emission with temperature, for wave-lengths farther away there is no change with temperature, and for wave-lengths still farther away there is a slight decrease in emission with increased temperature. Curves for emission per unit of incident light intensity as a function of wave-length show that the long wave limit at 600°C is $2700 \pm 20\text{\AA}$ while at room temperature it is $2610 \pm 30\text{\AA}$.

THE study of the photoelectric properties of silver was undertaken as a part of the general program of this laboratory which includes extensive study of the properties of thoroughly outgassed metals. In this laboratory the photoelectric properties of iron, cobalt, and tantalum have been studied by Cardwell,¹ molybdenum by Martin,² rhodium by Dixon,³ and gold by Morris.⁴ Previous work of DuBridge,⁵ Warner,⁶ Kazda,⁷ and Goetz⁸ dealt with platinum, tungsten, mercury, and tin respectively.

The purpose of this work is to study the variation of the photoelectric sensitivity and of the long wave limit of silver during prolonged outgassing, to determine the ultimate long wave limit when outgassing ceases and stable conditions are reached, and finally to study the effect of temperature on the photoelectric characteristics. The reflecting power for various wave-lengths of incident light is also studied as a function of temperature to determine its possible effect on the observed photo-emission.

The apparatus was similar to that used by Cardwell¹ and consisted essentially of a strip of silver approximately 0.025 mm thick and 3 mm wide suspended from tungsten seals in the form of a loop inside a molybdenum receiving cylinder, the whole being enclosed in a Pyrex tube having a quartz window

sealed on with a graded quartz to Pyrex seal. The tube was connected through two liquid air traps, and a mercury "cut-off" to a water-cooled mercury diffusion pump backed by a Cenco Hyvac fore-pump. The vacuum system included a McLeod gauge and an ionization gauge of the Dushman and Found⁹ type for measuring pressures. Wax or grease vapor was guarded against by having the stopcocks and the one wax joint on the opposite side of the liquid air traps from the research tube.

The silver for this study was obtained from the Adam Hilger Co. of London and was 99.99 percent pure containing minute traces of copper, lead, manganese, and calcium.

The photoelectric currents were produced by radiation from a quartz mercury arc and were measured by a Compton quadrant electrometer. Resistances ranging from 10^7 to 5×10^{11} ohms (depending on size of currents to be measured) were shunted across the electrometer quadrants so that the "steady deflection" method could be used.

During the outgassing the undispersed radiation from the arc was used, but for the $f(\lambda)$ curves, and for the temperature curves on a fixed wavelength, a Bausch and Lomb single monochromator was placed between the arc and the specimen. A vacuum thermopile, whose currents were measured by a Kipp ZC low resistance galvanometer (sensitivity 6×10^{-10} amps. per mm at a meter) with a two meter scale distance, gave the relative intensities of the various incident wave-lengths. The thermopile (when carefully evacuated) and its galvanometer system showed very good steadiness which made the intensity readings reproduce readily. However, even with these conditions the fainter lines gave deflections so small that the natural errors of reading made the relative errors large in these cases. A study is being made at present of means of increasing these deflections so that greater precision can be attained. Only points which are quite dependable have been plotted in the accompanying curves.

A careful study of the monochromator was made in the spectral region near the long wave limit with results similar to those shown by Goetz,⁸ but with perhaps a little less purity than he shows. The combination of 0.2 mm slit-widths for both entrance and exit slits was found to be as narrow as was consistent with the accuracy desired from the thermopile readings. The photocurrent and intensity measurements were taken together in rapid succession so that the effect of all arc fluctuations was eliminated. There is much left to be desired in obtaining really monochromatic illumination of sufficient intensity for photoelectric work. A double monochromator is to be substituted for the single monochromator used here as a partial answer to this problem. The impurity of the incident light was not sufficient to cause appreciable error in the points plotted on the $f(\lambda)$ curves since they are for lines sufficiently intense so that the error is small. However this lack of purity did eliminate from use certain faint lines near stronger ones so that the number of points available for a given $f(\lambda)$ curve was limited.

⁹ Dushman and Found, Phys. Rev. 23, 734 (1924).

The temperature of the filament was determined from its resistance. The resistance of the filament was measured by measuring the IR drop across it, and then the IR drop across a tenth-ohm oil-cooled standard resistance, using a Wolff potentiometer for potential measurements. The data for resistance as a function of temperature were taken from a paper by Northrup.¹⁰

During the initial stages of outgassing the pressures varied from 10^{-7} to 10^{-6} mm of Hg but in the latter part, when stable conditions had been reached and liquid air was placed on the second trap, the pressures varied only from 1 to 3×10^{-8} mm of Hg. At this stage no increase in pressure could be detected when the filament was heated.

OUTGASSING PROCEDURE

The receiving cylinder of the photoelectric tube was carefully outgassed before placing it in the tube. It was heated at white heat for six days in an auxiliary vacuum system and then transferred to the research tube. The silver filament was immediately sealed in place and the whole tube sealed to the vacuum system. The cylinder was exposed to the air less than four hours. Immediately on obtaining good vacuum conditions the long wave limit of the silver was obtained and heating started by a conduction current through the filament. The heating was started at a low temperature and increased very gradually since metals evaporate much more rapidly when gas-filled.¹¹ Since silver has a rather low melting point it had to be heated at a low temperature at all times and treated rather carefully to preserve it during the long outgassing required.

RESULTS

Figure 1 shows the outgassing curve. Photoelectric emission due to total arc radiation is plotted as ordinate against time of heating as abscissa. The temperatures written in along the curve show where the heating current was increased thus putting the filament at the temperature indicated. Between the temperatures written in it was maintained at the lower temperature of the interval. The general shape of this curve is similar to that for gold, cobalt, rhodium, and tantalum showing an increase in emission during the initial stages of outgassing and a subsequent decrease finally reaching a fixed value which is not changed with continued heating. It is interesting to note that the high maximum was passed over at 325°C and that increase in temperature did not cause the emission again to rise but to decrease to its final stable value.

After 760 hours of heating of the filament only, the whole tube was baked at about 500°C for 6 days at the end of which time the pressure was less than 10^{-7} mm of Hg with the furnaces at 500°C . The filament was maintained, during baking, at 100°C or more above the rest of the tube to prevent metallic vapors from condensing on it. After removing the furnaces the photo-emission was a little below its value before baking, but at the end of about seventy-five

¹⁰ Northrup, Jour. Frank. Inst. 178, 85 (1914).

¹¹ Cardwell, Proc. Nat. Acad. Sci. 15, 544-555 (1929); Berlinger, Wied. Ann. 33, 289 (1888).

hours of heating at 600°C it had recovered. Two hundred additional hours of heating at this temperature did not change the emission showing that stable conditions had been reached. This made a total heating time of about 1200 hours before final readings were taken. The filament was flashed many times at over 850°C for short intervals to determine whether higher temperature would change its ultimate characteristics, and no change was observed. The silver evaporated rapidly at these higher temperatures.

The long wave limit of the silver specimen was initially in the neighborhood of 2000Å and shifted to the longer waves during the first part of the outgassing reaching a value above 3300Å at 405 hours where the emission was a maximum. It then shifted to the shorter waves as the emission decreased reaching a final value in the vicinity of 2700Å when stable conditions

Fig. 1. Outgassing curve using full-arc radiation.

were reached. The long wave limits for various times have been indicated on the curve. This trend of long wave limits is in general agreement with what one would expect from the shape of the curve in Fig. 1.

At various times during the heat treatment, "fatigue" curves were taken by shutting off the heating current and reading the photo-emission as a function of the time of standing. During the initial stages this "fatiguing" caused a decrease (never large) of photo-emission but when stable conditions were reached no fatigue could be observed during more than an hour of standing. It is interesting to note that the fatigue, when it appeared, was always a decrease in photo-current even though the continued outgassing meant a shift to smaller photo-currents so that one would expect returning gas to increase the sensitivity. This phenomenon has not been explained satisfactorily, but has been observed on other metals.

Readings from this point on were taken using the Bausch and Lomb monochromator previously discussed.

TEMPERATURE CURVES

Figure 2A shows temperature curves for various wave-lengths of incident light while Fig. 3 shows the $f(\lambda)$ curve for 600°C and the one for room temperature. It is obvious that either set of curves could be plotted from the other but both sets were taken independently and repeated many times.

In Fig. 2A the photo-emission is plotted as a function of the heating current through the filament (hence of temperature) for various wave-lengths of incident radiation. The absolute values of the emission represented by these curves cannot be compared. The 2537A curve was plotted and then the curves for other wave-lengths (except 2652A) translated so that they agree with 2537A at room temperature. Observed points have been plotted for 2537A

Fig. 2. A. Temperature curves for fixed wave-lengths of incident light. B. Reflecting power as a function of temperature for 2537A incident light.

but to save confusion the points on the other curves have not been plotted. Observations were taken for both increasing and decreasing currents and were reproduced very nicely as indicated by the points plotted. 2652A is not effective below about 2.7 amperes heating current hence it has been plotted to a different scale. The corresponding temperatures have been written in on the heating current scale.

These curves show an effect which was noted first in gold by Morris⁴ and later in tantalum by Cardwell,¹ namely, that for wave-lengths in the neighborhood of the long wave limit there is an increase in photo-emission with temperature, for shorter waves there is no effect produced by temperature, and for still shorter waves there is a decrease in photo-emission with increasing temperature. This effect is shown best by tantalum, whereas for silver the

decrease in emission with increased temperature comes at wave-lengths so short that air and quartz absorb some of the incident light and thus make the incident intensity very small. The decrease is definite but the slits of the monochromator had to be widened until there is considerable doubt as to the wave-length at which the decrease began to appear.

In Fig. 2B is plotted a curve showing that the reflecting power of silver for 2537A is independent of temperature up to 600°C. Identical results were obtained for 2482A, 2323A, 2259A, and 2200A. These curves were taken by reversing the field between the silver filament and the molybdenum receiving cylinder so that the filament was charged positively with respect to the cylinder. The incident radiation had been carefully focused on the silver filament. Thus the light which was reflected from the filament and became in this

Fig. 3. $f(\lambda)$ curves.

way incident on the cylinder caused photoelectrons to be emitted. These electrons were collected on the filament and measured. The reverse photo-current would thus be proportional to the reflecting power of the filament, and the behavior of this current with respect to temperature would measure any change in reflecting power which might occur with change of temperature. Since these curves indicate no change in reflecting power, the change in photo-emission with temperature cannot be explained on the basis of changing reflecting power.

The curves in Fig. 3 show the long wave limit at about 600°C to be at $2700 \pm 20\text{Å}$ while at room temperature the long wave limit is $2610 \pm 30\text{Å}$. The curves for intermediate temperatures lie in between these two but for temperatures of 200°C or less the curves fall on top of the room temperature

curve as nearly as can be determined. This is to be expected from the shape of the curves in Fig. 2. From the Einstein photoelectric equation these values of the long wave limit make the work function at 600°C equal to 4.56 ± 0.06 volts and for room temperature 4.73 ± 0.07 volts.

Whereas 2652A is the last point on the 600°C curve, it was determined, with an electrometer sensitivity of 8000 mm per volt on rate of charge, that 2699A was effective but that no line above showed an effect.

CONCLUSIONS

There is a definite shift in long wave limit of thoroughly outgassed silver with temperature. The shift amounts to about 90A between room temperature and 600°C. The temperature curves in Fig. 2 indicate that for wave-lengths near the long wave limit there is a marked increase in sensitivity with increase in temperature, that wave-lengths farther away show no change with temperature, and that wave-lengths still farther away show a decrease in emission with increase in temperature.

The work function of thoroughly outgassed silver is shown to be 4.56 ± 0.06 volts at 600°C and 4.73 ± 0.07 volts at room temperature. Work is being carried forward to make more accurate determinations of the $f(\lambda)$ curves with more nearly monochromatic illumination.

In conclusion, the writer wishes to acknowledge his indebtedness to Mr. W. L. Hole, whose help was invaluable during this work, and to Professor C. E. Mendenhall, under whose direction this work was carried out.

ON THE TRANSFORMATION OF LIGHT INTO
HEAT IN SOLIDS. II

By J. FRENKEL

DEPARTMENT OF PHYSICS, UNIVERSITY OF MINNESOTA

(Received March 21, 1931)

ABSTRACT

The results arrived at in a preceding paper are generalized for diatomic crystals (§§1, 2, 3). A direct determination of the probability of light absorption in a linear lattice leads to the establishment of a selection rule amounting to the law of the conservation of momentum for the light quanta and the "excitation quanta." This rule enables one to explain the linear structure of the spectra of solid bodies at low temperatures (§4). The preceding results are generalized and applied to a new description of the process of light scattering in crystals (§5) and the theory improved by introducing the width of the excitation lines and allowing for the damping of the exciting light waves.

1. GENERAL CONSIDERATIONS FOR A DIATOMIC CRYSTAL

IN A previous paper under the same title¹ I have limited myself to the consideration of monatomic bodies. The first object of the present note is to generalize the above results for the case of a diatomic (binary) crystal; the further generalization for a more complicated body will be quite obvious and will, therefore, not require special consideration. The main difference between a diatomic (or polyatomic) crystal and a simple one consists in the fact that the heat motion is realized here not only by elastical vibrations, for which the relative positions of the atoms within one molecule are approximately constant, the molecule oscillating as a whole, but also by "molecular vibrations" which can be visualized as the (distorted) vibrations of the atoms constituting the separate molecules, the center of gravity of the latter remaining approximately at rest. Whereas the elastical vibrations have a practically continuous spectrum, extending from $\nu=0$ up to a certain maximum frequency ν_{\max} , the molecular vibrations are usually characterized by one particular frequency ν_c , described as the "characteristic ultrared frequency" of the crystal and detected by the absorption and reflection of ultrared light or the Raman scattering of the ordinary light.

As a matter of fact there is no sharp distinction between the vibrations of both types. This is clearly seen if one considers a simple crystal as a limiting case of a diatomic crystal with actually identical atoms of "different sort." Owing to the mutual action of the molecules the vibration frequency ν_0 , characteristic of an isolated molecule, is split up into a series of n (or $3n$, n being the total number of molecules in the crystal) frequencies $\nu_{c1}, \nu_{c2}, \dots, \nu_{cn}$ which, however, usually lie very close to each other and are, therefore, considered as a single characteristic frequency ν_c shifted more or less with respect to ν_0 . It must, however, be born in mind that the mutual action of the molecules

¹ Frenkel, Phys. Rev. 37, 17 (1931).

in a crystal produces not simply a shift of their characteristic frequency but causes it to split up into a number ($3n$) of components, corresponding one by one to the various frequencies constituting the elastical spectrum. In fact the corresponding vibrations must have in both cases exactly the same wavelength.

The general theory of the oscillations of a compound crystal lattice has been developed in great detail by M. Born.² In this theory Born treated the electrons and nuclei as capable of vibrating about certain equilibrium positions in accordance with the pre-quantum views. We shall have to reserve Born's treatment for the atoms (or ions in a case of an ionic crystal) as *wholes*, the motion of electrons within a single atom being described by specifying the quantum state, normal or excited, of the atom, as has been done in the preceding paper (I). The localization of the excitation state in a particular atom, just as in the case of a simple crystal, does not correspond to a stationary state of the crystal as a whole. Such stationary states are obtained by "diluting" the excitation state over all the atoms of *the same kind* in the form of excitation waves. To a first approximation these excitation waves are not influenced by the presence of atoms of other kinds (which produce a perturbation of the second order only). We thus get exactly the same picture of the excited states or sub-states in the case of a diatomic crystal as that which has been developed before for a simple one.

In the present case, just as in the former one, the excitation of the crystal must entail a slight alteration in its structure, size and vibration frequencies, which will provide an indirect coupling between the different heat oscillators representing these frequencies. To get the looked for generalization of our former theory we need but add to the $3n$ harmonic heat oscillators representing the elastic spectrum, an equal number of oscillators representing the molecular vibrations. With the same approximation which is implied in assigning to all the latter oscillators the same characteristic frequency ν_c we can determine their contribution to the probability of a "deactivation" process by means of the Eqs. (32) and (32a) of I. The probability of a radiationless transition of a diatomic crystal from some excited state or more exactly "sub-state" (2) to the normal state, with the transfer of the excitation energy to p molecular oscillators is thus proportional to the p th power of the quantity

$$\mu = \frac{\pi^2 m}{2h} \nu_c (\Delta L)^2 \frac{N}{n} \quad (1)$$

where $\Delta L = n \cdot \Delta \delta$ is the measure of the change of the distance between the atoms caused by the excitation of the crystal. This quantity must in general have different values for the molecular oscillators on the one hand and the oscillators representing the elastic vibrations on the other. Further, in the former case m is approximately equal to the sum of the masses of the two atoms of different kind ($m_a + m_b$), whereas in the latter it is given (with the same approximation) by the equation $1/m = (1/m_a) + (1/m_b)$.

² Born, "Dynamik der Kristallgitter," Leipzig, 1915. Atomtheorie des festen Zustandes, Leipzig, 1925.

2. QUANTITATIVE THEORY OF A UNIDIMENSIONAL MODEL

For the convenience of the reader we shall briefly sum up here the theory of the vibrations of diatomic crystals, replacing the latter for the sake of simplicity by a one-dimensional model which we shall call a "bar" and which consists of atoms a and b in alternating order. The consecutive atoms of different kind may be combined in pairs representing the "molecules." The distance from an atom a to the next b on the right of it δ_{ab} may be in general different from the distance δ_{ba} from b to the next a atom in the same direction (Fig. 1). The sum $\delta_{ab} + \delta_{ba} = \delta$ will represent the lattice constant; the smaller of the two distances δ_{ab} and δ_{ba} if they are different can be considered as corresponding to that pair of atoms which actually forms a molecule. Denoting

Fig. 1.

the displacements of the atoms forming the k th molecule from their equilibrium positions with u_k and v_k respectively (we shall consider longitudinal displacements only) we can represent the potential energy of the whole system by the expression

$$U' = U - U_0 = \frac{1}{2} \sum_{kl} a_{kl} u_k u_l + \sum_{kl} c_{kl} u_k v_l + \frac{1}{2} \sum_{kl} b_{kl} v_k v_l \quad (2)$$

and write the equations of motion in the form

$$-m_a \frac{d^2 u_k}{dt^2} = \sum_l a_{kl} u_l + \sum_l b_{kl} v_l$$

$$-m_b \frac{d^2 v_k}{dt^2} = \sum_l c_{lk} u_l + \sum_l c_{kl} v_l$$

In case of an unlimited bar (k, l varying from $-\infty$ to $+\infty$) these equations admit the solution

$$u_k = A e^{i(p k - \omega t)} \quad v_k = B e^{i(p k - \omega t)} \quad (3)$$

representing waves of frequency $\nu = \omega/2\pi$ and length $\lambda = 2\pi\delta/p$ travelling in a definite direction with the velocity $w = \omega\delta/p$. Substituting these expressions in the preceding equations and taking into account the fact that the coefficients a_{nl} , b_{nl} and c_{nl} depend only upon the difference $l-n$ of the two indices, we get the following two equations for the (complex) amplitudes A and B :

$$\left. \begin{aligned} A a_p + B c_p &= A m_a \omega^2 \\ A c_p^* + B b_p &= B m_b \omega^2 \end{aligned} \right\} \quad (4)$$

where

$$\begin{aligned} a_p &= \sum_l a_{0l} e^{ip l}, \quad l_p = \sum_l b_{0l} e^{ip l}, \\ c_p &= \sum_l c_{0l} e^{ip l}, \quad c_p^* = \sum_l c_{0l} e^{-ip l} = \sum_l c_{0l} e^{-ip l}. \end{aligned} \quad (5)$$

Equating the determinant of (4) to zero, we obtain the following equation for the frequency

$$(a_p - m_a \omega^2)(b_p - m_b \omega^2) = c_p c_p^*$$

whence

$$\omega^2 = \frac{1}{2} \left(\frac{a_p}{m_a} + \frac{b_p}{m_b} \right) \pm \left[\frac{1}{4} \left(\frac{a_p}{m_a} - \frac{b_p}{m_b} \right)^2 + \frac{c_p c_p^*}{m_a m_b} \right]^{1/2}. \quad (6)$$

It can be easily shown that the negative sign corresponds to the elastical vibrations and the positive to molecular vibrations. The corresponding ratios of the amplitudes A and B are:

$$B^\pm : A^\pm = \frac{1}{2} \left(\frac{a_p}{m_a} - \frac{b_p}{m_b} \right) \mp \left[\frac{1}{4} \left(\frac{a_p}{m_a} - \frac{b_p}{m_b} \right)^2 + \frac{c_p c_p^*}{m_a m_b} \right]^{1/2} : - \frac{c_p}{m_a}. \quad (6a)$$

If the difference $(a_p/m_a) - (b_p/m_b)$ is very small in regard to $|c_p| (m_a m_b)^{1/2}$ this equation reduces to

$$B^\pm : A^\pm \cong \pm \left(\frac{m_b}{m_a} \right)^{1/2} \frac{|c_p|}{c_p} = \mp \left(\frac{m_b}{m_a} \right)^{1/2},$$

if one takes into account that the coefficient c must in this case be real and negative. This result corresponds to the usual approximation implying that in the case of molecular oscillations the atoms belonging to the same molecule are vibrating with opposite phases. The frequency of these vibrations is approximately given by

$$\omega^2 = \frac{1}{2} \left(\frac{a_p}{m_a} + \frac{b_p}{m_b} \right) + \frac{|c_p|}{(m_a m_b)^{1/2}}$$

and is considered to be independent of the "wave number" p (or $p\delta/2\pi$), which of course is a quite unjustified assumption.

In the case of an unlimited bar the number p remains arbitrary. If the bar consists of n molecules, then p can have only the following series of values $0, 2\pi/n, (2\pi/n) \cdot 2, \dots, (2\pi/n) \cdot (n-1)$. Of course, running waves of opposite directions and of the same length (corresponding to $p_1 + p_2 = 2\pi$) have to be combined in this case with the same (or rather conjugate complex) amplitude into standing waves.

The normal co-ordinates ξ are connected with the displacements u_k, v_k by means of the equations

$$\left. \begin{aligned} u_k &= \sum_p (\xi_p^+ A_p^+ + \xi_p^- A_p^-) e^{ipk} \\ v_k &= \sum_p (\xi_p^+ B_p^+ + \xi_p^- B_p^-) e^{ipk} \end{aligned} \right\} \quad (7)$$

where A_p^\pm, B_p^\pm denote the normalized solutions of the Eqs. (4). Solving (7) with respect to the ξ we get

$$\xi_p^\pm = \sum_k (u_k A_p^{\pm*} + v_k B_p^{\pm*}) e^{-ipk}. \quad (7a)$$

The co-ordinates ξ_p^+ refer to the "molecular" and ξ_p^- to the "elastical" vibrations.³

The expression (2) represents the change of the potential energy of the bar due to the displacement of the atoms. The value of this energy in the equilibrium state U_0 as well as the equilibrium distances δ_{ab} and δ_{ba} are determined from the conditions

$$\frac{\partial U_0}{\partial \delta_{ab}} = 0 \quad \frac{\partial U_0}{\partial \delta_{ba}} = 0.$$

Now the energy U_0 is slightly different for an excited and a non-excited bar; the same must therefore be true with respect to the distances δ_{ab} and δ_{ba} . The corresponding changes in the normal co-ordinates can be determined in the same way as in the case of a monatomic crystal, namely, putting $u_k = k \cdot \Delta \delta$ and $v_k = k \cdot \Delta \delta + \Delta \delta_{ab}$ in (7a). We shall thus get values¹ of the same order of magnitude both for $\Delta \xi^+$ and $\Delta \xi^-$. In view, however, of the greater frequency in the "molecular" vibrations, their role in the deactivation transitions may be expected to be more important than that of the elastic vibrations according to (S). The increase of frequency is partially reduced, at least for comparatively low temperatures, by the decrease of the average quantum number N (it must be born in mind that the latter refers not to the initial but to the final state, so that in the initial state N can be equal to 0, the corresponding vibrations appearing only after the transition).

We shall illustrate the above results by considering the special case $\delta_{ab} = \delta_{ba} = \frac{1}{2} \delta$ (model of a symmetrical crystal of the NaCl type). We shall further neglect the forces between all but the next atoms (which are assumed to be different) and write accordingly the potential energy U' in the form

$$U' = \sum_k \frac{1}{2} f [(u_k - v_k)^2 + (u_k - v_{k-1})^2 + (u_{k+1} - v_k)^2]$$

which gives through comparison with (2)

$$a_{kk} = b_{kk} = 2f, \quad c_{kk} = c_{k+1,k} = -f$$

all the other coefficients a, b, c vanishing.

³ If we wish to deal with standing waves instead of running ones, the factor $e^{\pm ipk}$ in the above formula has to be replaced by $\cos pk$.

We thus get, according to (5)

$$a_p = b_p = 2f, \quad c_p = -f(1 + e^{ip}), \quad c_p c_p^* = 2f^2(1 + \cos p) = 2f^2 \cos^2 \frac{p}{2}$$

whence with the abbreviations $1/\mu = (1/m_a) + (1/m_b)$ and $m = m_a + m_b$:

$$\omega^2 = \frac{f}{\mu} \left(1 \pm \left[1 - \frac{4\mu}{m} \sin^2 \frac{p}{2} \right]^{1/2} \right).$$

For small values of p , that is for large wave-lengths $\lambda = 2\pi\delta/p$, this reduces to

$$\omega_+ \cong \left(\frac{2f}{\mu} \right)^{1/2}, \quad \omega_- \cong \left(\frac{2f}{m} \right)^{1/2} \frac{p}{2}$$

the latter expression corresponding to a velocity of propagation

$$w = \frac{\omega_- \lambda}{2\pi} = \delta \left(\frac{f}{2m} \right)^{1/2}$$

independent of λ . As the wave-length decreases, ω_- increases and ω_+ decreases. For the shortest wave-length corresponding to $p = \pi$ we have

$$\omega_{+ \text{ min}}^2 = \frac{f}{\mu} \left(1 + \left(1 - \frac{4\mu}{m} \right)^{1/2} \right), \quad \omega_{- \text{ max}}^2 = \frac{f}{\mu} \left(1 - \left(1 - \frac{4\mu}{m} \right)^{1/2} \right).$$

In the particular case $m_a = m_b$ when the atoms a and b can be considered as identical, these two limits coincide (since $4\mu = m$) and the two spectra, the molecular and the elastical, coalesce into one single elastical spectrum determined by $\omega^2 = f/\mu(1 \pm \cos p/2)$ which is equivalent to the usual formula

$$\omega^2 = \frac{2f}{m} (1 - \cos p') = \frac{4f}{m} \sin^2 \frac{p'}{2}$$

with $p' = (2\pi/2n)s$, $s = 0, 1, 2, \dots, 2n-1$.

3. MOLECULAR VIBRATIONS AS EXCITATION WAVES

The opposite limiting case when the two atoms have a very much different mass or when the distance δ_{ab} is different from δ_{ba} so that the molecular structure is more or less preserved within the crystal (represented by our "bar"), the molecular oscillations can be treated by a method entirely different from the preceding one (which must be preserved for elastic oscillations) and quite similar to that which has been used to describe the motion of the electrons within the individual atoms. We can namely describe the state of an individual molecule by specifying its vibrational quantum number N , referring to this state as "normal" if $N=0$ and "excited" if $N>0$. The stationary states of the crystal will be then described by "excitation waves" quite analogous to those which were introduced for the description of the electronic state. In fact we have but to replace the atoms and electrons of our previous theory by molecules and atoms respectively, to get these new "mole-

cular" excitation waves. The latter will be represented by functions

$$\chi_p = \sum_k \frac{1}{n^{1/2}} e^{ipk} \phi_k \quad (8)$$

ϕ_k being the product of the oscillator wave functions, ψ_N for the separate molecules, supposed to be all in the normal state $N=0$ with the exception of the k th molecule which may be in a given (N th) excited state. The excitation wave defined by (8) corresponds to the "molecular oscillation wave" of the classical theory given above and associated with the normal co-ordinate ξ_p^+ defined by (7a). The quantum number N of the excited molecule defines the amplitude of the oscillations and must coincide with the quantum number of the quantized oscillator describing them. The method of the excitation waves is nothing but a first approximation given by the perturbation theory to the exact quantum treatment which in our case consists in the preliminary introduction of the normal co-ordinates and their subsequent quantization and which has been used in the preceding section. It may be remarked that this method cannot be applied to the "elastic oscillations" because they are determined *solely by interaction forces*, which can be dealt with as perturbing forces then only if there are other more powerful forces associated with the separate particles (i.e., forces holding the electrons within the atoms, or the atoms within the molecules).

The theory of the excitation waves as developed in I was restricted to the simplest special case of the excitation if a single atom. Its application to molecular vibrations implies therefore that the excitation is restricted to one molecule only. So long, however, as the molecular vibrations are considered as strictly harmonic this limitation has no practical significance, a complex excitation state corresponding to n_1 molecules having N_1 quanta, n_2 having N_2 quanta and so on being practically equivalent to a simple excitation state with one molecule having $n_1 N_1 + n_2 N_2 + \dots$ quanta (this multiple excitation is of course diluted over all the molecules in the sense that it is not associated with a particular molecule, but is, so to say, travelling from one molecule to another).

Applying to molecular vibrations the method of the simple excitation waves, one can treat the radiationless transitions of the energy of a crystal from molecular vibrations to elastic ones or *vice versa* (that is the exchange of energy between the normal co-ordinates ξ^+ on the one hand and ξ^- on the other) in exactly the same way, as this has been done above for radiationless electronic transitions. In the present case the direct coupling between the different elastic oscillations must play a much more important role with respect to the indirect coupling (provided by the change in structure which is produced by molecular vibrations) than in the case of electronic transitions, since the energy quantum of the molecular vibrations is not a 100 times but at most only 10 times as large as that of the elastic vibrations of maximum frequency.

The transitions of energy between different elastic oscillations (that is between different ξ^-) must of course entirely depend on direct coupling only.

Such transitions have been studied in detail by R. Peierls⁴ in connection with the theory of heat conduction in crystals.

The treatment of the molecular oscillations by the method of excitation waves entails some formal modifications of the theory of the radiationless electronic transitions so far as the electronic excitation energy is transformed into the molecular excitation energy.

We shall not stop, however, on this question here, and shall now proceed to the investigation of radiation transitions, i.e. transitions accompanied by the absorption or emission of light, with a view of introducing an important amendment to the results of the last section of I, dealing with such transitions.

4. SELECTION RULE FOR TRANSITIONS DUE TO ABSORPTION OF LIGHT; ANALYSIS OF THE SPECTRUM OF CRYSTALS AT VERY LOW TEMPERATURES

We shall again confine ourselves, for the beginning, to the case of a mono-atomic crystal, represented by a linear model and shall determine the probability of the absorption of light propagated in the direction of our "bar."

We shall first suppose the light wave to be harmonic (infinitely narrow spectral line) and travelling in the same way as if there were no bar, so that the electric intensity at a point x along the bar will be represented by

$$E = E^0 \cos 2\pi(\nu t - \alpha x) \quad (9)$$

its value at the k th atom thus being

$$E_k = E^0 \cos (\omega t - qk) \quad (9a)$$

where $\omega = 2\pi\nu$ and $q = 2\pi\alpha\delta = 2\pi\delta/\lambda$, $\lambda = c/\nu$ being the wave-length of the light in vacuo. Denoting the electric moment of the l th atom in the direction of E (which is of course perpendicular to X) with U_l , we get the following expression for the perturbation energy:

$$V = -\frac{E^0}{2} \sum_{l=1}^n U_l (e^{i(ql-\omega t)} + e^{-i(ql-\omega t)}). \quad (10)$$

If our bar was initially in the normal electronic state

$$\chi_0 = \chi_0^0 e^{-i2\pi W^0 t/\hbar}$$

(χ_0^0 being a function of the electron co-ordinates alone) the probability that it will be switched to the excited (sub) state $\chi_p = \chi_p^0 e^{-i2\pi W^p t/\hbar}$ without any alteration of the vibrational states is determined by the matrix element

$$V_{0p} = \int V \chi_0 \chi_p^* d\tau$$

where $d\tau = d\tau_1 \cdot d\tau_2 \cdot \dots \cdot d\tau_n$ is the volume element of the electronic configuration space ($d\tau_k$ referring to the k th atom). According to (10) and (8) (the latter expression holding both for electronic and molecular excitation waves

⁴ R. Peierls, Ann. der Physik, 1930.

with a corresponding meaning of the functions ϕ and ψ , see I), this matrix element assumes the form

$$V_{0p} = -\frac{E^0}{2(n)^{1/2}} \left[e^{-i(\omega+\omega_{0p})t} \sum_k \sum_l e^{i(p-k+q)l} \int U_l \phi_0^0 \phi_k^{0*} d\tau \right. \\ \left. + e^{i(\omega-\omega_{0p})t} \sum_k \sum_l e^{i(p-k-q)l} \int U_l \phi_0^0 \phi_k^{0*} d\tau \right]$$

where $\omega_{0p} = 2\pi(W_p - W_0)/h$ and $\phi_0^0 = \chi_0^0$. Now the integral $\int \mu_l \phi_0^0 \phi_k^{0*} d\tau$ can be easily shown to be different from zero in the case only if $k=l$ (cf. I. p. 20) in which case it reduces to

$$U^0(I, II) = \int U_k \psi_I^0(x) \psi_{II}^{0*}(k) d\tau_k$$

i.e., to the amplitude of the matrix element of the electrical moment of any one of the atoms for the normal and the excited state of this atom.

The preceding expression for V_{0p} is thus reduced to

$$V_{0p} = -\frac{E^0 U^0(I, II)}{2(n)^{1/2}} \left[e^{-i(\omega+\omega_{0p})t} \sum_k e^{i(p+q)k} \right. \\ \left. + e^{i(\omega-\omega_{0p})t} \sum_k e^{i(p-q)k} \right] \quad (11)$$

We need here only to consider the second term in the bracket for the first term will not contribute appreciably to the transition probability in the neighborhood of the "resonance condition" $\omega = \omega_{0p}$ or $h\nu = W_p - W_0$. In addition to this condition which, from the corpuscular viewpoint is interpreted as the equation of the conservation of energy and which would hold just as well in the case of a single atom, we have to consider in our case a second condition of the same "resonance" type, namely $p=q$, which corresponds to sharp maximum of the sum $\sum_k e^{i(p-q)k} = n$ (this maximum is sharper the larger the number of atoms). This second "resonance" condition can be interpreted as the equation of the conservation of *momentum* if we assume that an excitation wave can be associated with an "excitation quantum" similar to a light quantum and having a momentum h/λ where λ is the corresponding wave-length. It may be remarked that the energy of this excitation quantum whose motion represents the travelling of the excitation through the crystal—is not related to the frequency of the excitation wave but is equal to the difference between the energy of the excited and normal state.

The absorption of light by a crystal can be thus visualised from the corpuscular point of view as the transformation of the incident light quantum into an excitation quantum having the same energy and *momentum*.

From the wave point of view the latter condition amounts simply to the equality between the wave-length of the exciting light ($2\pi\delta/q$) and that of the resulting excitation wave ($2\pi\delta/p$).

This condition can be regarded as a kind of "selection rule" reducing the n spectral lines corresponding to transitions between the normal state and the n excited substates, to a single line, for which both the frequency (energy) condition $\nu = W_p - W_0/h$ and the wave-length (momentum) condition $\lambda_{\text{light}} = \lambda_{\text{exc}}$ are simultaneously satisfied.

It must be emphasized that the conditions $\nu = (W_p - W_0)/h$ and $\lambda_{\text{light}} = \lambda_{\text{exc}}$ are *not equivalent* to each other and actually provide two equations for the unambiguous determination of ν . We have in fact, according to Eq. (15) of part I (for the unidimensional case)

$$W_p = V_0 + 2 V_1 \cos p/2 \quad (12)$$

whence with the abbreviations $(V_0 - W_0)/h = \alpha$ and $2 V_1/h = \beta$

$$\nu = \alpha + \beta \cos p/2$$

On the other hand we have $\lambda_{\text{exc.}} = 2\pi\delta/p$ or, since $\lambda_{\text{exc.}} = \lambda_{\text{light}} = c/\nu$, $p = (2\pi\delta/c)\nu$ so that finally

$$\nu = \alpha + \beta \cos (\pi\delta/c)\nu \quad (12a)$$

This equation has in general only one solution which can be found to a first approximation by substituting in the right side of (12a) the "zero approximation" $\nu = \alpha$ (so long as β is small compared with α) which gives

$$\nu \cong \alpha + \beta \cos \frac{2\pi\delta\alpha}{c} \quad (12b)$$

Thus, contrary to the view expressed at the end of I, the absorption spectrum of a crystal so far as transitions from the normal state are concerned which are not accompanied by a change of the vibrational state, *should not consist of continuous bands corresponding to the excitation multiplets, but of single lines corresponding one to one to the absorption lines of an isolated atom.*

This result provides an explanation of the remarkable phenomenon referred to in I, that the absorption spectra of solid bodies which at ordinary temperatures consist of continuous bands, at very low (liquid hydrogen or liquid helium) temperatures become more or less *linear*, as those of gases.

In fact the band structure of these spectra at ordinary temperatures must be attributed entirely to vibrational transitions which accompany the electronic ones, and which we did not take into account in the preceding considerations. The probability that a number of "heat oscillators," elastic or molecular, will participate in the electronic transition associated with light absorption, is determined in exactly the same way as in the case of radiationless transitions; provided, namely, that each oscillator jumps over one step only, it is represented in the expression of the resulting transition probability by the square of the factor (1), or rather of the factor

$$n_{\mu} = \frac{\pi^2 m}{2h^2} (\Delta L) N_s \nu_s \quad (1')$$

the number n in the denominator of (1) being cancelled by the factor expressing the number of possible ways of choosing this oscillator (the total number p of the latter participating in the transition being represented by a factor $p!$ in the denominator of the resulting probability). Now since $hN_s\nu_s$ denotes the vibrational energy of the respective oscillator (without the constant part $\frac{1}{2}h\nu_s$) which rapidly decreases as the temperature approaches the absolute zero, it is clear that the participation of the heat oscillators in the electronic transitions must become less and less active, which will result in the gradual splitting up of the absorption bands into single lines.⁵

It must be remembered that N_s in the preceding expression denotes the vibrational quantum number of the initial state if it *decreases* during the transition ($N_s \rightarrow N_s - 1$); in the contrary case which is in general the more important one, N_s means the vibrational quantum number in the final state; for the absolute zero of temperature upward jumps of N_s are only possible with the final value $N_s = 1$ (since the initial is zero). The same formula (1') shows that in this case, i.e., with all the N_s equal to 1, the probability that an oscillator will participate in the transition is proportional to the square of its frequency. Therefore at very low temperatures practically oscillators of the highest frequency only i.e. the molecular oscillators, and to some extent the elastic oscillators with the highest frequency ν_{\max} ("characteristic frequency" of Debye), will participate in the transitions.⁶ In the case of a simple (monoatomic) crystal only the latter come into consideration. We are lead thus to expect that the absorption spectrum of a monoatomic (non-metallic) crystal at or near the zero point of temperature must consist of *groups* of lines, corresponding to the absorption lines of an isolated atom, each group consisting of a series of equidistant lines with the constant spacing $\Delta\nu = h\nu_{\max}$. The lowest frequency line must have the largest intensity for it must correspond to the purely electronic transition, the next one, with a shorter wave-length and smaller intensity to a transition associated with the upward jump of one oscillator, the next with a still shorter wave-length and still smaller intensity, to a transition associated with the upward jump of two oscillators and so on. These lines must have a sharp edge on the high-frequency side and a rather diffuse one on the other side (since elastic oscillators of lower frequency will also, to some extent, participate in the transitions).

So far as the "selection principle" derived above for a monatomic crystal (i.e. the condition $\lambda_{\text{light}} = \lambda_{\text{exc.}}$) remains valid for a diatomic one, which can easily be shown to be the case, the preceding analysis of the zero-point spectrum can be immediately extended on diatomic crystals. In this case each

⁵ At the same time will decrease the natural width of these lines which is proportional to the probability of a radiationless transition from the excited state into the normal one.

⁶ The predominance of these oscillators is insured not only by their higher frequency but also in a three dimensional crystal, by their larger number, the number of oscillators with a frequency between ν and $\nu + d\nu$ being proportional to $\nu^2 d\nu$.

group of lines corresponding to a particular absorption line of one of the atoms (if they are different⁷) must be subdivided into two groups, the spacing in the one being $h\nu_{\max}$ and in the other $h\nu_c$, ν_{\max} being as before the maximum frequency of the elastic spectrum, and ν_c the molecular vibration frequency. The lines of the second group can be expected to have larger intensities than those of the first. In both cases increasing frequency must correspond to decreasing intensity.

As the temperature increases the satellites, due to the participation in the transitions of the elastic oscillators, must become more and more diffuse on the short frequency side, owing to the rapid increase of the energy $N_s h\nu_0$ and consequently the "activity" (in the sense of their participations in the transitions) of the lower frequency oscillators until each group of lines will be transformed into a diffuse continuous band. Thus on our theory the continuous character of the absorption bands in the spectra of solid bodies at ordinary temperatures is to be ascribed to the equi-partition of energy between the elastic oscillators of different frequencies, resulting in an equal participation of all these oscillators in the transitions associated with the absorption of light.⁸

5. GENERALIZATION OF THE THEORY AND APPLICATION TO THE SCATTERING OF LIGHT

The conclusions of the preceding paragraph have been reached on the basis of a result ("selection principle") whose derivation has been neither general, for we have limited ourselves to a unidimensional model of a monoatomic crystal, that was supposed to be initially in the normal state, and did not take into account the vibrational motion, nor rigorous, for we have assumed that the incident light wave were travelling through the crystal, as if the latter was absent, and did not allow for the finite spectral width of this light.

We must now remove these defects and thereafter revise the above conclusions in the light of the improved theory.

(a) We shall examine first of all the generalization from the unidimensional to the three-dimensional crystal lattice. This generalization amounts to the replacement of the numbers k , specifying the position of a given atom in the lattice by triplets of numbers k_1, k_2, k_3 which can be considered as components of a vector k and a similar substitution of vectors p and q for the scalars p and q characterizing the wave-length of the excitation waves and of the light waves. The direction of these vectors defines the direction in which the respective waves are propagated; their magnitude is connected with the wave-length in the same way as before ($\lambda_{\text{light}} = 2\pi\delta/q$, $\lambda_{\text{exc.}} = 2\pi\delta/p$). The components of the vector p can of course assume values of the type $p_i = 2\pi r_i/n_i$ where r_i are integers and n_i denote the numbers of atoms along

⁷ If they are identical we have to deal with a molecular lattice and compare its spectrum, not with that of one of the atoms, but rather with that of an isolated non-rotating molecule.

⁸ Another cause of the broadening of the lines lies in the radiationless transitions from the excited state into the normal one, the probability of the the transitions being a measure of the breadth of the lines. It is, however, difficult to estimate the value of this breadth.

the different edges of the crystal (supposed to be of rectangular shape and to have a cubical lattice with the constant δ).

The formula (11) which serves to determine the transition probability will remain valid for the three-dimensional case if the product of p_k and q_k is replaced by the *scalar products* of the corresponding vectors. As a result we shall obtain our "selection principle" in the form $\mathbf{p} = \mathbf{q}$ expressing the equality not only of the magnitudes of the vectors \mathbf{p} and \mathbf{q} but also of their directions, or from the point of view of the quantum interpretation, the transformation of the incident light quantum into an excitation quantum with a momentum of the same magnitude and direction.

(b) The generalization of the preceding result for a diatomic (or many atomic) crystal is quite simple. We have, namely, seen that in case of *different* atoms the excitation waves for the atoms of one kind are to a first approximation completely independent of the presence of the atoms of the other kind. Equation (11) in the "vectorized" form will, therefore, apply to the atoms of each kind separately.

The situation is somewhat different if the atoms supposed to be of different kind differ only with respect to their position, but are actually of the same kind. This corresponds to a molecular lattice, such as the lattice of I_2 (solid iodine) for example. In this case it is convenient to replace the atoms as elements of the crystalline structure by the molecules and deal with the molecular vibrations in the same way as with the electronic ones, i.e. describe them by means of the excitation waves.

(c) This remark brings out the following interesting point. We have just shown that the excitation waves must be associated with "excitation quanta" possessing a momentum in the direction of propagation, and that the "selection principle" $\mathbf{p} = \mathbf{q}$ can be regarded as the equation of the conservation of momentum in the process of the absorption of a light quantum. Now if molecular vibrations (both in the case of equal or different atoms) are described by excitation waves, it seems possible to combine an electronic transition with a transition of some molecular vibration type in such a way that the equation $\mathbf{q} = \mathbf{p}$ should be replaced by an equation $\mathbf{q} = \Sigma \mathbf{p}$ for the different excitation waves involved in the transition, so that the electronic transitions will no longer be restricted by the above selection principle.

This argument is, however, erroneous. Let us remark first of all that if a few different types of excitation waves (corresponding to states with approximately the same energy) would be generated simultaneously forming a combined wave of the type $\chi = c' \chi_{p'} + c'' \chi_{p''} + \dots$ the momentum equation would run $\mathbf{q} = |c'|^2 \mathbf{p}' + |c''|^2 \mathbf{p}'' + \dots$. It can further be easily seen that it should be fulfilled for each of the constituting waves (representing a stationary excited state) separately, so that $\mathbf{q} = \mathbf{p}' = \mathbf{p}'' = \dots$. Since $|c'|^2 + |c''|^2 + \dots = 1$ the preceding equation actually reduces to $\mathbf{q} = \mathbf{p}$ for any one of the waves.

It must finally be born in mind that such excitation waves can be generated only for which the matrix element of the electric moment / (I, II) of an atom, or a molecule, is different from zero. In case of a diatomic homopolar

crystal of the type of I_2 this condition would obviously not be satisfied for excitation waves of a purely molecular vibration type. In general the proportionality of V_{0p} to $U(I, II)$ shows that excitation waves can be generated only which correspond to the optically excitable states of the separate atoms or molecules of which the crystal is built up.

It follows from the preceding considerations that the vibrational motion of the atoms (or molecules) in a crystal, or the transitions from one vibrational state to another, which may accompany the electronic transitions, do not impair the "selection principle" provided by the equation $q = p$ for these electronic transitions.

This result requires but a very slight amendment in connection with the following circumstances. In consequence of the vibrational (heat) motion the atoms no longer form a regular lattice, which they were assumed to form in the derivation of the above equation. Taking again for the sake of simplicity the case of a linear lattice we can define the displacements of the atoms from their equilibrium positions by adding to their ordinal (integral) numbers k small fractions u_k , whose products with δ are equal to the respective displacements. Now u_k can be represented as a superposition of Debye waves in the form

$$u_k = \sum_{p'} a_{p'} e^{i(p'k - \omega' t)}$$

where $a_{p'}$ are very small amplitudes.

The factors $e^{\pm i q l}$ in the perturbation function (10) must be replaced accordingly by $e^{\pm i q(l + u_l)}$ or, since u_l is very small, by $e^{\pm i q l}(1 \pm i q u_l)$. Effecting the same substitution in (11) we must replace $\omega - \omega_{0p}$ by $\omega - \omega_{0p} - \omega'$ and the sum $\sum_k e^{i(p-q)k}$ whose maximum value has to be sought for the determination of our "selection principle" by

$$\sum_k e^{i(p-q)k} - i q \sum_{p'} a_{p'} \sum_k e^{i(p-p'-q)k}. \quad (13)$$

The latter expression has besides the main maximum for $p = q$ secondary maxima for $p = q + p'$ which can be interpreted from the quantum corpuscular point of view as the equations for the conservation of momentum of the light quanta, excitation quanta and "heat-quanta" or "sound-quanta" corresponding to the Debye waves. The resonance condition for the frequencies $\omega = \omega_{0p}$ is in *all cases* replaced by $\omega = \omega_{0p} + \omega'$ which can be interpreted as the energy equation for the above three types of quanta.⁹ This equation is consistent both with the equation $p = q + p'$ and with the equation $p = q$ which means simply that in the transition process two standing sound waves of opposite directions, forming a standing wave with no resulting momentum, are generated. Since the main maximum of the expression (13) which is approximately equal to the number of atoms n is much more important the secondary ones

⁹ These results are identical with those obtained by Ig. Tamm in his rather elaborate theory of the scattering of light in crystals. The notion of "sound quanta" is also due to this author.

which have the order of magnitude of nqa , the vibrational motion of the atom has practically but a very small influence on the position of the groups of absorption lines in the spectrum of the crystal. Nevertheless we must be prepared to find with rising temperature new groups in the form of continuous bands to appear which correspond to the "unusual" selection rules $p = q + p'$ and whose intensity must increase linearly with the absolute temperature (in the equipartition region).

(d) The last generalization that we have to carry out is the allowance for absorption transitions not from the normal state to an excited one, but from one excited $\chi_{p'}$ state to another $\chi_{p''}$ (with a higher energy). It is clear that the preceding results will still be valid for this case if we replace $\omega_{0p} = 2\pi(W_p - W_0)/h$ by $2\pi(W_{p''} - W_{p'})/h$ and the vector p by the vector difference $p'' - p'$, so that the two "resonance conditions" for the frequencies and the wave-lengths, i.e., the equations of conservation of energy and momentum, assume the form

$$h\nu = \frac{W_{p''} - W_{p'}}{h}, \quad q = p'' - p' \left(q = \frac{2\pi\delta}{\lambda_{\text{light}}}, \quad p' = \frac{2\pi\delta}{\lambda_{\text{exc}}}, \quad p'' = \frac{2\pi\delta}{\lambda_{\text{exc}}''} \right)$$

if the effects of the heat motion and if the corresponding (vibrational) transitions are neglected.

The preceding results must obviously hold not only for the absorption but also for the emission of light (in a definite direction) and can be still further generalized to allow for its scattering (by replacing ν and q by the differences $\nu' - \nu''$ and $q' - q''$ for the incident and scattered light). We shall not engage into a detailed investigation of this question and shall satisfy ourselves with the following remarks. *First*, that the present theory of light scattering in crystals so far as the relations between energy (frequency) and momentum (wave number) are concerned is the exact analogon to Schrödinger's theory of the Compton effect, i.e., of the scattering of light by free electrons, the electron waves being replaced in our case by the excitation waves. In fact the above considerations form the basis of a theory of the Raman effect, which, as well known, is the analogon of the Compton effect for bound electrons and atoms bound together into molecules. The analogy between the two effects is most clearly brought out by means of the conception of the excitation waves as the analogon of cathode waves. *Second*, that the Raman shift of the frequency of the incident light $\nu' - \nu''$ can be calculated either by considering molecular vibrations by the method of excitation waves, or by incorporating them into the heat motion and allowing for the latter according to section (c). *Third*, that the development of the theory sketched above in the quantitative direction, i.e. to enable one to calculate the intensity of the scattered lines, both shifted and unshifted, does not present any difficulty, for this calculation can be easily reduced to the corresponding calculation for an isolated atom or molecule (if the molecular vibrations are described by excitation waves).

6. IMPROVEMENT OF THE THEORY; FINITE WIDTH OF THE EXCITATION LINES, AND INFLUENCE OF THE DAMPING OF THE LIGHT WAVES

We must now turn to the improvement of our theory of light absorption with respect to rigour.

(a) We have assumed the light to be strictly homogeneous, which of course is not the case. This circumstance can, however, easily be taken into account in exactly the same as this is done for a single atom. The result will be that the probability of the transition $\chi_0 \rightarrow \chi_p$ in the case of a linear crystal lattice considered in §4 will be equal to the probability of the corresponding transition for a single atom (which is proportional to $|U(I, II)|^2$) multiplied with the square of the modulus of the factor

$$S = \frac{1}{n^{1/2}} \sum_{k=1}^n e^{i(p-q)k} \quad (13a)$$

(cf. Eq. (11)). The maximum value of the sum $\sum e^{i(p-q)k}$ for $p=q$ being n , the total probability for the light absorption by the crystal turns out to be equal, for the lines "allowed" by the "selection rule" $p=q$, to n times the corresponding probability for a single atom. This is just what would be expected on the assumption that the atoms of the crystal do not influence the propagation of the light waves.

The result obtained, which obviously holds for a three-dimensional crystal lattice just as well as for a unidimensional one, requires strictly speaking, some modification. In calculating the transition probability under the action of a spectral line of finite width, one has to take into account the variation of $q = 2\pi\delta/\lambda = \delta\omega/c$ in the factor (12a) with the frequency of the light $\nu = \omega/2\pi$. This would amount to replacing the product of $|S|^2$ with the integral

$$\int_{-\infty}^{+\infty} \left| \frac{e^{i(\omega - \omega_{0p})t} - 1}{\omega - \omega_{0p}} \right|^2 d\omega$$

occurring in the theory of light absorption by a single atom by the integral

$$\int_{-\infty}^{+\infty} \left| \frac{e^{i(\omega - \omega_{0p})t} - 1}{\omega - \omega_{0p}} \right|^2 |S|^2 d\omega$$

It can be easily shown, however, that maximum of $|S|$ about $q=p$ is much flatter than the maximum of the function

$$\left| \frac{e^{i(\omega - \omega_{0p})t} - 1}{\omega - \omega_{0p}} \right|^2 = \frac{\sin^2 (\omega - \omega_{0p})t/2}{((\omega - \omega_{0p})/2)^2}$$

about the corresponding point $\omega = \omega_{0p}$ so that in carrying out of the integration $|S|^2$ can be replaced by its maximum value (n) corresponding to $\omega = \omega_{0p}$ with a proper choice of p , of course. The dependence of $|S|^2$ on $q-p$ can be easily determined. We have namely for a unidimensional lattice if k is varied from 0 till $n-1$

$$S = \frac{1}{n^{1/2}} \frac{e^{i(p-q)n} - 1}{e^{i(p-q)} - 1}$$

whence

$$|S|^2 = \frac{1}{n} \frac{\sin^2 n(p-q)/2}{\sin^2 (p-q)/2} \quad (13b)$$

The effective width of the maximum of $|S|^2$ can thus be determined for a definite value of q and a variable p by

$$\Delta(p-q) = \Delta p \cong 2\pi/n$$

or, since $p = 2\pi\delta/\lambda_{\text{exc}}$ (λ_{exc} = wave-length of the excitation wave)

$$\frac{|\Delta\lambda_{\text{exc}}|}{\lambda_{\text{exc}}} = \frac{\lambda_{\text{exc}}}{n\delta} = \frac{\lambda_{\text{exc}}}{L} = \frac{\lambda_{\text{light}}}{L} \quad (14)$$

where $L = n\delta$ is the total length of the lattice.

This result can be easily generalized for the case of a three-dimensional lattice, L denoting in this case one average linear dimension of the latter. The width of the absorption region, i.e., the frequency interval $\Delta\nu$ for which transitions from the normal state to excited sub-states can take place according to our "unsharp" selection rule is given according to (12) by

$$\Delta\nu = \frac{\beta}{2} \sin \frac{p}{2} \Delta p$$

that is

$$\Delta\nu = \frac{\pi V_1}{hn} \sin \frac{\pi\delta}{\lambda} \quad (14a)$$

where λ can be identified with the wave-length of the light. Since δ/λ is for ordinary light a very small quantity we can put $\sin(\pi\delta/\lambda) = \pi\delta/\lambda$ and consequently

$$\Delta\nu = \frac{\pi^2 V_1}{h} \frac{\delta}{L} \quad (14b)$$

Thus the width of the absorption lines, so far as the vibrational transitions are not taken into account, remains very small at least for crystals of ordinary size. The incompleteness of "resonance" with respect to the wave-lengths, i.e., the departure of $\lambda_{\text{light}} - \lambda_{\text{exc}}$ from zero, does not therefore contribute appreciably to the width of the lines. At very low temperatures this width must be determined mainly by the probability of the radiationless transitions, whereas at higher temperatures the linear pattern of the spectrum is wiped out by the participation of the low frequency heat (sound) vibrations in the transitions as has been explained above (§4).

(b) It remains for us now to take into account the fact that the propagation of light in a real three-dimensional crystal is substantially affected by the latter, especially in the region of selective absorption, with which we are particularly interested. This influence can be accounted for by replacing the vacuum wave-length of the light λ_0 or the corresponding quantity $q = q_0 = 2\pi\delta/\lambda_0$ by a certain complex quantity $q = q_1 - iq_2$ determining the effective wave-length $\lambda_1 (q_1 = 2\pi\delta/\lambda_1)$ and the absorption coefficient q_2/δ .

In the case of the unidimensional lattice ("bar") considered above, the intensity factor (13a) assumes under this condition the form

$$S = \frac{1}{n^{1/2}} \frac{e^{i(p-q_1-q_2)n} - 1}{e^{i(p-q_1)-q_2} - 1}$$

whence

$$|S|^2 = \frac{1}{n} \frac{1 - 2e^{-q_2n} \cos(p - q_1)n + e^{-2q_2n}}{1 - 2e^{-q_2} \cos(p - q_1) + e^{-2q_2}}$$

For large values of n this reduces to

$$|S|^2 = \frac{1}{n} \frac{1}{1 - 2e^{-q_2} \cos(p - q_1) + e^{-2q_2}} \quad (15)$$

the maximum of this expression for $p - q_1 \cong 0$

$$|S|^2 = \frac{1}{n(1 - e^{-q_2})^2} \quad (15a)$$

being of course smaller and flatter than in the case of $q_2 = 0$. The flatness of this maximum must increase the width of the absorption lines and might in fact lead to their transformation in comparatively broad bands even without the participation of the low frequency vibrations. The width of the maximum of $|S|^2$ may be roughly put equal to q_2 if q_2 is sufficiently small, which gives for $\Delta\nu$ the effective width of the absorption line, the expression

$$\Delta\nu \cong \frac{V_1}{h} q_2 \sin \frac{p}{2} = \frac{\pi V_1 q_2 \delta}{h\lambda} \quad (16)$$

The ratio q_2/δ represents the value of the absorption coefficient of the light per unit length of path and its product with λ , $q_2\lambda/\delta = \mu$ the absorption coefficient per wave-length. Substituting this in the preceding formula we get

$$\Delta\nu = \frac{\pi V_1}{h} \mu \left(\frac{\delta}{\lambda} \right)^2 \quad (16a)$$

This formula shows that unless μ is unreasonably large $\Delta\nu$ remains actually small. It may be remarked that the ratio V_1/h represents a frequency which is about at least 10 times smaller than the frequency of ordinary light.

The preceding results can be easily generalized for the case of an ordinary three-dimensional crystal.

(c) In conclusion the following point should be noted. Since the resonance conditions for the frequencies and for the wave-lengths are both unsharp, the excitation state of the crystal induced by the absorption of light must be represented not by *one* definite excitation wave, but by a superposition of a number of such waves with approximately equal lengths and frequencies, i.e. by a group of excitation waves. The corresponding group velocity can be considered as the velocity with which the "excitation quantum," i.e., the excitation state supposed to be localized in a definite atom and described as a corpuscle, should travel through the crystal (cf. I, §2).

THE CRYSTAL LATTICE OF ANHYDROUS SODIUM SULPHITE, Na_2SO_3

By W. H. ZACHARIASEN AND H. E. BUCKLEY
UNIVERSITY OF CHICAGO AND UNIVERSITY OF MANCHESTER

(Received April 11, 1931)

ABSTRACT

The crystal structure of Na_2SO_3 has been investigated by means of the Laue, the ionization, the rotation and the powder methods. The hexagonal unit cell containing two molecules was found to have dimensions: $a=5.441\text{\AA}$ $c=6.133\text{\AA}$. The observations seemed to be in conflict with all hexagonal and trigonal space groups. The difficulty was, however, overcome by assuming the crystals to be twins with the c -axis as twinning axis. The space group C_{3v}^1 was under this assumption found to be the only possible one. All parameters involved were determined from the observed intensities with the following result:

4 atoms Na in position $1a$ (000), $1b$ ($00\frac{1}{2}$) and $2d$ ($\frac{1}{3}\frac{2}{3}u_1$), ($\frac{2}{3}\frac{1}{3}\bar{u}_1$) with $u_1=0.67$

2 atoms S in positions $2d$ ($\frac{1}{3}\frac{2}{3}u_2$), ($\frac{2}{3}\frac{1}{3}\bar{u}_2$) with $u_2=0.17$

6 atoms O in positions $6g(xy\bar{z})$, ($y-x, \bar{x}, z$), ($\bar{y}, x-y, z$), ($\bar{x}\bar{y}\bar{z}$), ($x-y, x, \bar{z}$), ($y, y-x, \bar{z}$) with $x=0.14$, $y=0.40$, $z=0.25$.

Two of the Na atoms are surrounded by 6 oxygens at a distance 2.469 \AA ; while the remaining two sodium atoms are surrounded by 3 oxygens at a distance 2.461 \AA and by 3 at 2.870 \AA . The structure shows the presence of groups SO_3 . The distance from sulphur to the 3 surrounding oxygens is 1.39 \AA , while the oxygens in the equilateral triangle have a distance of 2.24 \AA . The sulphur atom has a displacement of 0.51 \AA out of the plane of the oxygens. The form of the SO_3 -group is thus like a low trigonal pyramid, being of the same type previously found for the groups $(\text{ClO}_3)^-$, $(\text{BrO}_3)^-$, $(\text{AsO}_3)^{3-}$ and $(\text{SbO}_3)^{3-}$.

1. INTRODUCTION

CRYSTALS of anhydrous sodium sulphite were first prepared and described by H. Hartley and W. H. Barrett.¹ The symmetry is reported as hexagonal, with an axial ratio $c/a=1.1246$. The crystals are short prisms with predominating forms (10.0) and (00.1) small faces (10.1), (10.2) and very small (11.1) faces. Further observations by Hartley and Barrett are: perfect cleavage parallel to (00.1); birefringence strong, negative; density at 15°C, 2.633.

2. OBSERVATIONS

Our chief interest in the x-ray analysis of the Na_2SO_3 was the determination of the shape and dimensions of the SO_3 -group. In the following paragraphs we will describe the complete determination of the crystal structure. The investigation was started at the University of Manchester, where part of the observations were taken. Additional observations were collected in Ryerson Physical Laboratory, University of Chicago, where the investigation was completed.

¹ Hartley and Barrett, Trans. Chem. Soc. (London) 95, 1178 (1909).

Due to certain difficulties met during the investigation (see section 4), it became obvious that we must secure unusually reliable sets of observations, and apply as many different methods as possible. Our observations consist of the following.

(1) Complete rotation photographs and oscillation photographs around the hexagonal axis, and around the two different sets of horizontal axes. Oscillation angles of 5° , 15° and 30° were used. Crystal to plate distance was 5.0 cm. Radiation: $\text{MoK}\alpha$. Bernal's² graphical method of indexing the reflection spots was used throughout, thereby securing the most reliable indexing. In order to test the absence or presence of important reflexions many long exposures with an oscillation angle of 5° were taken.

(2) Laue photographs perpendicular to (00.1) and (10.0), and inclined a few degrees to the former directions. The photographs were indexed by converting the diagrams into gnomonic projection. The lower wave-length limit in the incident beam was tested on a number of known crystals.

(3) Intensity measurements on the ionization spectrometer of all reflections $hk.0$ up to 33.0 and of the reflexions $00.l$. The series of intensities $hk.0$ was transformed into absolute measure by a method described in section 4, below. The crystal was completely bathed in the x-ray beam; the observed intensity was taken proportional to

$$|F|^2 \frac{1 + \cos^2 2\theta}{\sin 2\theta},$$

where $|F|$ is the structure amplitude. $\text{MoK}\alpha$ radiation was used.

(4) Powder photographs with a high resolving camera, with sodium chloride as reference substance.³ The unit cube of sodium chloride was assumed to have the edge $a = 5.628\text{\AA}$. The wave-length used was taken as $\text{MoK}\alpha_1 - \lambda = 0.70783\text{\AA}$.

3. THE UNIT CELL AND SPACE GROUP CONSIDERATIONS

All observations agree with the following hexagonal cell:

$$a = 5.441 \pm 0.004\text{\AA} \quad c = 6.133 \pm 0.007\text{\AA} \quad c/a = 1.127$$

The correctness of the unit cell was carefully tested by means of long-exposure Laue photographs. No reflection spots could be found which indicated a larger unit cell than the one given above. By means of the directly determined density we find $1.98 \sim 2$ molecules of Na_2SO_3 connected with each unit cell. The calculated density for two molecules is 2.66.

The Laue photographs and the oscillation photographs possess the symmetry of the space groups C_{3h}^n , C_6^n and C_{6h}^n . Vertical planes of symmetry are definitely not present.

A further limitation of the space groups was obtained through observations of the spectra $00.l$. At ordinary exposures only the even order reflections from the base appear in the oscillation photographs. However, on several oscillation diagrams taken with 5° oscillation angle and long exposures the reflexion 00.3 was unmistakably present. These observations rule out all space groups save C_{3h}^1 , C_6^1 and C_{6h}^1 .

² Bernal, Proc. Roy. Soc. London A113, 117 (1926).

³ We are indebted to Mr. F. Barta for taking the powder photographs.

4. THE DETERMINATION OF THE STRUCTURE

From an inspection of all our observations according to the four different methods certain regularities in the observed intensities at once become apparent, and will have to be accounted for by the atomic arrangement. We will consider only the intensities of reflections occurring at large values of $\sin\theta/\lambda$. These regularities we have collected in the following table:

I Reflexions $hk.0$

- | | |
|---|----------------------------------|
| (a) $2h+k=3n$ ($n=0, 1, 2, \dots$) | Intensities are very strong |
| (b) $2h+k \neq 3n$ ($n=0, 1, 2, \dots$) | Intensities are very weak or nil |

II. Reflexions $hk.l$ with even l .

- | | |
|---|--|
| (a) $2h+k=3n$ ($n=0, 1, 2, \dots$) | Intensities are strong for $l=6$ and very weak or nil for $l=2, 4, 8$, |
| (b) $2h+k \neq 3n$ ($n=0, 1, 2, \dots$) | Intensities are very strong for $l=2, 4, 8$; very weak or nil for $l=6$ |

III. Reflexions $hk.l$ with odd l .

Intensities are very weak or nil

These regularities are valid with no exceptions at large values of $\sin\theta/\lambda$, but do not fit the observations quite so well at small values of $\sin\theta/\lambda$ although giving a fairly good agreement. There is only one way of explaining this fact: the regularities given above must be characteristic of the cation lattice, but not for the oxygen lattice. Therefore the regularities will hold absolutely at large values of $\sin\theta/\lambda$, where the influence of the oxygen lattice with good approximation can be left out of consideration; but at small values of $\sin\theta/\lambda$ these regularities will be destroyed to some extent through the overlapping influence of the oxygen lattice.

In the unit cell we have 4 Na and 2 S atoms. As a first approximation we will consider the scattering power of sodium and sulphur to be the same. Our first problem will thus be to arrange 6 cations in the cell in such a way that the observed regularities in intensities of reflections are accounted for. (It has to be remembered that these 6 cations are of two kinds, so they cannot all be structurally equivalent.)

The regularity Ia and Ib tells us that the cations are evenly distributed on the 3 available threefold axes. As the c -axis has a length of only 6.13Å, it is obvious that only 2 cations can lie on each axis, for otherwise cations would come closer than 2.04Å, which is highly improbable. The positions of the cations are consequently according to regularity I: $00z_1, 00z_2, \frac{1}{3}\frac{2}{3}z_3, \frac{1}{3}\frac{2}{3}z_4, \frac{2}{3}\frac{1}{3}z_5, \frac{2}{3}\frac{1}{3}z_6$.

The regularity III shows that the cations are situated along the threefold axes at intervals of $c/2$. Thus: $z_2 = z_1 + \frac{1}{2}, z_4 = z_3 + \frac{1}{2}, z_6 = z_5 + \frac{1}{2}$.

Finally the regularity given under II tells us that the cations are arranged in layers parallel to the c -face coming at intervals of $c/6$. We have thus: $z_3 = z_1 + \frac{2}{3}, z_5 = z_1 + \frac{1}{3}$ and the coordinates of the cations must be:

$$(00z)(00z + \frac{1}{2})(\frac{1}{3}\frac{2}{3}z + \frac{2}{3})(\frac{1}{3}\frac{2}{3}z + \frac{1}{6})(\frac{2}{3}\frac{1}{3}z + \frac{1}{3})(\frac{2}{3}\frac{1}{3}z + \frac{5}{6}).$$

This result is rather astonishing. The symmetry of the cation lattice is

that of D_{3d} only, while the observed symmetry is that of C_{6h} . We have as a matter of fact shown that no space group in the hexagonal and trigonal systems can account for the observations. The assumptions upon which we have based our deductions obviously cannot be correct. We have accordingly made a diligent search for a plausible explanation of the contradiction which exists between the observations.

An inspection of all our observations left no doubt as to the reported symmetry, neither could we find any other way of explaining the observed regularities than the one given above. The possibility of a bigger cell had also to be rejected from our observations. The assumption of another symmetry system likewise is highly improbable (it had to be either monoclinic or triclinic) with the nice development of the faces and the definitely uniaxial optical properties. Nor have we any justification for mistrusting the space group theory. We found rather that the only plausible explanation was to assume that all our observations were taken not on single crystals but on twins. We must emphasize, that we have not succeeded in finding direct evidence with which to back this assumption. Nevertheless the good agreement we have obtained between observed and calculated intensities assuming twinned crystals, as well as the plausibility of our final structure, must be taken as an indirect proof of the correctness of our assumption.

If the crystals are twins with the c -axis as twinning axis, the symmetry of our photographs would also be in agreement with that of the space groups C_3^n and C_{3i}^n . Only C_3^1 and C_{3i}^1 can account for the observations in the 00.1 spectra. *The distribution of the cations which we determined from the observed regularities also can be obtained from the special positions of these space groups.* The only difference between C_3^1 and C_{3i}^1 is the additional center of symmetry in the latter.

The oxygen atoms will have to lie in general positions (xyz) as no vertical planes of symmetry have been observed in the diagrams. The vertical distribution of the oxygen atoms with regard to the cation positions can easily be found from the spectra 00.1. The only odd order reflexion from the c -face which we observed is 00.3. This means that the oxygen atoms are lying in two layers parallel to the c -face at a distance of $c/2$. The fact that we have observed 00.3 with very small intensity cannot be interpreted as meaning that the oxygen layers have a distance slightly different from $c/2$, as we did not observe 00.5. But we must ascribe the presence of 00.3 to the difference in scattering power of Na and S, which means that the two sulphur atoms must lie on 2 different threefold axes. From the observed intensities of the even orders of 00.1 and the known distribution of the cations along the c -axis we find that the oxygen layers parallel to the c -face must be displaced an amount $c/12$ against the cation layers. Summarizing our considerations so far we have found that the space group is C_3^1 or C_{3i}^1 . We know the positions of the cations and the distribution in the c -direction of the oxygens referred to the cation lattice.

We have tried both space groups and finally selected C_{3i}^1 as the correct one. In fact a trial with C_3^1 showed that in order to get good agreement we had

to choose such values of the parameters as would give the symmetry of C_{3i}^1 . The remaining unknown parameters in the structure were easily determined by means of the observed intensities.

As a final result we arrived at the following crystal structure which gave the best agreement with the observed intensities:

Space group C_{3i}^1 .

Na in $1a: (000) + 1b (00\frac{1}{2}) + 2d (\frac{1}{3} \frac{2}{3} u_1) (\frac{2}{3} \frac{1}{3} \bar{u}_1)$ with $u_1 = 240^\circ$

S in $2d: (\frac{1}{3} \frac{2}{3} u_2) (\frac{2}{3} \frac{1}{3} \bar{u}_2)$ with $u_2 = 60^\circ$.

O in $6g \pm (xyz) (y-x, \bar{x}, z) (\bar{y}, x-y, z)$ with $x = 50^\circ$ $y = 145^\circ$ and $z = 90^\circ$.

The very good agreement between observed and calculated intensities is seen from an inspection of the tables.

The F -curves used are given in Table VI. They are essentially the same as the Na, Cl and O F -curves used by one of us in the determination of structure of NaClO_3^4 and NaClO_4^5 .

The relative intensities of the spectra $hk.0$ measured on the ionization spectrometer were transformed into absolute values by the following consideration; We assumed that the structure amplitude of the reflexion 33.0 was equal to 4 Na + 2 S (chemical signs mean scattering power at the value of $\sin\theta/\lambda$ under consideration), as we with good approximation can leave the oxygen contribution out of consideration for such high values of $\sin\theta/\lambda$. All the observations were therefore reduced in such a way as to give an observed structure amplitude for 33.0 equalling the theoretical contribution of

$4\text{Na} + 2\text{S}$, which we get from our *F*-curves. It will be seen from Tables I and II that extinction effects obviously have reduced the intensity of the stronger reflexions to a certain extent.

Due to the twinning with the *c*-axis as twinning axis, the reflections hkl and $h\bar{k}l$ having different intensities will fall on the same spot in all the photographs.

DISCUSSION OF THE STRUCTURE

In Fig. 1 is given a projection of the structure on the *c*-face. In the structure we can pick out groups SO_3 . The structure of the SO_3 -group is the one predicted by one of us.⁶ The characteristic feature of the SO_3 -group which distinguishes it from the CO_3 and NO_3 groups is the fact that the sulphur atom is displaced an amount $\Delta = 0.51\text{\AA}$ out of the plane of the oxygen atoms. Analogous results have been found for other groups RO_3 .⁶ A more accurate

⁶ W. H. Zachariasen, Vid. Akad. Skr. I Kl. No. 4 p. 142, 1928 Oslo; Zeits. f. Krist. 71, 527 (1929).

discussion of these results will be given in a following paper by one of us. The distance S-O is 1.39A.

There are two kinds of Na atoms in the structure, but both show the coordination number 6. The sodium atoms in positions (000) ($00\frac{1}{2}$) are surrounded by 6 oxygens forming the corners of a nearly regular octahedron, the distance Na-O being 2.469A. The sodium atoms of the other kind have 3 oxygens at a distance 2.461A and 3 at a distance 2.870A. This oxygen octahedron is much distorted, and the sodium does not lie accurately in the center. The SO_3 -groups share only corners with the Na_I -octahedra, while a face is shared with the Na_{II} -polyhedra. It is obvious that this sharing of a face in the

Fig. 1. Projection of the structure on (00.1). Numbers represent height of atoms above (00.1)-plane in A. Valency bonds are represented by connection lines.

latter case will cause some deformation.⁷ In the first place we should expect a shortening of the edges bounding the shared face, that is the O-O distance in the SO_3 -group will be shorter than normally. But we also should expect a displacement of the cations due to the one-sided configuration. This displacement we should expect to be greater for the cation with small valency; i.e., we should expect the sodium to be displaced in a direction away from the shared face. All these deformations are actually present: the displacement of the sodium atoms results in the two distances to oxygen. The shortening of the edges bounding the shared face will be noticed by a comparison of the SO_3 -

⁷ L. Pauling, Journ. Amer. Chem. Soc. 51, 1021 (1929).

group with the ClO_3 -group. One finds namely that the O-O distance in the SO_3 -group is smaller than in the ClO_3 -group.

The reported strong negative birefringence of the crystals is a result of the fact that all the SO_3 -groups are arranged with the plane of the oxygens parallel to the c -face. From a determination of the refractive indices one should be able to give an estimate of the O-O distance in the group. The cleavage parallel to the c -face is also in accordance with the structure.

Empirical observation shows the twinning probably is due to the existence of pseudo-elements of symmetry in the crystal structure. In the Na_2SO_3 -structure the c -axis will be a pseudo twofold screw axis so the formation of twins with the c -axis as twinning axis can be explained. The fact that all the crystals we have examined according to our interpretation of the observations must be twins has worried us, and we must admit that we very strongly feel the lack of direct proof of the assumed twinning.

We tried to prepare etching figures on the crystals we had at our disposition. The result was not good but the figures we obtained did seem to indicate a polarity of the crystals. The symmetry of C_{3i}^1 does not give etching figures with the symmetry observed. It is a well-known fact however, that there are many examples where the etching figures indicate lower symmetry than that of the crystal. The results of etching experiments are thus not reliable.

The intensity calculations on the basis of our structure have, however, given so good agreement with all the observations we have collected that the principal correctness of our structure does not seem to be in doubt.

We are very much indebted to Dr. Hartley for providing us with crystals of Na_2SO_3 .

THE CRYSTAL STRUCTURE OF POTASSIUM PERMANGANATE

By R. C. L. MOONEY

RYERSON PHYSICAL LABORATORY, UNIVERSITY OF CHICAGO

(Received March 30, 1931)

ABSTRACT

The crystal structure of potassium permanganate was determined from Laue and x-ray single crystal oscillation photographs. It was found that the unit cell is orthorhombic, contains four molecules, and has the dimensions:

$$a = 9.09\text{\AA} \quad b = 5.72\text{\AA} \quad c = 7.41\text{\AA}$$

The symmetry of the crystal is $2Di-16$ (V_h^{16}), and the structure may be given by the following parameters, expressed as fractions of the unit cell dimensions:

Four K at $4c$:	$u=0.06$	$v=0.16$	
Four Mn at $4c$:	$u=0.18$	$v=0.67$	
Four O at $4c$:	$u=0.00$	$v=0.61$	
Four O at $4c$:	$u=0.26$	$v=0.49$	
Eight O at $8d$:	$x=0.19$	$y=0.22$	$z=0.80$

The agreement between the observed intensity and the calculated structure amplitude is satisfactory. The crystal, isomorphous with barytes, celestine and anglesite, has a closely similar structure, though the parameters are different. The manganese is surrounded by four oxygen atoms at an average distance of 1.59Å, the arrangement being a nearly regular tetrahedron. The average oxygen-to-oxygen distance in a tetrahedron is 2.62Å. The smallest distance between oxygens in different tetrahedra is 2.72 Å. The potassium is surrounded by nine oxygens at a mean distance of 2.97Å.

1. UNIT CELL AND SPACE GROUP

ALTHOUGH the cell size and the space group of potassium permanganate have been reported by James and Wood¹ and by Basche and Mark,² no complete structure determination of this crystal has appeared. Since potassium permanganate is isomorphous with the sulphates of strontium, barium and lead, the atomic arrangements must also be analogous.³

Crystals of sufficient size and perfection were grown by the slow cooling of an aqueous solution saturated at about thirty-five degrees. From these, both Laue and oscillation photographs were obtained. Laue photographs were taken with the incident beam parallel to the crystallographic axes and were indexed in the usual way by conversion to gnomonic projections. Numerous oscillation photographs (oscillation angle 15° or 30°) around the three principal axes were indexed according to the graphical method described by Bernal.⁴

³ P. von Groth, Chemische Krystallographie, Vol. 5; Englemann (1908). J. A. Wasastjerna, Phil. Mag. 7, 2 (1926); Soc. Sci. Fennica (Physico-Math.) 2, No. 19-30 (1927).

⁴ J. D. Bernal, Proc. Roy. Soc. A113, 117 (1926).

The following values were found for the lattice dimensions:

$$a = 9.09\text{\AA} \quad b = 5.72\text{\AA} \quad c = 7.41\text{\AA}$$

There are four molecules in the unit cell. In agreement with the results of previous investigations, the space group was shown to be $2Di-16$ (V_h^{16}).

2. DETERMINATION OF THE STRUCTURE

Since the space group and the number of molecules per unit cell were known, it was possible, by means of the theory of space groups, to list all the arrangements of the twenty four atoms compatible with the symmetry of the crystal. The number of possibilities was limited by some justified assumptions. Because of the isomorphism with the sulphates of strontium, barium and lead, as well as with the perchlorates of potassium, rubidium, caesium and ammonium, the existence of groups MnO_4 in the crystal may well be taken for granted. These MnO_4 groups must of necessity be linked together by the potassium ions. This assumption together with considerations of the intensities showed that only the following distribution of the atoms among the available positions was possible: (See Wyckoff's tables⁵) 4K in $4c(u0v)$; 4Mn in $4c(u0v)$; 4O_I in $4c(u0v)$; 4O_{II} in $4c(u0v)$ 8O_{III} in general positions $8d(xyz)$. There are, therefore, eleven parameters in the structure.

From considerations of the intensities of reflections occurring at large glancing angles (where the influence of the oxygens becomes negligible) the parameters for potassium and manganese were determined. The values obtained agree very well with those given for Ba and S in BaSO_4 . (Compare James and Wood.¹)

The intensities of reflections from about fifty planes with simple indices were used for the determination of the seven oxygen parameters. Some simplification was obtained by the conception of tetrahedral MnO_4 groups with dimensions somewhat larger than those of the SO_4 group; further, all arrangements were rejected if they gave an oxygen-to-oxygen distance considerably less than 2.5\AA . In this way a set of approximate parameter values was easily derived. Then a series of changes in the parameter values was made so as progressively to better the agreement between observed and calculated intensities, until by this process of trial and error a satisfactory agreement was obtained. The final set of parameter values is given in the Table I. In Table II the calculated values of the structure amplitude are compared with the

TABLE I. *Parameter values.*
(Given in fractions of the length of the unit cell sides)

Potassium:	$u=0.06$	$v=0.16$

3. DISCUSSION OF THE STRUCTURE

In Fig. 1 is given a projection of the structure on the *c*-face. It is true that some use has been made of atomic distances in deriving the approximate

Fig. 1. Crystal structure of potassium permanganate projected on *c*-face. Large circles are potassium, medium circles are oxygen and small circles are manganese.

parameter values. The more accurate evaluation of the positions was, however, made on the basis of intensities alone.

Manganese is surrounded by four oxygens (one O_I , one O_{II} , and two O_{III})

^a The values are taken from: W. L. Bragg and J. West, *Zeits. f. Krist.* 69, 118 (1928).

forming a nearly regular tetrahedron. The manganese-to-oxygen distances are: Two O at 1.58Å; one O at 1.68Å, and one at 1.52Å, the average being 1.59Å. The oxygen-to-oxygen distances in the tetrahedron are:

$$O_1-O_{III}=2.62\text{\AA}$$

$$O_{III}-O_{III}=2.53\text{\AA}$$

$$O_{III}-O_{II}=2.70\text{\AA}$$

$$O_1-O_{II}=2.54\text{\AA}$$

The average O to O distance is 2.62Å.

For comparison it may be remarked that the silicon-to-oxygen distance in the SiO_4 group is given as 1.54–1.64Å;⁷ the sulphur-to-oxygen distance in the SO_4 group is 1.5Å;⁸ the phosphorus-to-oxygen distance in the PO_4 group is 1.56Å;⁹ and chlorine-to-oxygen distance in ClO_4 is 1.56Å.¹⁰

In KMnO_4 , potassium is surrounded by nine oxygens at a mean distance of 2.97Å; one at 3.37Å; two at 2.93Å; two at 2.96Å; one at 2.94Å; one at 3.05Å; and two at 2.79Å. The potassium-to-oxygen distance in other crystals with coordination number nine is reported as 2.96Å and 2.94Å.¹¹

The smallest distance between oxygens belonging to different tetrahedra is 2.72Å.

In conclusion I wish to express my most sincere thanks to Dr. W. H. Zachariasen for his interest and assistance in this investigation.

THE MOBILITY OF AGED IONS IN AIR IN RELATION
TO THE NATURE OF GASEOUS IONS

BY NORRIS E. BRADBURY

PHYSICAL LABORATORY, UNIVERSITY OF CALIFORNIA

(Received April 10, 1931)

ABSTRACT

The mobility of gaseous ions in air formed by intense x-radiation has been studied by the method of Tyndall and Grindley. The mobility of ions less than 0.08 seconds of age was found to be 2.21 cm/sec per volt/cm for the negative ion and 1.59 cm/sec per volt/cm for the positive ion in agreement with values observed by Loeb and by Tyndall and Grindley. A modification of the apparatus permitted the mobility of ions which had been aged for times up to 1.5 seconds to be studied. In this case a decrease in mobility was observed to values of 2.04 and 1.46 for the negative and positive ions after 1.5 seconds aging. The ionization chamber and source of ionization were the same as those employed by Luhr in recombination measurements. From the theoretical mobility equation of Langevin, the observed decrease in mobility cannot be correlated with the probable increase in ionic mass occurring in recombination measurements under the same conditions. A much larger decrease in mobility is predicted on this basis than is observed in these experiments.

INTRODUCTION

THE properties of gaseous ions have been studied for many years with diverse methods and under a variety of conditions, but the exact nature of the ion as it exists under normal conditions of temperature, pressure, and purity can hardly be said to be known. The early stages in the life of the ion (up to ages of the order of 0.01 second) are not, however, difficult to explain. The electron is first torn off from a neutral molecule in a manner dependent upon the ionizing agent employed, thus leaving the molecule positively charged. After a period of time depending upon its kinetic energy, the number of impacts with neutral molecules, and the attachment coefficient of the gas in question, the electron may attach itself to a molecule forming a negative ion. In the case of gases in which positive and negative ions are usually studied, this time of attachment is almost instantaneous and can be completely neglected in the further history of the ion. Exactly what takes place after the formation of the positive or negative monomolecular ion in this manner is not clear. The work of Erikson¹ and others shows that an aging effect takes place in the case of the positive ion causing a lowering to the ordinary values observed in the first 0.01 second. This aging appears to take place in a single step, and while observed for positive ions in air doubtless occurs for both ions in many gases, perhaps in shorter time intervals than observed by Erikson. Further, the work of Loeb² on mobilities in mixtures of gases has shown, depending on the nature of gases used, that either clustering of a statistical type or definite cluster formation may take place, the na-

¹ H. A. Erikson, Phys. Rev. **28**, 372 (1926).

² L. B. Loeb, Phys. Rev. **32**, 81 (1928).

ture of the change observed indicating the formation of clusters of but a few molecules. It is also possible that the initially charged molecule gives up its charge to other and larger molecules of impurities present. However, whatever processes occur, the result is a single class of ions in a given gas which may be termed the normal ion in that gas within a given time interval (i.e. 0.01–0.1 seconds). Regardless of their constitution, which may be monomolecular or a group of very few molecules (2–6), their properties, as shown by their mobility, apparently change very little in the first 0.1 second.

The work of L. C. Marshall³ and O. Luhr⁴ on the coefficient of recombination of ions, however, showed that after this time, certain of the ions were undergoing marked changes. These investigators, employing methods and apparatus of considerable accuracy, studied the recombination of ions in air and other gases at normal temperatures and pressures over periods of time from 0.001 second to two seconds after ionization. They found that in the first 0.0125 sec. the value of the coefficient of recombination is not constant, but decreases sharply from a value several times greater to 1.2×10^{-6} . This high initial value, which had been observed before, was attributed by Plimpton⁵ and independently by Loeb and Marshall⁶ to the initial non-random distribution of ions in the gas; the positive and negative ions being formed in pairs, recombine more rapidly at first than after separation caused by the thermal agitation of the neutral molecules. This phenomenon has been treated by Loeb and Marshall,⁶ who showed that it followed from the predictions of the Brownian movement equations when the ionic fields had been taken into account.

Moreover, Luhr⁴ found that, after this rapid initial drop, the value of α , the coefficient of recombination, did not become constant but continued to decrease, although at a very much slower rate. When the age of the ions was made as great as two seconds, values of α as low as 0.4×10^{-6} were found. Such a decrease in α could not be accounted for by any theory of recombination which assumes an ion of constant dimensions. The only tenable interpretation seemed to be that the ions changed their character with time by picking up products formed by the intense hard x-rays to which the gas had been subjected. Evidence that this explanation was the correct one was found in the case of hydrogen in which no change in the value of the recombination coefficient with time was found. In this case no formation of impurities analogous to the formation of ozone, nitric oxides, H_2O_2 , and the like, as in mixed gases, could take place. Certain impurities, e.g. water vapor, are also always unavoidably present in small amounts which could combine to form nuclei with the above chemical reaction products. On this supposition, the smaller and faster ions recombine first leaving the slower and heavier ions to recombine more slowly. The conclusions to be drawn from such a decrease in the recombination coefficient will be considered later, but it may be noted

that α is inversely proportional to the square root of the mass of the ion; hence an increase in mass would very properly result in a lowering in the rate of recombination.

The very pronounced character of this effect in the case of ionic recombination made it obvious that the loading up occurring under these conditions must affect the mobility of ions aged over similar periods of time. Thus the existence and magnitude of a change in the mobility of ions formed under the same circumstances and in gases of the same degree of purity as those used in recombination measurements becomes of significance in gaining some insight into the nature of the gaseous ion.

It was for the purpose of studying these problems that the experiments about to be described were carried out. The first attempts were made with a modification of the simple Rutherford alternating current method⁷ for mobility measurements with x-ray ionization. The construction of the apparatus, however, was such that "asymptotic feet" in the curves obtained could not be avoided, and the resolving power was, therefore, very small as is the case with all A.C. methods of this type. Hence any small change in mobility with age was undetectable.⁸ In order to establish definitely the value of the mobility of ions produced in air by x-rays at normal temperature and pressure, and also to study the behavior of ions formed under such conditions as a function of their age, the apparatus was arranged so that the *absolute method* developed by Tyndall and Grindley⁹ could be employed. This method is capable of yielding quite accurate and consistent results and can easily be modified to study the effects of aging. It also has the highest resolving power of any accurate method.

METHOD

The essential features of the apparatus employed are shown in Fig. 1. A Coolidge x-ray tube, run at 80 K.V. and 4 m.a. pure D.C. under conditions particularly designed for extreme constancy of voltage and current, is used as the source of ionizing radiation. The beam of x-rays passes through two meters of air and a series of defining slits before reaching the chamber; the width and position of the beam in the chamber can thus be sharply determined. Perpendicular to the beam and in its path is a heavy brass disk from which a variable sector has been cut. As this disk is rotated x-rays are intermittently cut off or permitted to pass through to the chamber. Affixed to the same axle with the disk is a commutator having a single metal segment; the angular width of the latter, as well as its position with respect to the sector cut from the disk, may be varied. Two brushes, separated by an angle slightly greater than that of the commutator segment, make contact with the commutator surface. These brushes are connected to the positive and negative terminals of a high potential battery bank, some point near the middle being grounded. As the commutator revolves, an intermittent alternating potential,

⁹ Tyndall and Grindley, Proc. Roy. Soc. 110, 341 (1926).

shown in Fig. 2, is applied to the lower plate of the ionization chamber. By changing the relative setting of the commutator and sector opening, the phase position of the x-ray flash in the chamber with respect to the potential on the plates may be varied. When neither of the brushes is in contact with the segment, the lower plate is maintained at zero potential by means of a half megohm resistance to ground; at such times the space between the plates is field free.

Ionization takes place between two parallel brass plates mounted on amber insulators in a heavy brass chamber with aluminum windows. The plates are approximately 10×20 cm and 7.5 cm apart. The upper plate, upon which the ions are collected, is surrounded by a guard ring and connected to ground through an electrometer. The chamber has a heavy glass top (which serves as a mounting for the upper plate) sealed on with stopcock grease. Vapor from the grease, however, is prevented from coming in contact with the gas in the

Fig. 1. Diagram of apparatus.

chamber by a special double seal and groove. A purifying system for the gases used is connected to the chamber, and the whole may be evacuated to 10^{-4} mm.

Standard technique was observed in the purification of the gases which were passed over CaCl_2 , NaOH , and P_2O_5 , and through liquid air traps. Before taking any measurements, the chamber was first pumped out as completely as possible, flushed out with purified gas, and finally refilled with pure gas to atmospheric pressure. No difficulty was experienced in obtaining gas of sufficient purity to give the usual values of mobility.

The lead defining slits outside the chamber are adjusted to give the beam a width of a centimeter or less and a position just grazing the lower plate. The commutator is set so that the x-ray flash occurs approximately in the position γT of the cycle. (Fig. 2 shows the cycle of potentials applied to the lower plate.) The values of the potentials are adjusted so that V_r , the retreating potential, is approximately equal to $1.6 V_a$, the advancing potential. This is done in order that V_r , acting during the time βT , may be sufficiently great to clear the chamber of all ions.

The operation of the cycle may now be considered in the following man-

ner: Let T be the time of one complete commutator revolution. Fractions of this period will be denoted by αT , βT , γT , and δT as in Fig. 2. During the time γT , while the x-ray flash is in the chamber, and for a time δT afterwards, the ions are acted on by the field V_r . This field acts in such a direction that those ions whose mobility is being measured are drawn towards the lower plate. Hence at the end of δT , only a thin sheath of the originally formed ions (depending upon the magnitude of $(\gamma + \delta)T$) remain in a layer just above the lower plate. A potential of the opposite sign and of magnitude V_a is then applied to the plates, and the ions being studied are drawn towards the upper plate for a time αT . Ions of opposite sign are drawn back to the lower plate and cleared from the volume. Thus if αT is sufficiently long, all ions not caught by the lower plate at the conclusion of αT , will be caught by the upper plate and produce a deflection of the electrometer. If, however, αT is not long enough to draw all the ions across the space between the plates, the lower

Fig. 2. Cycle of potentials applied to lower plate by the commutator. Ions are formed during γT , drawn toward lower plate during γT and δT , and drawn across volume to upper plate during αT . Volume cleared of all ions not caught at plates during βT . "A" shows cycle for new ions and "B" the cycle for aged ions.

part of the sheath, or even all of it, will escape capture at the upper plate. All ions not caught at the upper plate at the conclusion of αT are swept out of the volume by V_r acting during βT . The volume is thus prepared for the repetition of the cycle, which is repeated at each revolution of the commutator and disk.

The number of ions reaching the upper plate (and hence affecting the electrometer) during a cycle will depend upon the speed of rotation of the commutator. If the speed of rotation is too slow, δT will be sufficiently long to permit V_r to remove all the ions from the sheath before V_a can operate, and the electrometer current will be zero. On the other hand, if the commutator speed is too high, αT will not be long enough to allow V_a to draw any of the ions not caught during δT to the upper plate, and again the electrometer current will be zero. Between these limiting speeds a maximum of current to the electrometer will occur. Tyndall and Grindley⁹ show that the position of this maximum is given by

$$\alpha T = D/kV_a$$

where k is the mobility of the ions, D , the distance between the plates, α the fraction of the commutator covered by the segment, T , the period of one commutator revolution at maximum current to the electrometer, and V_a the advancing field strength. It is seen that the expression is independent of the retarding voltage, V_r , the width of the beam, and the time of retardation. These facts which arise from the mathematics of the cycle, were amply verified by experiment.

Since α , β , γ , and δ are merely constant fractions, the times during which the potentials act are varied by varying T . This is accomplished by driving the commutator and disk with a D.C. motor whose speed is variable and determined by the voltage from a direct connected tachometer magneto. Speeds are thus varied and kept constant at different points with considerable ease. A lead shutter is provided which may be interposed between the x-ray tube and the brass disk. X-rays can thus be kept from the chamber while the disk and commutator are being brought to constant speed. When this shutter is removed, ionization takes place in the chamber and an electrometer deflection is observed whose rate is proportional to the number of ions caught by the upper plate during each cycle. Changing to another speed and repeating the process gives a different rate of deflection, and a series of points taken in this manner may be plotted from which the position of the maximum rate of deflection is determined. Both V_a and V_r , as well as α , β , γ , and δ are kept constant while a run is being taken. The value of the speed, N , at the point of maximum current makes it possible to calculate T ($=1/N$) and with this the mobility k may be determined from the other constants of the experiment.

Fig. 2 shows the two possible adjustments of the commutator system. In (A) αT follows immediately upon δT and so-called "new" ions are studied. In (B), however, the entire insulated section of the commutator is allowed to pass after δT before the ions are drawn across during αT . Ions are thus permitted to age in the gas for that length of time, after which their mobility is measured. Two types of measurement are thus possible, and a change in mobility with age should result in a shift of the position of the maximum of the curve if other conditions are kept the same.

In actual practice α was either $1/4$ or $1/8$ and γ and δ 0.0194. Speeds of rotation were of the order of magnitude of 15 to 300 r.p.m., and could be measured with an accuracy of 0.5 percent with the tachometer. V_a varied from 10 to 50 volts/cm depending upon the conditions of the experiment, and was read upon a 0-300 volt instrument which had been checked against the laboratory standard. In order to check upon any change of mobility in the gas during the time of measurements, runs were made in the following way: the commutator was set in the position to study *aged* ions, and sufficient readings taken to determine the position and shape of the maximum; the commutator was then shifted to the position for *new* ions and the position of the peak again determined. If this latter value did not give the standard mobility determined from a long series of experiments on new ions, the readings were rejected. This was done in order that spurious effects resulting from an impure sample of gas might be eliminated, and was very rarely necessary. When

the commutator speed was very slow, some aging took place during αT . This was taken into account in making the check runs on new ions.

RESULTS

Measurements were carried out on both positive and negative ions under a variety of experimental conditions in an effort to determine the conditions of greatest resolving power consistent with maintaining measurable electrometer currents. Changes in any of the factors not contained in the equation

$$\alpha T = D/kV_a$$

were never observed to influence the position of the peak, but only the magnitude of the current and the slope of the curve. The average of all measurements on positive ions less than 0.08 sec. old gives 1.59 cm/sec. per volt/cm for the mobility of the positive ion in air at 20° and 760 mm. Under the same conditions the mobility of the negative ion in air is found to be 2.21 cm/sec per volt/cm. These values are in good agreement with those obtained by Loeb, and by Tyndall and Grindley⁹ with absolute methods. The consistency of the values obtained is shown by the following series of values given by ten consecutive runs on different samples of gas. The mobility k was found to be for the

<i>Negative ion</i>		<i>Positive ion</i>	
2.21	2.18	1.56	1.61
2.20	2.21	1.58	1.56
2.20	2.21	1.56	1.58
2.19	2.21	1.61	1.58
2.22	2.22	1.61	1.60

It is seen from these values that the normal ions formed by intense hard x-radiation are apparently identical with ions formed by photoelectric and radioactive methods—a result quite to be expected.

After the value of the mobility of positive and negative ions of short age had been established, experiments were carried out on ions which had been aged for increasing intervals of time. This was done in the manner described above. Mobility curves taken under these conditions yielded quite different results. A series of curves for negative ions in air is shown in Fig. 3. It is seen that as the age of the ions is increased from 0.04 to 0.9 sec. the mobility drops from 2.22 to 2.04. This decrease, as evidenced by the shift of the point of maximum rate of electrometer deflections is accompanied by a distinct broadening of the curve at its maximum. This flattening of the curve seems to indicate the presence of a range of mobilities, although the resolving power of the apparatus is not sufficient to distinguish between two close groups. Unavoidable experimental variations in the setting of the commutator caused slight changes in the slopes of the curves, but the change itself and its approximate magnitude are very apparent. A similar series of curves was observed in the case of positive ions in air. In this case the lowest value observed was 1.46 after 1.3 sec. aging. Greater ages than this could not be studied as the very slow commutator speed and decreased electrometer currents (owing to recombination and loss of ions by diffusion) made measurements uncertain.

The possibility of attributing the observed effect to some defect in the apparatus or method has been carefully considered. The effect of space charge due to the cloud of ions of opposite sign to those measured has been shown to be negligible. During the γT and δT parts of the cycle, these ions are driven away from the lower plate and remain in the volume throughout the aging period. The resultant effect of this cloud would be to draw the ions measured away from the lower plate with a consequent decrease in effective D . Hence an apparent *increase* in mobility would be observed. However, minimizing any effect of space charge by narrowing the entering beam to 3 mm gave no change in observed mobilities. Further, a delay in the charge leaking off the lower plate through the half megohm resistance would cause αT to be longer than calculated when new ions were being measured. This would result in high values for new ions and a consequent apparent decrease in the mobility of aged ions. However, the fact that the time constant of the system was only

Fig. 3. Curves showing effect of aging upon ^{*}negative ions in air. Right hand arrow indicates *normal* positions of peak for *new* ions. Left hand arrow indicates position of peak taken for calculation of *aged* ion mobilities.

10^{-3} seconds speaks against this possibility as does the fact that the substitution of a lower resistance did not change the values of mobility previously obtained. Furthermore, a definite gap of several degrees was left between the δT and αT phases in the case of aged ions to give the same conditions as exist in the new ion measurements.

DISCUSSION OF RESULTS

It has been pointed out by Luhr that the only plausible explanation for the continued decrease in the value of the coefficient of recombination is one which assumes some of the ions to load up with impurities formed by the intense x-radiation. From J. J. Thomson's theory of recombination the magnitude of this increase in mass which would give the observed value for the recombination coefficient was calculated, and found to be roughly ten times

the original mass of a new ion. Such a change in ionic mass must necessarily result in a considerable increase in ionic dimensions, though the exact magnitude of this increase cannot be calculated without much more exact knowledge as to the nature of the clustering and the molecules involved. At any rate, the increase in the radius of the ion will cause a decrease in its mean free path, neglecting any effects of the charge on the ion. Moreover, this change will be more pronounced the fewer the molecules in the cluster. Now all mobility equations, with the exception of that deduced by Loeb,¹⁰ which employs mass points as ions, contain either the mean free path directly, or a term which is closely related to it or to the ionic radius. The effect of this term in the equations is either one of proportionality or of even greater weight in the case of the rigorous Langevin equation. Hence a change in the mass of the ion which would double its radius and halve its mean free path would cause a theoretical decrease in the mobility to at least half the normal value. Yet such an increase in the radius of the ion is of the order of that predicted on recombination coefficient measurements. Such a decrease has not been observed either in these experiments, or in the less rigorous experiments of Luhr and Bradbury. It should be pointed out that, in the mobility measurements carried out by the method of Tyndall and Grindley, the majority of the positive and negative ions are not aged in each other's presence, so the selective effect of recombination in removing the smaller faster ions is not wholly operative. Hence, unless all the ions age at the same rate, a sharp effect would not be obtained. The experiments of Luhr and Bradbury, on the other hand, which employed the Rutherford alternating current method, permitted the ions to be aged together so that recombination of the faster ions could take place before the mobility measurements were made. Although this method was of insufficient resolving power to detect small changes in mobility, a change of greater than twenty percent would have been readily apparent. The negative results thus obtained, even with the advantage of selective recombination, preclude all possibility of any change in mobility with age to a degree at all comparable with that predicted by theory. Hence if the increase in ionic dimensions takes place as seems probable from recombination measurements, this discrepancy between theory and experiment in the case of ionic mobilities must point to some important and inherent defect in even the most rigorous theoretical equations which have so far been developed. The extent of the inadequacy of the mobility equations and the error in the assumptions involved will be considered in another paper.

In conclusion the author wishes to express his sincere appreciation of the interest and suggestions of Professor L. B. Loeb in the carrying out of these experiments.

THE RESIDUAL IONIZATION IN AIR AT NEW HIGH PRESSURES, AND ITS RELATION TO THE COSMIC PENETRATING RADIATION¹

BY JAMES W. BROXON
UNIVERSITY OF COLORADO
(Received April 10, 1931)

ABSTRACT

Measurements of the residual ionization in air were made with a new spherical chamber of 13.8 liters capacity at pressures up to 170 atm., at an altitude of 5400 ft. Lead and water shields were used. The slopes of the ionization-pressure curves continued to decrease at the higher pressures, becoming zero in the neighborhood of 130 to 140 atm. The ionization-pressure relation and the effects of shielding are explained on the basis of the production of ions solely by secondary radiations excited in the walls of the vessel by the cosmic penetrating radiation. The theoretical consequences of such an assumption are discussed.

MEASUREMENTS of the residual ionization in several gases contained in a large chamber at pressures up to 80 atmospheres, were made a few years ago by the writer² and other students³ of Professor Swann. These experiments showed that the primary ionization due directly to any very penetrating radiation was considerably less than that which would correspond to the residual ionization at atmospheric pressure. However, the observed increases in ionization per atmosphere increase in pressure at the highest pressures were usually of the order of magnitude of the ionization at atmospheric pressure attributed by other experimenters to the cosmic penetrating radiation. Later, in 1926, Swann⁴ found that the ionization at all pressures up to 68 atmospheres increased with altitude in accordance with the theory that a primary cause of the ionization consists of an ultrapenetrating radiation having its origin outside our atmosphere.

In order to investigate further the residual ionization and particularly its relation to the cosmic radiation, a new ionization chamber⁵ was constructed and arrangements made for rather elaborate shielding.

APPARATUS AND MATERIALS

The chamber was formed by excavating a spherical cavity 11-23/32 inches in diameter from a cylindrical, nickel-steel ingot 15-1/8 inches in diameter and 17-3/8 inches long. The volume occupied by the air under investigation was

¹ Reported at the Cleveland meeting of the American Physical Society, December, 1930.

13805 cc. The central electrode, guard system and ebonite insulation were incorporated in the form of cones in a plug which was seated upon a narrow fiber gasket. This chamber sustained a hydraulic test pressure of 5000 lbs. per sq. in. for half an hour with no indication of weakening.

The chamber was mounted approximately in the center of a wooden tank 14 ft. in diameter and 13.5 ft. high, in the basement of Macky Auditorium at the University of Colorado, Boulder, at an altitude of 5400 ft. and latitude 40°N . The chamber could be surrounded by a cylindrical lead shield 2 in. thick. This could be covered by a water-tight hood 2 ft. in diameter and 2 ft. high, and surrounded by water. The photograph, Fig. 1, shows the ionization chamber with the hood removed and part of the lead shield in position. A Brown recording thermometer bulb was inserted in a small hole drilled about 4 in. into the bomb near its base, the entire instrument being insulated carefully at the potential of the bomb. The connection with the central electrode was effected by means of a wire stretched along the axis of a 2 in. pipe.

Fig. 1. Photograph of apparatus.

The air used in these measurements was dried, freed from dust, and allowed to age at least 4 weeks in each instance.

The ionization chamber was never allowed in any building which had contained radioactive supplies. Care was also taken that the shields be as free as possible from radioactive contamination. The lead shield was cast from discarded overhead telephone cable sheaths. The water used was the city tap water. The source of the Boulder city water consists entirely of surface water from the Arapahoe Glacier and snow deposited between the altitudes of 10200 and 13500 feet. This is brought down to the city through iron pipes which are nowhere imbedded to any appreciable extent. While making a survey of the radioactive waters of Colorado several years ago, Dean O. C. Lester tested the Boulder city water and was unable to detect any radioactive content. The ionization currents measured provide evidence that the ionization chamber and shields were rather unusually free from radioactive contamination.

The pressures were measured by means of an American-Schaeffer and Budenberg gauge, calibrated by the U. S. Bureau of Standards. The applied compensating potentials were measured by means of a Jewell Instrument

Company voltmeter calibrated at a few voltages by the Bureau of Standards and over the entire scale in our own standardization laboratory by means of a standard resistance and potentiometer. The induction coefficient of the auxiliary or compensating condenser was measured by a null method of mixtures, the electrometer being used as the indicator and the comparison being made with a new variable standard air condenser constructed by Günther and Tegetmeyer. Comparisons were made with six different settings of the standard condenser. The average of these gave 26.3 cm as the induction coefficient of the compensating condenser relative to the central system, a value agreeing fairly well with an approximate calculation from the dimensions of the condenser. The corresponding induction coefficient of the ionization chamber was found to be about 4.5 cm at local atmospheric pressure.

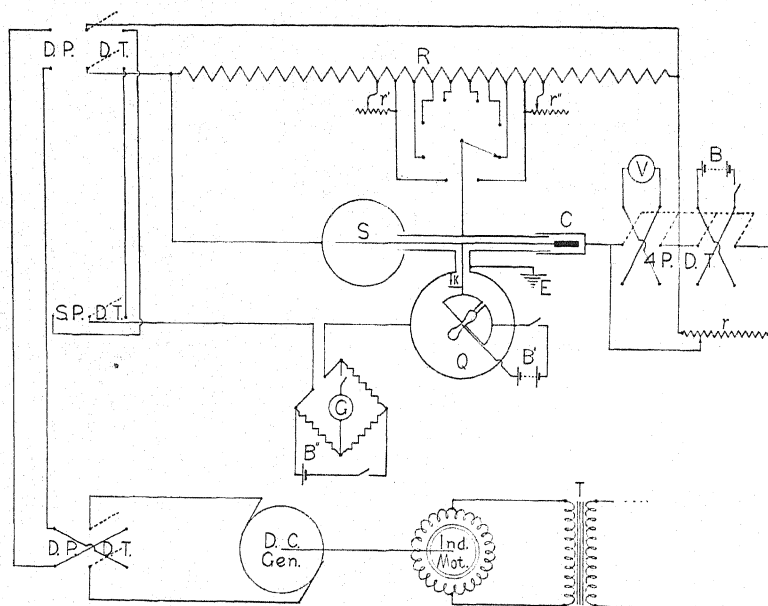

Fig. 2. Diagram of electrical arrangement.

PROCEDURE

As shown by the wiring diagram, Fig. 2, the same sort of arrangement was employed in measuring the ionization as in the former investigations. The Wheatstone bridge was incorporated for the purpose of determining the dielectric constant of the air as discussed elsewhere.⁶ The method of ionization measurement has been described carefully, particularly by Swann.⁴ Distinct advantages of the arrangement consist of the provision for electrical shielding, eliminating almost entirely the possibility of effects due to the solid dielectrics, and the employment of the electrometer merely as an indicator, thus eliminating effects due to possible changes in sensitivity. In the present in-

⁶ Reported at the meeting mentioned in note 1. The complete report constitutes the succeeding paper of this issue.

stance, the auxiliary condenser was fixed and the compensating potential was applied to this rather than directly to the ionization chamber. Thus the rate of application of the compensating potential was directly proportional to the ionization current whereas with the other arrangement the change in the induction coefficient of the ionization chamber relative to the central system with variation in pressure of the gas must be considered.

On account of inductive effects, the detailed construction of a guard system is very important. Termini of the system used here are shown in Figs. 3 and 4

Fig. 3. Longitudinal section of ionization chamber.

which represent longitudinal sections of the ionization chamber and the auxiliary condenser, respectively, drawn approximately to scale. This system proved to be very satisfactory. Because the guard system in this case was necessarily in electrical contact with the earth, particular care had to be taken to insulate all other portions of the set-up from earth, including the sources of e.m.f.

Of course, it was exceedingly important to ascertain that saturation currents were being measured. No appreciable decrease of the ionization current could be detected when the applied P.D. was decreased about 20 percent when the largest currents were being measured at the highest pressures.

Therefore it is considered certain that saturation currents were measured throughout. It should be noted in this connection that although the high pressures necessitated low mobilities, the largest ionization currents were very small and hence practical⁷ saturation was not difficult to establish.

When tests were to be made the air was admitted slowly into the ionization chamber to a maximum pressure of about 170 atmospheres. If measurements were made immediately after filling, larger values were obtained than after the establishment of equilibrium conditions. Therefore, from two to six

Fig. 4. Longitudinal section of compensating condenser.

hours were always allowed to elapse after filling the chamber before measurements of the ionization were begun. After three or four measurements, each over about an eight minute interval, had been taken at a given pressure, the pressure was usually decreased by three to six atmospheres at the higher pressures. Then at least half an hour was allowed to elapse before any measurements were taken at the lower pressure. Extension of this period to several hours in some instances had no effect. The gas leak was slight, although it was found necessary to remove the bomb and tighten the large plug after making two or three sets of observations.

OBSERVATIONS

The observations have been represented graphically. In Fig. 5 the ionization current in ions/cc. sec. has been plotted against the total pressure in at-

Fig. 5.

Fig. 6.

mospheres at 18°C. It may be worth mentioning in this connection that the slopes of the curves are so small in the region where the departure from Boyle's law is considerable, that if the ionization is plotted against the gas

density instead of the pressure, the curves obtained are scarcely distinguishable from those shown here. Curve I was obtained with no shielding other than that provided by the heavy steel walls of the ionization chamber, by the building, and by the atmosphere. Curve II was obtained with the chamber surrounded by the 2-in. lead shield; curve III, with no lead shield but with the tank filled with water; and curve IV, with both the lead and water shields in position. The ionization current in each instance was measured at pressures between atmospheric pressure and about 170 atmospheres. At the higher pressures observations were made at shorter intervals than in the lower pressure region previously investigated.

The data represented by the curve of Fig. 6 were obtained with the lead shield in position and with the air in the bomb maintained at pressures between 166 and 169 atmospheres. Here the ionization was again plotted along the ordinate axis, but the abscissae represent the position of the surface of the water in the tank. Depth of the water level beneath the center of the bomb is designated by negative values, and height of the water level above the center of the bomb is designated by positive values. The end points designated by two concentric circles represent data recorded in Fig. 5. The one representing no water in the tank gives the maximum ionization of curve II, while the one representing the tank filled with water gives the maximum ionization of curve IV.

DISCUSSION

One rather striking feature of the measurements is the very low value of the ionization measured in each case at the local atmospheric pressure. These values varied from 2.26 with no shield to 1.45 ion/cc·sec with both shields, at 0.82 atm. and 18°C. The smallness of these values together with the fact that the percentage decrease in the ionization due to shielding was in each instance only slightly less at atmospheric pressure than at the highest pressures, indicated that the ionization chamber, itself, was remarkably free from radioactive contamination.

The ionization-pressure curves resemble those obtained previously, over the pressure range of the earlier observations. In particular, there is a close correspondence between curve II, Fig. 5, and the curve obtained by Swann⁴ with a similar lead shield at Colorado Springs at about the same altitude. The ratio of his values to those of curve II at corresponding pressures is 1.87 at 100 lbs./sq. in., but decreases to 1.32 at 500 lbs./sq. in. and then only to 1.29 at his maximum pressure of 1000 lbs./sq. in. or about 68 atm. His larger values at low pressures are probably due mostly to a slight radioactive contamination of the older chamber, while the nearly constant ratio at the higher pressures is of about the magnitude to be expected when the increased shielding provided by the heavier walls of the bomb and the building in the present instance is considered. Obviously, a better method of comparison is one based upon the *differences* between the absolute values of the ionization observed in the two instances at corresponding pressures. Thus there is an increase of only about 1.7 ion/cc·sec in this *difference* in the pressure interval from 500 to 800

lbs./sq. in., and practically no further variation at higher pressures. At the higher pressures, then, where the effects of chance radioactive contaminations become inconsequential, the forms of the curves become identical, showing a remarkable agreement between the two independent investigations.

The most interesting portions of the ionization-pressure curves lie in the new pressure range. In every case the pressure rate of increase of ionization is seen to have continued to decrease at the higher pressures, and the slopes of the three curves obtained with the chamber shielded are zero at pressures above about 130 atm. In curve I there appears to be a possible continued slope of about 0.04 ion/cc·sec·atm. at the highest pressures, but in the other three curves the slopes at the high pressure ends certainly are not greater than 0.02 ion/cc·sec·atm. over a range of 40 atmospheres, and probably are considerably less.

It would appear, then, that the immediate cause of the ionization was a radiation which was almost entirely absorbed at a pressure of 130 atm. If the source of this radiation were in the gas itself, the ionization should have continued to increase with the pressure. If the source were outside the chamber, either it would have been absorbed entirely by the shields or it would not have been absorbed considerably by the gas. Presumably, then, the source of the ionizing radiation was in the walls of the ionization chamber.

That the primary cause of the ionization was a much more penetrating radiation is shown by the continued decrease in the ionization produced by successively greater shielding. It seems that the situation might be explained, then, by the assumption that the primary cause of the ionization in the cases of the three lower curves was a very penetrating radiation which excited in the walls of the vessel a softer radiation, perhaps recoil electrons, and that the ionization was almost entirely due to this secondary radiation. That none should be excited in the gas, itself, seems remarkable in view of the amount of air present in the chamber at the high pressures, but if any appreciable portion of the secondary radiation were to originate in the gas, surely the ionization would continue to increase with the pressure to a correspondingly appreciable extent at all the pressures.

That the source of the radiation capable of penetrating the lead shield was above the level of the chamber is shown clearly by Fig. 6. Apparently, local gamma-radiations were practically entirely absorbed with the lead shield in position, since variation of the water shield below the level of the chamber had very little effect in this case. That local γ -radiations did contribute to the ionization with the chamber unshielded, is shown by the value, 58.21 ions/cc·sec, designated by an x in Fig. 5 and measured with no lead shield but with the water tank filled to the center of the bomb.

Absorption coefficient of the primary radiation

The decreases in ionization produced by the shields were of sufficient magnitude to give fair estimates of the average absorption coefficients of the primary radiation in the materials used. As has been pointed out, the ionization recorded in the shielded curves at the high pressures may be considered

to be due entirely to the penetrating radiation. The maximum values of the ionization in curves I, II, III and IV are 69.14, 52.00, 45.43 and 42.60 ions/cc. sec, respectively. In the case of the lead shield, if we assume exponential absorption and disregard obliquity, we have for lead $\mu = [\log_e(45.43/42.60)]/5.08 = 0.0127 \text{ cm}^{-1}$. Proceeding similarly in the case of water, we obtain $\mu = [\log_e(50.38/42.60)]/166 = 0.0010 \text{ cm}^{-1}$. In this case, the thickness of the water shield has been taken as the 5.45 ft. depth of the top of the hood beneath the highest level of the water, and the initial intensity as that measured with the water level at the top of the hood, which would be correct if the radiation were directed entirely vertically.

In the case of the water shield we may calculate an upper limit for the absorption coefficient by assuming that the radiation approached the chamber uniformly from all directions above the horizontal. In the case represented by Fig. 6, the decrease in ionization was produced by horizontal disks of water placed above the chamber. If P is a point on the axis of a *thin* disk of thickness t and radius a , at a distance x from the disk, while the total intensity of all radiation originally approaching P through the solid angle 2π on the side next the disk is I_0 , then the intensity of the radiation arriving at P after having passed through the disk is

$$I_a = I_0 \int_0^{\tan^{-1}(a/x)} e^{-\mu t \sec \theta} \sin \theta d\theta = I_0 \int_1^{(1+a^2/x^2)^{1/2}} y^{-2} e^{-\mu t y} dy.$$

The latter integrand may be expanded into a series which is uniformly convergent in the region designated. When this is integrated and terms involving powers of t higher than the first are discarded, the value obtained is

$$I_a = I_0 [1 - (1 + a^2/x^2)^{-1/2} - \mu t \log_e (1 + a^2/x^2)^{1/2}].$$

Now $2\pi [1 - (1 + a^2/x^2)^{-1/2}]$ is the solid angle subtended by the disk at P . Therefore, $I_0 [1 - (1 + a^2/x^2)^{-1/2}]$ is the intensity of the radiation which would have approached P through the solid angle subtended by the disk if the disk had been absent. Therefore, the decrease in intensity of the radiation arriving at P due to the presence of a disk of radius a and thickness dx at a distance x , is

$$-dI = \mu I_0 \log_e (1 + a^2/x^2)^{1/2} dx.$$

Then when the ionization chamber is so situated that its dimensions are small in comparison with both a and x , the slope of the absorption curve obtained by shielding with disks in the above manner is

$$-dI/dx = \mu I_0 \log_e (1 + a^2/x^2)^{1/2}.$$

If from Fig. 6 we take the values $I_0 = 42.6$, $-dI/dx = 9.1/196.6$, $a = 7$ and $x = 6.45$, we obtain $\mu = 0.0028 \text{ cm}^{-1}$. This, of course, merely represents an upper limit for the average μ in water, just as the value first calculated represents a lower limit. Due to the absorption of the walls of the building and to the great absorption of the atmosphere in directions approaching the hori-

zontal, the penetrating radiation would be much more intense in the vertical direction providing it entered the atmosphere with uniform intensity in all directions.

The values obtained for the average absorption coefficients agree quite well with those obtained by others⁸ for the cosmic radiation. It should be emphasized, however, that this investigation was not planned for the purpose of determining coefficients of absorption, and does not permit their accurate evaluation. It is chiefly because the values obtained might be expected to be of the right order of magnitude, and because they do agree with values yielded by experiments designed primarily with this end in view, that they are mentioned. The approximations show quite unequivocally that the prime ionizing agency consisted of the "cosmic penetrating radiation."

Explanation of the ionization-pressure relation

In a former paper⁹ the author deduced I - P relations which would follow from various assumptions as to the origins and characteristics of the ionizing radiations. The rather complicated combination chosen to represent the experimental curves was necessitated largely by the fact that the ionization passed through a minimum as the size of the chamber was varied. As has been pointed out, it appears that the ionizing radiations in the present instance must have originated in the vessel walls. This would necessitate a continuous increase in ionization with decrease in the size of a thick-walled vessel, because of the corresponding increase of the ratio of area to volume. In view of the present measurements it is strongly suspected that the variation of ionization with size of vessel obtained in the former experiments depended partly upon a chance radioactive contamination of the outer, high-pressure chamber. In the case of the two smaller containers which were constructed at the same time under the same conditions, the ionization increased with decrease of size.

Let us now make some very simple assumptions which can only be expected to lead to a very rough approximation of the observed relation. Suppose the ionization to have been due entirely to recoil electrons generated uniformly throughout the walls of the vessel by the cosmic radiation. Suppose further that these were all emitted in directions normal to the spherical surface (an exceedingly crude assumption) and were absorbed linearly both in the vessel walls and in the gas. As a preliminary step in the investigation of the variation with pressure of the ionization which would be produced under such circumstances, let us consider a still simpler case.

If we plot the ionization per cm of path of a homogeneous beam of linearly absorbable, parallel rays against the distance from their origin, we obtain a straight line. The intercepts of this line upon the coordinate axes respectively represent the maximum or initial ionization per cm of path along the beam, and the range of the beam or the distance from the origin within

⁸ V. F. Hess, "The Electrical Conductivity of the Atmosphere and Its Causes," p. 138.

⁹ J. W. Broxon, *Phys. Rev.* **28**, 1071 (1926).

which total absorption occurs. The area of the right triangle enclosed by the straight line and the coordinate axes represents the total ionization which the beam can produce. Also, the portion of the area of this triangle which is included between the ionization/cm axis and a normal to the distance axis at any point represents the ionization produced within that distance from the origin.

Suppose, for some reason, we should want to deal with the ionization due to a precisely similar beam after it had traversed the first quarter of its range. Everything would be represented as in the previous instance by a right triangle formed between the coordinate axes and a straight line. This triangle would also have the right angle at the coordinate origin and would be similar to the first one in every respect, but corresponding dimensions would be just three-fourths as great as in the first instance. If we desired to deal with a similar beam after it had traversed the first half of its range, we should obtain a similar triangle with dimensions half as great as in the first instance. If three-fourths of the range had been traversed, the similar triangle would have dimensions only a quarter as great as the first, etc. If, then, we were to have all four of the above mentioned beams starting normally from a certain plane such as the inner surface of an ionization chamber, and ionizing simultaneously, we might represent the ensuing ionization by means of the four triangles, piling them one upon the other. If they were cut from pieces of paper and fitted upon the coordinate axes in the proper manner in the order of decreasing size, a sort of pyramid would be formed. The total volume of the the paper pyramid could then be considered to represent the total ionization produced by the four beams. Moreover, the volume included between a plane normal to the distance axis at the origin and another normal to the distance axis at any given distance from the origin would represent the ionization produced by the four beams within that distance from the surface of origin of the beams.

If the ionizing radiation in the present investigation originated throughout the walls of the ionization chamber and proceeded normally to the inner surface in the simple manner that has been postulated, it would not be homogeneous upon entering the chamber, but the corpuscular velocities would be distributed practically uniformly between zero and a maximum. In other words, we might consider that at the inner surface the beam would consist of an enormous number of similar parallel beams with the then untraversed portions of their ranges distributed uniformly between zero and a maximum for electrons just starting at the inner surface. The ionization in this case, then, could be represented by a pyramid similar to the one above, but with the steps smoothed out. Or the entire pyramid might be thought of as being compressed into the base triangle, forming a right triangular mass with a density varying directly as the distance from the hypotenuse, the line which would represent the variation with distance from the inner surface, of the ionization/cm due to a homogeneous beam of electrons originating at the inner surface. If, then, we think of a triangle endowed with mass and with a density varying in the above manner, we need only change from area to mass in order

to change from a homogeneous beam to a nonhomogeneous beam of the above type. This procedure appeals to the writer as preferable to continuing with the pyramid. The intercept, a , on the ionization/cm or y -axis may be considered to represent the ionization per cm of path due to a corpuscle of maximum velocity, and the intercept, b , on the distance axis, to represent the maximum range. The total mass of the triangle would represent the total ionization which could be produced by all the electrons entering the chamber. Also, the mass of the portion of the triangle included between the ionization/cm axis and a normal to the distance axis at any point would represent the ionization produced by the nonhomogeneous radiation within that distance from the surface of entrance of the radiation into the chamber.

In the present instance, if tertiary radiations, etc., be disregarded, the ionization recorded at any pressure would represent the ionization produced within an effective distance from the wall approximately equal to the product of the inner diameter of the chamber and the pressure, and hence approximately proportional to the pressure. Hence we may consider the pressure, P , to represent distance in the present case.

If we write the equation of the hypotenuse of the triangle in the form

$$mP - y + a = 0,$$

where $m = -a/b$, the normal distance from the hypotenuse to any point (P, y) within the triangle is equal to $(mP - y + a)/(m^2 + 1)^{1/2}$.

Therefore, we may express the ionization, I , at pressure P in the form

$$\begin{aligned} I &= k/(m^2 + 1)^{1/2} \int_0^P dP \int_0^{mP+a} (mP - y + a) dy \\ &= [ka^2/6b(a^2 + b^2)^{1/2}](3b^2P - 3bP^2 + P^3), \end{aligned}$$

k being merely a proportionality constant.

I_m , the maximum ionization produced, is found by putting $P = b$. Hence $I_m = ka^2b^2/6(a^2 + b^2)^{1/2}$, and

$$I = I_m(3P/b - 3P^2/b^2 + P^3/b^3).$$

This equation holds, of course, only for $0 \leq P \leq b$. Pressures greater than b correspond to complete absorption of the ionizing radiation, and hence to a constant $I = I_m$.

In this case there is little seeking for arbitrary constants. I_m is the final maximum ionization and b is the lowest pressure at which this maximum is obtained. In curve III, for instance, $I_m = 45.43$. In this case the maximum ionization appears to occur first at about 130 atm. However, the pressure rate of increase of I at high pressures is so very small that the actual maximum range probably corresponds to a somewhat higher pressure. Taking $b = 140$ atm., the values represented by the open circles in Fig. 7 were obtained. These are rather low between 1 and 60 atm.

Arbitrarily assuming $4/5$ of the final maximum ionization to be due to radiation of the above type with a maximum range corresponding to 150 atm. in the bomb, and the remaining $1/5$ to be due to a similar radiation with a maximum range corresponding to 40 atm., the values represented by crosses in Fig. 7 were obtained. These fall very close to the experimental curve.

The actual situation must have been much more complicated than that postulated in the above analysis. For instance, the initial recoil electrons would not be expected to be emitted in none but radial directions, and there would probably be several consequent radiations with decreasing energy content. It is hoped that a more careful analysis with more likely assumptions may be effected in the future. However, the writer opines that these considerations show, in so far as the observed $I-P$ relation is concerned, that it is reasonable to assume the ionization to have been produced entirely by secondary radiations, perhaps recoil electrons, excited in the walls of the vessel by the primary penetrating radiation.

Fig. 7.

Significance of the the recoil electron assumption

If the explanation suggested above is correct and the ionizing radiation really consisted of recoil electrons, their range in the air should give some information concerning the penetrability of the primary radiation. Millikan and Cameron¹⁰ have shown in detail how to calculate by means of Compton's¹¹ equations the range of the recoil electrons which would be generated by a very penetrating radiation of known coefficient of absorption. In the present instance we may proceed in precisely the reverse order.

If we consider recoil electrons of range about 140 diameters of the bomb at 18° C or 38 meters in air at N. T. P., and use the 1926 procedure of Millikan and Cameron based upon the work of Bohr and Varder, we obtain 10.94×10^6 volts for their initial energy. According to the empirical formula found by Feather¹² to hold for penetrating β -rays, the energy would be 10.09×10^6 volts. As Millikan and Cameron pointed out, at such high energies

¹⁰ R. A. Millikan and G. H. Cameron, Phys. Rev. **28**, 851 (1926).

¹¹ A. H. Compton, Phys. Rev. **21**, 483 (1923).

¹² N. Feather, Phys. Rev. **35**, 1559 (1930).

the Compton theory predicts the equipartition of the energy of the incident quant between the recoil electron and the scattered quant. Thus, using the first value above, the primary radiation would have an energy-value of 21.89×10^6 electron-volts, or a wave-length of 0.00052A. Substitution of this in the Compton absorption formula gives an absorption coefficient in water of 0.0025 cm^{-1} .

The agreement of the value of μ just calculated with the experimental values is rather startling in view of the fact that the Compton theory, based upon the older quantum mechanics, is now in bad grace. Klein and Nishina¹³ have calculated for the scattering coefficient, which may be regarded as the absorption coefficient for sufficiently high frequencies,

$$S = \frac{2\pi N e^4}{m^2 c^4} \left\{ \frac{1 + \alpha}{\alpha^2} \left[\frac{2(1 + \alpha)}{1 + 2\alpha} - \frac{1}{\alpha} \log(1 + 2\alpha) \right] + \frac{1}{2\alpha} \log(1 + 2\alpha) - \frac{1 + 3\alpha}{(1 + 2\alpha)^2} \right\}.$$

In this formula, based on wave-mechanics, $\alpha = h\nu/mc^2$, e is the electron charge, m the electron mass, c the velocity of light, ν the frequency of the incident radiation, and N the number of "external" electrons per cc. S represents loss of energy from the incident radiation due both to the energy transferred to the scattered radiation and to the recoil electrons. It was obtained directly by multiplying the expression

$$I = I_0 \frac{c^4}{2m^2 c^4 r^2} \frac{1 + \cos^2 \theta}{[1 + \alpha(1 - \cos \theta)]^3} \left\{ 1 + \alpha^2 \frac{(1 - \cos \theta)^2}{(1 + \cos^2 \theta)[1 + \alpha(1 - \cos \theta)]} \right\}$$

for the intensity of the radiation scattered per electron at an angle θ , in terms of I_0 , the intensity of the incident radiation, by ν/ν' , the ratio of the frequencies of the incident and scattered radiations, and by $Nr^2 d\Omega/I_0$, and integrating over the entire solid angle about a point. If we proceed in the same manner without multiplying by the term ν/ν' , we obtain

$$S_s = \frac{2\pi N e^4}{m^2 c^4} \left[\frac{\log(1 + 2\alpha)}{2\alpha^3} + \frac{\alpha^2 - \alpha - 1}{\alpha^2(1 + 2\alpha)} + \frac{4\alpha^2 + 6\alpha + 3}{3(1 + 2\alpha)^3} \right].$$

This represents loss of energy by virtue of the scattered radiation alone, and corresponds to N times Compton's¹¹ σ_s , or "true scattering coefficient" per electron.

The ratio $(S - S_s)/S = E/h\nu$, where E is the energy of the scattered electron, is the ratio of the mean energy per scattered electron to the energy of an incident quant. If we take $E = 11 \times 10^6$ electron-volts, we find the last equation is approximately satisfied by $\lambda = 0.000892\text{A}$. With this value of the wave-length of the incident radiation we obtain $S = 0.020 \text{ cm}^{-1}$ for water, and $E/h\nu = 0.8$. Thus, according to the Klein-Nishina theory, the energy at very

¹³ O. Klein and Y. Nishina, *Zeits. f. Physik* 52, 853 (1929).

high frequencies is not distributed equally between the scattered quant and the recoil electron, but most of it is absorbed by the latter, the recoil electron in the present instance absorbing 4/5 of the energy of the incident quant. Using the supposedly observed range of the recoil electrons, we have calculated by the Klein-Nishina theory an absorption coefficient for the primary penetrating radiation which is one order of magnitude higher than that calculated by the Compton theory and found experimentally.

An absorption coefficient of 0.0024 cm^{-1} of water corresponds, according to the Klein-Nishina formula, to a primary wave-length of about 0.00006\AA . Substitution of this in the above expression for $E/h\nu$ gives 1.8×10^8 electronvolts for the energy of the recoil electrons. If we consider the range of an electron of high energy content to be proportional to its energy, the range to be expected according to this theory is about $38 \times 180/11 = 622$ meters in air at N. T. P., some 16 times that assumed to have been measured in this investigation.

The two theories of scattering agree very well in the x-ray region, but differ greatly at very much higher frequencies, as shown above. The Klein-Nishina theory has recently been found by several investigators¹⁴ to agree much better with observations in the region of very penetrating γ -rays than does the Compton theory. This would indicate that the final, constant maximum ionizations observed in the present investigation do not correspond to complete absorption of the recoil electrons. If, on this basis, the suggested explanation in terms of some sort of secondary radiation from the walls of the vessel is considered entirely untenable, then it seems to the writer that the true explanation must depend upon some characteristics of gaseous ionization at high pressures or of absorption in that region, which are not known.

In this connection it may be mentioned that Skobelzyn¹⁵ has observed by the Wilson cloud method paths which he considers to have been due to recoil electrons excited by the cosmic radiation, and whose energy he has estimated from the curvature of the path in a magnetic field, to have been about 15×10^6 volts at the beginning of the observed portion of the path. He points out that this value was to be expected on the basis of the older theory but is inclined to discard it in favor of the newer, and suggests the possibility of the corpuscles originating outside the expansion chamber, or of the mechanism of absorption of energy in the region of such high frequencies being of a different sort from that ordinarily postulated in Compton scattering, perhaps with the ejection of H particles from the nuclei. (Note also the suggestion of nuclear absorption in the papers of reference 14.) "In diesem Zusammenhang könnte man auch an die Möglichkeit, dass die H-Strahlen mit der Energie von dem Betrage der "Ultra- γ -Energie" erzeugt werden können, denken. Diese H-Strahlen würden die Geschwindigkeit von der Ordnung 1,5 bis $2 \cdot 10^{10}$

haben." Taking the lower of the values suggested and Rutherford's¹⁶ value of 3.07×10^9 cm/sec for the initial velocity of an H atom of range 28 cm in air, and assuming the ranges proportional to the cubes of the velocities, we have $R = 0.28(15/3.07)^3 = 33$ meters in air, a value comparable to the range of the secondary radiation discussed in this paper. Of course, the "Ultra- γ -Energie" has been calculated on the basis of absorption measurements and the assumption of electron scattering, so that it is questionable as to what weight may be given the suggestion. If one might suppose that such positive corpuscular radiations could produce considerably more ionization than the recoil electrons in the present instance, however, there would be a possibility of using the notion in explaining the observed variation of ionization with pressure.

Possibly it is worth while pointing out that in so far as the present investigation indicates the very considerable importance of secondary radiations excited by the cosmic radiation and suggests by virtue of their relatively low penetrating power that they are corpuscular in nature, the penetrating corpuscular radiations detected by some investigators¹⁷ may be suspected of being secondary in nature.

It would appear to be a rather conservative conclusion, on the basis of the experiments herein presented, that the ionization in a closed vessel which is properly attributable to the penetrating radiation depends to a considerable extent upon the vessel and other circumstances. Such dependence does not seem to have been taken into account, for instance, by Hulburt¹⁸ in calculating the contribution of the cosmic penetrating radiation to the ionization of the free atmosphere at various altitudes. He takes as the value at sea-level, 1.4 ion/cc sec which was the value measured by Millikan in two different electroscopes. But in the case represented by curve II, with a 2-in. lead shield at an altitude of 5400 ft., only 52 pairs of ions were actually produced in 1 sec in a region which was occupied by a quantity of air which would occupy about 159 cc at N. T. P. Presumably, this ionization was due partially to energy absorbed from the penetrating radiation by the walls of the vessel as well as by the air itself. It would seem, then, that the ionization produced by the cosmic radiation in the atmosphere, if free from dust or other suspended particles, would be considerably less than that calculated on the basis of 1.4 ion/cc·sec at sea-level. This situation has been emphasized by Swann¹⁹ on the basis of the earlier ionization-pressure experiments. To quote: "Thus, the actual ionization in the vessel, due to primary and secondary emission from the gas, will be less at one atmosphere than at any higher pressure. If then, the ionization-pressure curve should show a very small increase of ionization per atmosphere increase at high pressures, we know from the above that such increase per atmosphere is nevertheless greater than the portion

of the ionization due to primary and secondary action in the gas within the vessel at one atmosphere. We may infer that any greater ionization found at atmospheric pressure is to be attributed to radiation from the walls of the vessel; this radiation, owing to its absorption at the higher pressures, results in a diminishing rate of increase of ionization with pressure. . . . If one were to accept this parallelism without reservation, he would be forced to conclude that the portion of the ionization within the vessel which was attributable to the direct or indirect action of the (penetrating) radiation on the gas was immeasurably small."

Naturally, if one ionization chamber is used by each observer throughout his investigations, values of the absorption coefficient of the penetrating radiation measured by different observers should agree fairly well, as they do.⁸ However, the estimates of the intensity of the radiation based upon ionization measurements would be expected to differ and such agreement as exists probably depends upon the fact that no vast differences have existed among the experimental conditions. The writer is inclined to believe that differences in the effects of secondary radiations may in some instances play even a more important part than the "zeros of their instruments"²⁰ in explaining the lack of agreement among different experimenters as to the intensity of the primary cosmic radiation.

Dependence upon time

The question of the variation with time of the natural ionization in gases has been a matter of investigation for a good many years, with a great deal of resultant disagreement. Very recently a diurnal variation in the ionization produced by the cosmic radiation has been observed by Millikan²¹ and by Hess.²² They both agree that this ionization is somewhat greater during the day than during the night, an indication of which was formerly observed by the writer.²

Hess explains the variation on the basis of penetrating radiation originating in the sun, while Millikan considers it to be due to variations in atmospheric absorption, and shows a correlation with variations of atmospheric pressure. Whatever the explanation, it has probably occurred to the reader that this effect might serve to explain the constancy of the ionization observed in this investigation at the very high pressures. If the ionization at the highest pressure were observed when the intensity of the cosmic radiation happened to be at a minimum and if the ionization at successively lower pressures were measured with an increasing radiation intensity, a high-pressure slope which might have existed could the measurements at different pressures have been made simultaneously, could conceivably have been compensated. However, this was not the case. Millikan²¹ found the intensity of the cosmic radiation to pass through a maximum in the late afternoon and a

²² V. F. Hess, *Nature* **127**, 10 (1931).

minimum at night or in the early morning. In the cases of curves I-IV, the observations at the highest pressures were begun in the respective instances at 5:31 P.M. Apr. 26, 4:14 P.M. May 24, 6:00 P.M. July 19, and 3:23 P.M. June 21, 1930. In the cases of curves I, II and IV the low pressure ends of the practically horizontal portions of the curves at about 130 atm., were reached at about 2:00 A.M. of the following days, and in the case of curve III, at midnight. Atmospheric pressure was usually reached by the evening of the second day.

The observed constancy of the ionization at the high pressures might therefore be considered to constitute evidence against variations of the type mentioned. This need not follow when it is considered that we have here only three instances of extreme constancy. In particular, during the period of the observations for curve II a sensitive barograph was kept in the room with the other apparatus where the temperature was very uniform, and no fluctuations of more than 1 mm occurred during the entire period. The barometric pressure was not observed in the other instances except in connection with the readings at atmospheric pressure, whence a similar constancy may have happened to exist. However, the observed constancy of ionization, in connection with the way the end points fit into the curve of Fig. 6, otherwise observed Aug. 16-17, tends to provide interest in a careful investigation of the variation with time of the ionization in the vessel at the very high pressures.

In conclusion, the writer desires to express his sincere appreciation of assistance received from several sources. Funds in aid of this research were provided by the American Association for the Advancement of Science. The Mountain States Telephone and Telegraph Co. on behalf of the Bell System provided some two tons of lead. The staffs of the several Engineering Departments of the University rendered very generous assistance; in particular, Professor S. L. Simmering and Mr. C. A. Wagner of the Department of Mechanical Engineering compressed all the air used in this investigation. Assistance in recording observations was given by Professor G. B. Williston and by Messrs. Louis Strait, J. M. Porter, Sydney Hacker and Ralph Warren. The photograph was taken by Mr. R. A. Merrill. Professor Swann has read and criticized the paper.

THE DIELECTRIC CONSTANT OF AIR AT HIGH PRESSURES¹

BY JAMES W. BROXON
UNIVERSITY OF COLORADO

(Received April 10, 1931)

ABSTRACT

The dielectric constant of aged, dry, dust-free air was measured at pressures up to 170 atmospheres by an electrometric method. It was found to increase linearly with the pressure.

FREQUENTLY quoted values of the dielectric constant of air at high pressures are those obtained by Tangl,² in 1908, at pressures up to 100 atmospheres. In 1913, Occhialini and Bodareu³ made measurements up to 334 atmospheres. In both these investigations, the Clausius-Mossotti relation was found to hold. Both Tangl⁴ and Occhialini⁵ had announced in earlier papers, however, that the Clausius-Mossotti relation did not hold.

More recent measurements of dielectric constants have been made largely by means of modern high-frequency methods. These have been criticized by Cagniard⁶ who has drawn attention to the very large variations among the values of the dielectric constant of air at atmospheric pressure obtained by these methods by various observers, and has contrasted them with the better agreement among values obtained by the older methods.

Very recent investigations by Keyes and Kirkwood⁷ of the dielectric constants of carbon dioxide and ammonia have given interesting information concerning their variations over large ranges of density, and the considerable deviations from the Clausius-Mossotti relation.

In the present paper are presented measurements of the dielectric constant of dry air between pressures of 0.821 and 169.4 atmospheres at 18°C, made by a method closely resembling that of Occhialini and Bodareu.³

PROCEDURE

In connection with recent measurements of the residual ionization⁸ in air at high pressures, the mere addition of a Wheatstone bridge to the equipment otherwise required, and the measurement of two resistances, yielded the values of the dielectric constant of the gas at the various pressures at which observations of the ionization were made. The reader should refer to the

preceding paper⁸ on the residual ionization for details regarding apparatus, conditions of experimentation and procedure which it is considered unnecessary to repeat here.

The wiring diagram is given in Fig. 2 of the preceding paper. The applied potential difference was impressed across the high resistance system, R , r' , r'' , and leads run from this to the ionization chamber S (see also Fig. 3 of preceding paper), the guard system, and the exterior cylinder of the auxiliary condenser C (also see Fig. 4 of preceding paper), in order to eliminate effects of fluctuations of the applied P.D. At each pressure, before observations of the ionization current were begun, the apparatus was "balanced" by adjusting the resistance contacts until no deflection of the quadrant electrometer occurred when the large P.D. was suddenly applied or withdrawn from the high resistance system. Due to the rather large residual ionization currents at the high pressures, an accurate balance could be obtained at these pressures only by adjusting the resistances so that sudden removal of the impressed P.D. caused no permanent variation in the small deflection which existed at the instant of removal.

If we designate by V_s and V_c the absolute values of the potential differences between the guard system and the outer conductors of the ionization chamber and the auxiliary condenser, respectively, and by q_{21} and q_{31} the corresponding induction coefficients of these relative to the central system, then we have under the above conditions of balance,

$$q_{21}V_s = q_{31}V_c.$$

This relation is readily established by the following considerations. Let V_1 , V_2 , V_3 , V_4 and V_5 be the respective potentials of the central system, the ionization chamber, the outer cylinder of C , the guard system, and the needle. Let q_{11} , q_{21} , q_{31} , q_{41} and q_{51} be the corresponding induction coefficients of these relative to the central system. Then the charge on the insulated central system may be expressed by

$$Q_1 = q_{11}V_1 + q_{21}V_2 + q_{31}V_3 + q_{41}V_4 + q_{51}V_5.$$

Suppose, for convenience, we consider the potential of the guard system to be the arbitrary zero. Then when the P.D. across R is suddenly removed Q_1 , V_4 and V_5 individually remain constant, and in order that V_1 may remain constant while V_2 and V_3 are each reduced to zero, we must have

$$q_{21}V_2 + q_{31}V_3 = 0$$

or

$$q_{21}/q_{31} = -V_3/V_2 = V_c/V_s.$$

Now we may put

$$V_c/V_s = R_c/R_s,$$

where R_c and R_s , respectively, represent the resistances at balance between

⁸ Broxon, Phys. Rev. 37, 1320 (1931). Preceding paper in this issue.

the auxiliary condenser and the guard system and between the ionization chamber and the guard system, across which, in series, the total P.D. of about 1050 volts was applied. Substituting, we have

$$q_{21} = q_{31}(R_c/R_s).$$

The auxiliary condenser, C , being fixed and always at atmospheric pressure, q_{31} remained constant.

If, now, the ratio R_c/R_s be plotted against the total pressure in the ionization chamber, the intercept of this curve upon the ratio axis represents $1/q_{31}$ of the value of q_{21} with the ionization chamber entirely evacuated, while other points on the curve represent $1/q_{31}$ of the values of q_{21} at the corresponding pressures. Hence the value of R_c/R_s at any pressure, when divided by the intercept value, gives the dielectric constant of the gas in the chamber at that pressure, referred to $K = 1$ in vacuo.

OBSERVATIONS

The curve of Fig. 1 was obtained in the above manner. The circles represent observations made with the ionization chamber unshielded and the crosses represent values obtained four weeks later with the lead shield in

Fig. 1.

position. The two sets of readings give values of R_c/R_s at some 35 distinctly different pressures distributed well over the range. It is seen that both sets of points fall remarkably close to a straight line. Inasmuch as the curve remains straight over a range of nearly 170 atmospheres, and further, since Wolf⁹ has

⁹ Wolf, Phys. Zeits. 27, 588 (1926).

found that the dielectric constants of the chief constituent gases of air vary linearly with the pressure to small fractions of an atmosphere, it was considered justifiable to extrapolate by continuing the straight line to zero pressure. Division of the ordinates of the curve by the intercept so obtained, shows that the dielectric constant of air increases uniformly by 555×10^{-6} for each atmosphere increase in pressure at 18°C .

DISCUSSION

If $(K-1)/P = \text{const.}$, then inasmuch as σ , the density of the air, varies from proportionality with P , $(K-1)/\sigma$ can not be constant. Also, the Clausius-Mossotti relation

$$(K-1)/\sigma(K+2) = \text{const.}$$

can not be true.

The present investigation, then, confirms the constancy of the first ratio, and denies the constancy of either of the latter ratios, unless the variations in either of these lie within the limits of the experimental error.

This latter possibility deserves careful consideration. According to the Landolt-Börnstein tables (1923), Amagat found the values of PV and hence P/σ for air at 16°C to pass through a minimum in the neighborhood of 80 atmospheres, increasing at higher pressures and reaching atmospheric value at about the upper pressure limit of the present measurements. Using these values and the observed values for K at 18°C , the values of $(K-1)/\sigma$ are found to pass through a corresponding minimum about 2 percent less than the value at atmospheric pressure. $(K-1)/\sigma(K+2)$ is similarly found to pass through a minimum at about 90 atm., which is about 3.7 percent less than the value at atm. pressure.

Accuracy of the measurements

The resistances were measured by means of a Leeds and Northrup portable bridge. Individual resistances of this bridge have a guaranteed accuracy of only 0.1 percent. However, an investigation of the particular coils used in this instance showed the error to be only about 0.01 percent in the resistances measured, apart from inaccuracies in the bridge ratio-resistances, and these latter inaccuracies as well as errors due to temperature variations, cancelled in the ratio R_c/R_s . The error in a particular value of R_c/R_s , then, was probably about 0.02 percent. Since the same coil was used throughout for the first significant figure of R_c , a similar situation holding for R_s , the fractional error in R_c/R_s was in the same direction and of the same order of magnitude throughout, whence the fractional error in $(R_c/R_s)/(R_c/R_s)^0$ may be expected to be of one smaller order of magnitude than the error in a single ratio. Hence the error in K may be estimated to be of the order of 0.002 percent, or an error of less than 1 percent of $(K-1)$ at all pressures above 4 atmospheres. Since the curve was not unduly weighted by the readings at atmospheric pressure, we may therefore expect an error of less than 1 percent in $(K-1)$ throughout the range.

In the above, it is assumed that other conditions were ideal. It was not necessary that the resistivity of the materials constituting the measured resistances remain constant during a series of observations, but it was essential that no change of this type should occur between the time of "balance" and the time when the resistances were measured. No appreciable error could have occurred on this account. R consisted of about 102,000 ohms formed by winding coils of silk-covered high resistance wire of low temperature coefficient, in single layers over thin paraffined paper upon 108 long vertical brass tubes submerged in kerosene. r' and r'' consisted of two large, open tubular slide-wire rheostats, each of about 3000 ohms resistance, shunted across two or three of the thousand-ohm coils of R , one on each side of the earthed point. The maximum current through any of these was of the order of 0.01 ampere. No appreciable heating occurred, and certainly no sudden changes in temperature were possible. The measured values were found in no instance to vary with the time interval between balance and the resistance measurement.

Lead resistances were negligible. The largest ionization currents in parallel with the current in R_s were only of the order of 3×10^{-13} amp. The sensitivity of the electrometer as an indicator of the condition of "balance," with the P.D. employed, was sufficient to detect changes in the resistance ratio which could not be measured with the bridge. Constancy of the applied P.D. was not required.

Errors in the corrected pressure gauge readings were probably of the order of 0.1 percent at the upper end of the scale. The atmospheric pressure could be determined with this accuracy, of course. With the temperature measuring device employed, and with the precautions taken to ensure equilibrium conditions, it is believed that the temperature of the air did not vary by 0.5°C from the recorded temperature in any instance. Moreover, the total variations in temperature were very small. In the first set of readings the temperature varied from 18.3°C to 16.85°C , and in the second set from 18.0°C to 17.0°C over the whole range with the exception of the reading at atmospheric pressure which was made at a temperature of 16.8°C . In view of the small variations in temperature, reductions of pressures to equivalent pressures at 18°C were made on the basis of the proportionality between P and the absolute temperature.

The constancy of q_{31} may be appreciated when it is mentioned that the air in C was always at atmospheric pressure, and that during the second set of observations the atm. pressure did not vary by more than 1 mm of Hg.

From the dimensions, form and material of the ionization chamber and of the central electrode, it appears that no appreciable errors could have resulted from their deformations at the high pressures. Considerations of various conditions, particularly of the agreement between the two independent sets of readings, lead the writer to believe that no appreciable disturbance was caused by deformations of the ebonite insulators.

Perhaps the most outstanding advantage of this method of measurement is that it permits the use of a guard system which, when properly designed, effectively excludes the influence of the solid insulators due to their dielectric

properties, surface charges, etc. The necessary presence of solid insulators constitutes a perpetual hazard in other methods of measurement.

In view of the above considerations it would seem that apart from personal errors, an estimated error of 1 percent in the values of $(K-1)$ and their pressure variations would not represent too optimistic an attitude, and that the investigation ought to be capable of testing the accuracy of the Clausius-Mossotti relation. As a further test of this conclusion, it was thought worthwhile to calculate the value of R_c/R_s which would have been required at 100 atm. in association with the intercept value herein used, in order to provide the same value of the Clausius-Mossotti function at that pressure as at atmospheric pressure. This value is designated by the small square in Fig. 1, and is seen to be decidedly farther from the curve than any but the first of the individual readings taken.

Comparison with other investigations

As mentioned above, there is a lack of agreement with the conclusions of Tangl² and of Occhialini and Bodareu³ in that they found the Clausius-Mossotti relation to hold for air at high pressures. In earlier investigations both Tangl⁴ and Occhialini⁵ had concluded that the $C-M$ function decreased as the pressure increased, in general agreement with the present investigation. In this earlier paper Tangl concluded that $(K-1)$ varied directly with the density. In his 1908 paper, although Tangl concluded that the $C-M$ function was constant, the function actually decreased slightly, according to the tabulated values, with increasing pressure in the case of each of the gases investigated, hydrogen, nitrogen and air.

$(K-1)/\sigma$ and $(K-1)/P$ both decreased with increasing pressure in the case of hydrogen, and increased with increasing pressure in the cases of nitrogen and air. In the case of air, the decrease in $(K-1)/\sigma(K+2)$ between one and 100 atmospheres amounted to nearly 1.5 percent of its value at atmospheric pressure, about 1 percent less than the corresponding increase in $(K-1)/P$.

In the region between 64 and 334 atmospheres, Occhialini and Bodareu found $(K-1)/P$ to decrease about 10 percent, $(K-1)/\sigma$ to increase about 4 percent, and $(K-1)/\sigma(K+2)$ to show no unidirectional tendency, the fluctuations amounting only to about 1 percent.

In connection with the increase in the $C-M$ function observed in the present investigation at pressures above 90 atm., it is interesting to note that Keyes and Kirkwood⁷ found the function to increase in the case of carbon dioxide at high densities, approaching a constant value in the liquid state.

The value of K for air at atmospheric pressure is of special interest. Tangl's 1908 value for K at 1 atm. and 19°C is 1.000536. If this be reduced to 1 atm. and 0°C on the basis of the constancy of $(K-1)/P$ and of P/T in this interval, the value obtained is 1.000573. On the same basis, the values obtained in the present investigation are 1.000555 at 18°C and 1.000592 at 0°C. The corresponding value obtained by Occhialini and Bodareu on the basis of the constancy of the $C-M$ function is 1.000585. On the basis of sepa-

rate investigations some values obtained by other experimenters for air at N. T. P. are: Boltzmann (1875), 1.000590; Klemenčič (1885), 1.000586; Waibel¹⁰ (1923), 1.000584; Carman and Hubbard¹¹ (1927), 1.000594. Cagniard⁶ lists several others.

To explain the differences between the conclusions of the present investigation and others cited does not appear to be a simple matter. It is perhaps significant that Tangl could not have eliminated entirely the effects of solid insulation in the compression condenser. Also, his results depended upon variations in the capacity of a movable plate condenser. In the investigation by Occhialini and Bodareu, extreme constancy of the e.m.f.'s of the batteries they employed was necessary. The relatively low potential differences they used would produce a smaller sensitivity than in the present instance, with the same electrometer sensitivity. In the present investigation, greater accuracy could have been secured by having q_{21} and q_{31} more nearly equal, and by the employment of a more accurate bridge. Some difference between these observations and those of Tangl might be attributed to the fact that he removed both the water vapor and the carbon dioxide, whereas in this investigation only the water vapor was removed, together with possible dust particles.

A feature of some interest consists of the very small residual ionization of the compressed air used in this investigation, probably much less than in any other, and the fact that this ionization was determined at each pressure at which measurements were made.

THE VARIATION OF THE SPECIFIC HEATS (C_p) OF OXYGEN, NITROGEN AND HYDROGEN WITH PRESSURE

BY E. J. WORKMAN*

BARTOL RESEARCH FOUNDATION OF THE FRANKLIN INSTITUTE

(Received April 6, 1931)

ABSTRACT

The specific heats, C_p , of oxygen at 26° and 60°C, nitrogen at 26° and 60°C and hydrogen at 50°C have been measured as a function of pressure over the pressure range 10 to 130 kg/cm². A continuous flow method is used, by which the ratio of C_p at a pressure p to $(C_p)_0$ of the same gas at a pressure of one atmosphere is measured. The theory of the method shows that the experimental results are practically independent of the usual errors arising from heat leakage and the Joule-Thomson effect. Complete experimental curves as well as tabulated values are shown for $C_p/(C_p)_0$ as a function of pressure. Details of construction and use of the apparatus are given.

IN A previous paper¹ the author has described an experimental method for determining the variation of the specific heat C_p of a gas with pressure. A method of continuous flow calorimetry was used whereby the ratio of C_p at a pressure p to $(C_p)_0$ at a pressure of one atmosphere was measured. The present paper presents values of this ratio obtained by the use of improved apparatus over the pressure range of 10 to 130 kg/cm², for oxygen at 26° and 60°C, nitrogen at 26° and 60°C and hydrogen at 50°C.

I. THEORY OF THE METHOD.

A schematic representation of the new apparatus is given in Fig. 1. A gas at a high pressure enters a temperature-controlled bath at a where it comes to a fixed temperature. From the bath the gas is conducted through a *heat interchanger* and then to a *pressure reduction valve* where the pressure is reduced to approximately one atmosphere. At the low pressure the gas passes through a second bath, (different in temperature by 10° from the first) and again passes through the *heat interchanger* and escapes. In the interchanger the two gas streams are in such intimate thermal contact that they emerge at approximately the same temperature. The temperature of each gas stream is measured just before it enters and leaves the interchanger at T_1 , T_2 , T_3 and T_4 where $T_2 - T_1 = \Delta t$ and $T_4 - T_3 = \Delta t_0$ are the temperature changes in the high and low pressure streams respectively.

After passing through the region where the interchange of heat takes place both gas streams are thermally connected to some conducting *base (for wall)* on which is mounted a conducting surface (*interchanger wall*) which encloses the entire *interchanger* including some length of the gas conduits with their respective radiation-convection shields S_1 , S_2 , S_3 and S_4 . With this construction it is possible to regulate the temperature of the heavy copper

* National Research Fellow.

¹ E. J. Workman, Phys. Rev. 36, 1083 (1930).

heater guard in such a way that the *interchanger wall* will be an isothermal enclosure equal in temperature to the *heater guard*. The conduits leading to and from the interchanger are of low thermal conductivity and arranged with the view of minimizing the net heat leakage through the wall of the interchanger.

If we assume that a steady state of gas flow and temperature distribution has been attained, we see that there is an interchange of heat between the two gas streams, and that a simple relation exists between C_p for each gas stream and the four measured temperatures indicated above. The resistance

Fig. 1. Schematic diagram of apparatus.

to the flow of gas between the points where their temperatures are measured will give rise to a small Joule-Thomson temperature change in each stream. Let us indicate these temperature changes by $\mu\Delta p$ and $\mu_0\Delta p_0$ in the high and low pressure lines respectively. Also let q be a net amount of heat per gram of gas gained through leakage by the two gas streams. Since the pressure and temperature differences over each gas stream in the interchanger are small we can now write

$$q = \bar{C}_p[\Delta t + \mu\Delta p] - (\bar{C}_p)_0[\Delta t_0 + \mu_0\Delta p_0] \quad (1)$$

where C_p and $(C_p)_0$ are average values over the temperature intervals indicated by Δt and Δt_0 respectively. Solving (1) for $\bar{C}_p/(\bar{C}_p)_0$ we have

$$\frac{\bar{C}_p}{(\bar{C}_p)_0} = - \frac{\Delta t + \mu_0\Delta p_0 - q/(\bar{C}_p)_0}{\Delta t + \mu\Delta p} \quad (2)$$

Expanding the right hand number of Eq. (2) we have

$$\frac{\bar{C}_p}{(\bar{C}_p)_0} = - \frac{\Delta t_0}{\Delta t} - \phi \quad (3)$$

where ϕ is a correction term, given by the relation

$$\phi = \left[\frac{\mu\Delta p\Delta t_0}{\Delta t} - \mu_0\Delta p_0 - \frac{q}{(\bar{C}_p)_0} \right] \left[\frac{1}{\Delta t} - \frac{\mu\Delta p}{\Delta t^2} \dots \right] \quad (4)$$

With the usual methods of flow calorimetry it is difficult to deal with correction terms of the type of ϕ in Eq. (3). It seems therefore that perhaps the greatest virtue of the method, outlined above, rests on the fact that it is possible to eliminate, almost completely, errors of this kind by interchanging the bath temperatures and taking the mean value of the two results thus obtained. If a set of temperature readings be taken when, for example $T_1 = 45^\circ\text{C}$ and $T_3 = 55^\circ$ and a similar set taken for the reverse arrangement $T_1 = 55^\circ$ and $T_3 = 45^\circ$ we see, when applying these readings toward the determination of $\bar{C}_p/(\bar{C}_p)_0$ in Eq. (3) that the correction term is changed in sign but not appreciably in value in going from one arrangement to the other. This result is apparent from Eq. (4) if we bear in mind the fact that $\mu\Delta p$ does not differ greatly from $\mu_0\Delta p_0$ and that they are both small in comparison to the measured temperature intervals. Furthermore q is small in comparison to the amount of heat available for transfer between the two gas streams in passing through the interchanger and is approximately the same in each arrangement of bath temperatures. The fact that in either case, T_2 and T_4 do not differ much from the mean of T_1 and T_3 justifies the assumption that the factors which determine the magnitude of q will be about the same in these two experiments.

These arguments indicate that it is possible to conduct a set of experiments whereby a value of $\bar{C}_p/(\bar{C}_p)_0$ is obtained which, to a very high degree of approximation will be independent of the Joule-Thomson effect and small heat leakages of the type q . Moreover, if we assume that the values of the specific heats here involved have a linear variation with temperature over the small range T_1 to T_3 , we see that $\bar{C}_p/(\bar{C}_p)_0$ becomes simply the value of $C_p/(C_p)_0$ at the mean temperature $(T_1 + T_3)/2$.

RESULTS

With apparatus designed with the aim of meeting the requirements set forth in the foregoing paragraphs, values for $C_p/(C_p)_0$ have been determined for oxygen at 26° and 60°C , nitrogen at 26° and 60°C and hydrogen at 50°C over the pressure range of 10 to 130 kg/cm^2 . In all cases the temperature difference in the two gas streams as they enter the interchanger ($T_1 - T_3$) has been $\pm 10^\circ\text{C}$.

The results of the measurements are shown graphically in Fig. 2 where $(T_4 - T_3)/(T_1 - T_2)$ are plotted as ordinates against the pressure in kg/cm^2 as abscissae. In all these cases the upper curves are obtained when the bath temperatures are arranged such that $T_1 < T_3$ i.e. when the high pressure gas is warmed and the low pressure gas is cooled in the interchanger. The lower curves represent the data for the reverse arrangement of bath temperatures. The mean curves in Fig. 2a, b, c, d and e give the values of $C_p/(C_p)_0$ as a function of pressure.

In Table I values of the ratio $C_p/(C_p)_0$ for the gases studied are given with their corresponding pressures and molecular density ratios. The density

specific heat ratios were obtained from the carefully drawn mean curves. The probable error is less than 0.2 percent. The curves in Fig. 3 show $C_p/(C_p)_0$ as a function of the molecular density.

DISCUSSION OF RESULTS.

In the first part of this paper it is shown that the separation of the two experimental curves for each case given in Fig. 2 a, b, c, d, and e is due to the existence of a correction term ϕ (Eq. 3). Although this term involves, as well as the Joule-Thomson effect, a small heat leakage q , it is of interest to consider the Joule-Thomson effect alone.³

With oxygen and nitrogen the Joule-Thomson effect is a cooling effect under these conditions of temperature and pressure. In the series of experiments where $T_1 < T_3$ this cooling would therefore have the effect of decreasing the magnitude of $T_1 - T_2$ and increasing that of $T_4 - T_3$. As a result the values of $C_p/(C_p)_0$ calculated by the relation $C_p/(C_p)_0 = (T_4 - T_3)/(T_1 - T_2)$ would be too large. By similar reasoning we see that corresponding values would be too small when the reverse arrangement of bath temperatures is used, i.e. when $T_1 > T_3$. A separation in this direction is observed in the cases of oxygen and nitrogen. With hydrogen, however, we expect the Joule-Thomson effect to warm the gases slightly under the conditions of this experiment. It is in this case where a large Joule-Thomson effect does not predominate in producing a separation of the curves that we see most clearly the effect of a small heat leakage. A further study of heat leakage in the case of hydrogen was made by increasing the flow of gas to double the normal rate. The increased flow of gas may alter the relationship between q and the regular interchange of heat. This would be shown by a change in the interval between the two curves. The dotted points of Fig. 2e show the effect of the increased flow for hydrogen, where the points above the mean curve are associated with conditions which produced the upper curve and the other points result from the inverse arrangement of bath temperatures. *The symmetry in the position of the "dotted" points, with respect to the mean curve, gives additional proof that the mean value curve is independent of the term ϕ in Eq. (3).*

It is of interest to examine the curves for evidence of the Joule-Thomson effect in the region of lower pressures. If the rate of gas flow in grams per second remains constant, it is apparent that the volume of gas passed per second in the high pressure line of the interchanger will increase at the lower pressures with the result that the Joule-Thomson effect will come more and more into effect in this region. This is shown with remarkable certainty in all three gases. The behavior of hydrogen in this region is of peculiar interest because the Joule-Thomson effect is observed as a warming effect instead of cooling as in oxygen and nitrogen.

In passing the discussion of the curves presented here, it should be stated

³ In this treatment we have not considered the effect of temperature on the specific heats of gases in relation to the interval between the curves. It is easy to show that such a consideration would give rise to a second term in Eq. (3) which, like ϕ , almost completely vanishes in the mean curve.

that in general, care should be taken in attaching any particular significance to the shape of the upper and lower curves except in so far as the mean curve is affected. It must be remembered that the conditions of gas flow in the high pressure stream are different for all values of the pressure. As a consequence the temperature gradients along the conduit leading to the interchanger may change in such a way as to change the magnitude of the heat leakage. Indeed it has been possible in the case of nitrogen at 60°C to change the flow over such a wide range that q changed in sign. In connection with limitations just mentioned it may be of equal importance to say that to one using this method to study the specific heat of gases, the character as well as the position of the individual curves may point to the imperfections of the apparatus at hand. For example, we can be reasonably certain that in the present apparatus the net heat transfer q arises from an excessive heat conduction along the line leading from the low pressure bath to the heat interchanger.

The data indicate that the heat leakage and the Joule-Thomson temperature effect are both within the allowable magnitude specified in the theory of the method. The intercepts of the mean curves on the pressure axis indicate that there is no trouble in measuring temperatures as was certainly the case in the work previously reported by the author.¹ The errors in this earlier work were due to the fact that the temperature gradients which gave rise to an error in temperature measurements in one region of pressure differed more in another region than was expected at that time. In the light of further work, however, it is made clear that this variation is to be expected when temperatures are measured as in the earlier work.

The oxygen and hydrogen used in this work was obtained from the Philadelphia plant of the Paschall Oxygen Company, and the nitrogen from the Linde Air Products Company of New York City. By special analysis at the respective plants these gases were shown to be better than 99.5 percent pure. The gas was dried over phosphorus pentoxide before it was passed through the apparatus.

DETAILS OF CONSTRUCTION AND USE OF THE APPARATUS.

A simple scale drawing of the apparatus is difficult to realize because of its compactness and lack of symmetry in a single plane. Fig. 4 is a "sectional" drawing which may serve to show the actual construction of the several parts as well as the complete gas circuit. The scale is distorted but dimensions of the interchanger parts may be estimated if the various parts (thermometer tubes, shields etc.) are considered as drawn to scale, connected as shown but spread out laterally in the plane of the paper. The cylindrical boundary of the interchanger must therefore be thought of as being 2.25 inches in diameter and 5 inches long rather than 4.5 inches in diameter and 5 inches long as the scale might indicate. The same consideration must be made for the heater guard w which is 3 inches in diameter and 7 inches long. The high pressure gas conduits, where low thermal conductivity is desired, are nickel silver tubes 0.063 inches outside diameter with 0.010 inches wall. The corresponding low pressure tubes are of nickel silver with 0.125 inches outside diameter and 0.005

wall. Other tubes are drawn to a corresponding scale. All nickel silver parts are thinly gold plated.

The gas circuit is as follows: Gas from the high pressure reservoir is conducted to the tube *c* through which it passes to the temperature controlled bath *b*. The inner bath *ib*, being heat insulated from *b* serves to smooth out temperature fluctuations due to slight periodic changes in the heating current applied to the outer bath, which surrounds it. The gas stream now passes through the nickel silver tube *e* which conducts it through the boundary of

Fig. 4. Sectional diagram which shows the actual construction of the several parts of the apparatus as well as the complete gas circuit.

the interchanger *h* to *g* where the light walled tube turns back sharply and is soldered, for thermal contact, to the copper radiation shield *r*. From *m* to *j* the conduit is developed into the form of a spiral helix which terminates at *j* where another shield *i* is attached. The circuit passes from *j* to the chamber *s* where nearly all the interchange of heat between the two gas streams takes place. From this enclosure the high pressure gas passes into a copper tube at *u* which winds about between the two copper walls *v*, to which it is soldered for thermal contact, leading to the nickel silver tube *l* which passes the gas through the outlet thermometer tube *o*. A radiation convection shield *n* is soldered to *l* as shown. From the outlet thermometer tube the gas passes, along the path indicated, to the reduction valve *f* where the pressure is re-

duced. After passing the point z the gas at a pressure of approximately one atmosphere is conducted to a second temperature controlled bath a . The course of the low pressure gas through the apparatus is exactly similar to that of the high pressure stream except that in the region between t and l the low pressure stream is constrained to move in a spiral path through the duct formed by the high pressure line and the two copper walls v . From the point g' the low pressure gas escapes into the air.

The temperature controlled baths are made by machining thick-walled copper tubes in such a way that one fits snugly inside an outer tube. Helical grooves cut on the smaller tube serve as a conduit for the gas streams. The two baths thus constructed consist essentially of a solid block of copper about 5 inches long and 2.5 inches in diameter. The outer baths are equipped with electrical heating coils for maintaining constant temperatures while the inner baths are allowed to "float" at a temperature determined by the temperature of the gas which flows through them. The relative sizes of the outer and inner baths are represented approximately in the drawing.

The interchanger, as will be seen, is constructed in such a way that the regions of large temperature differences are in its inner folds while the outside is very nearly equal in temperature to the temperature of the two gas streams as they leave the interchanger. With this arrangement it is possible to have an isothermal surface h on the interchanger which can be thermally protected by keeping the temperature of the surroundings equal to the temperature of the surface. This is accomplished by means of the heavy copper heater guard w which is kept at the same temperature as the surface of the interchanger by maintaining a zero reading on a five junction copper-constantan thermocouple connected to their respective surfaces.

The thermocouple which measures temperature change on the high pressure line has one end inserted in the hole d in the inner bath. It passes through a german silver tube e , a copper tube k and terminates in the thermometer tube p . Since the thermometer tube is very nearly equal in temperature to the interchanger surface and the heater guard, conduction from the interchanger along the thermocouple wire is minimized by passing the thermocouple wires through the tube k which is soldered to the heater guard. Practically the entire temperature gradient along the thermocouple wires exists along the length between the bath and the wall of the heater guard. Tube f is a thin-walled nickel silver tube which is soldered to b and extends through the first heater guard wall, having the purpose of protecting the wires and smoothing out the temperature gradient along them. Other thermocouples measure the temperatures of ib and the heater guard to an ice bath. The temperatures on the low pressure side are measured by exactly similar methods.

The temperature difference between the two baths is maintained at 10°C . Temperature gradients therefore exist between the points where the inlet temperatures are measured and some point inside the interchanger where the interchange of heat between the two gas streams starts. In order to minimize the net transfer of heat along the entrance tubes, it is desirable to prevent the interchange of heat for some distance after the gas streams pass through the boundary of the interchanger. To accomplish this, the tubes in addition to

being poor heat conductors are gold plated to give a surface of low emissivity to radiation at these temperatures. The radiation-convection shields i and r are of copper thinly gold plated. Small dewar flasks df and df' further serve to isolate these regions. It is found by direct measurement that with these precautions the temperature changes along the tubes from e to q and the corresponding length e' to q' are of the order of 1 percent of the total changes. The thermal conductivity per unit length of the two inlet tubes is approximately the same and since the temperature changes are in all cases almost equal and opposite, a compensating effect should reduce the net transfer of heat along them.

On the outlet side little trouble with heat conduction is met, because the temperatures to be measured are so nearly equal to the surrounding temperatures. The interchange of heat between the two gas streams has been made as complete as is easily possible in order to produce this condition of temperature equality at the outlet side. The amount of interchange is somewhat dependent upon the gas used and the condition of flow but for all conditions the deficiency in interchange does not exceed 0.2 percent.

The enclosure defined by the walls v and h will therefore be at about the same temperature as the outlet thermometers and the shielding here represented is considered adequate for the purpose of isolating the region where the temperatures are measured. Measurements are carried out at different temperatures and since it is desired to have similar conditions for each experiment the entire assembly is enclosed by a constant temperature boundary which in all cases is maintained at a temperature 10° lower than the mean of the two bath temperatures. This boundary is a temperature controlled cylindrical shell about 18 inches long and 6 and 8 inches inside and outside diameters. Since the difference in bath temperatures is always 10°C one will be five degrees and the other 15°C above the temperature of the enclosure. To prevent this temperature distribution from producing dissimilar conditions when the bath temperatures are interchanged the shield g which is thermally connected to w is provided.

The temperature of enclosure x is controlled by a thermostat while the two bath temperatures are controlled manually by the observer. All temperature measurements are made by the use of five-junction constantan-copper thermocouples, used with a White double potentiometer and the usual auxiliary equipment.

The flow of gas is controlled by producing a constant rate of delivery to the low pressure bath. This is accomplished by maintaining a constant pressure on a capillary leak z (Fig. 2). In general the flow of gas on the low pressure side was maintained at 70 cc/sec. for oxygen, 80 for nitrogen and 160 for hydrogen.

Pressure measurements were made with a high class Bourdon spring gauge developed for this work, in the shops of this laboratory. It was calibrated against a dead weight gauge.

The author is indebted to the staff of the Bartol Research Foundation for providing facilities for this work, and the United States Gauge Company for calibrating pressure gauge.

ELECTRICAL RESISTANCE OF NICKEL AND IRON WIRES AS
AFFECTED BY LONGITUDINAL MAGNETIC FIELDS

BY O. STIERSTADT

LABORATORY OF APPLIED ELECTRICITY, UNIVERSITY OF GOETTINGEN

(Received February 11, 1931)

ABSTRACT

In a paper on electrical resistance of nickel and permalloy wires as affected by longitudinal magnetization and tension, L. W. McKeehan pointed out that further investigation and discussion of some special questions regarding change of resistance of ferromagnetic substances in magnetic fields were highly desirable. In the present paper the following subjects are treated, partly on the basis hitherto unpublished measurements by the author. (1) Change of resistance in small fields. As the literature shows, the question whether this is independent of the magnetic history of the sample is not yet settled. Anomalies often observed are not real. (2) The early saturation of the magneto-resistance effect, a condition which is reached in considerably weaker fields with ferromagnetic bodies than with para- and diamagnetic bodies. An explanation on the basis of the electron theory is suggested.

INTRODUCTION

IN A very interesting paper on the change of electrical resistance of nickel and permalloy in longitudinal magnetic fields McKeehan¹ treated extensively the question of variation of the electrical resistance of permalloy in magnetic fields under the influence of tension as dependent upon the variation of the nickel content of the permalloy. He finds certain phenomena which present a remarkable analogy with the change of resistance of ferromagnetic bodies in magnetic fields. For this reason he discusses in great detail the most important papers on magneto-resistance and elasto-resistance.

In the present paper only the papers of the first group dealing with magneto-resistance will be discussed. McKeehan quotes as the most interesting of the recent papers in this field that of Fr. Vilbig.² Vilbig describes in this paper a number of strange phenomena, viz., change of sign of the effect, "stable" and "labile" curves, etc., which are supposed to be exhibited in the change of resistance of ferromagnetic bodies in small longitudinal magnetic fields. Such anomalies, in addition to normal curves, are to be found in almost all previous papers of other authors. They are, however, most remarkable and most extensively discussed in the paper of Fr. Vilbig. For this reason McKeehan thinks it one of the most important problems to study and explain "the irregular progress of magneto-resistance changes in low applied fields."

In a detailed paper "Die Änderungen der elektrischen Leitfähigkeit ferromagnetischer Stoffe in longitudinalen Magnetfeldern"³ the author briefly

¹ L. W. McKeehan, *Phys. Rev.* **36**, 948 (1930).

² Fr. Vilbig, *Arch. f. Elektrotechn.* **22**, 194 (1929).

³ O. Stierstadt, *Phys. Zeits.* **31**, 561 (1930).

pointed out how these anomalies are to be explained. In this paper were also presented more accurate and previously unpublished measurements on the peculiarities in low fields of the curves in question. These often observed anomalies in low fields are further discussed in the present paper.

PART I

A brief discussion of some of Vilbig's results is desirable. Fig. 1 shows the change of resistance of a nickel wire 0.051 mm in diameter over its complete magnetic cycle as observed by him. Remarkable are the frequent intersections of the various parts of the curve. Those in low magnetic fields, where the relative change of resistance becomes negative, i.e. where it passes into a decrease of resistance, seem to be particularly interesting. These parts were very thoroughly investigated by Vilbig and he established a number of regularities

Fig. 1. Change of resistance of nickel. (Taken from Vilbig's paper.)

of which the most important are summarized here in order to make the following discussion clearer.

He finds in the negative parts of the curves of hysteresis of resistance (Fig. 1) two types of curves, which he terms "stable" and "labile," respectively. These types of curves appear when in the negative parts the field is no longer increased but is made to decrease from any point. The appearance of these curves depends upon whether this lowering of the field is produced *before* or *after* passing the minimum, and upon whether the zero line has already been reached or passed before the field is lowered. Fig. 2, taken from Vilbig's paper shows on an enlarged scale these "stable" and "labile" curves below the zero axis. Fig. 3 shows their appearance when on lowering the field the zero axis has been already passed. The number of arrows indicates the succession of the reversed variations of field. For more details, the original paper of Vilbig must be consulted. Unfortunately he makes no attempt to explain the observed phenomena.

The present author examined these phenomena thoroughly and found that these observations are completely explained when a fundamental error

Fig. 2. Negative change of resistance of nickel. (Taken from Vilbig's paper.)

which underlies the whole paper of Vilbig is recognized. He writes in italics at the beginning of his paper that "the change of resistance dw vanishes at once

Fig. 3. Negative change of resistance of nickel. (Taken from Vilbig's paper.)

with the magnetic field." This is, however, an error. On the contrary, the change of resistance in the magnetic field shows far-reaching analogies with

Fig. 4. Resistance hysteresis of nickel.

ordinary magnetization. Above all it shows quite a definite residual magnetism, a coercive force, etc., as a curve taken from the paper of the present

author demonstrates (Fig. 4). This essential fact passes unnoticed by Vilbig. Even the component of the earth's field may introduce errors, as found by measurements on very soft, extraordinarily pure, vacuum melted electrolytic iron (99.998 percent Fe).

The wire samples should, therefore, be carefully orientated perpendicularly to the earth's field for exact measurements.

The measurements reported herein were taken in an *exactly homogeneous* magnetic field, provided by a magnetizing coil approximately 1 m in length. Vilbig used the field between the poles of an electro-magnet. With a pole distance of 13 cm he considers the middle 5 cm as approximately constant. This field shows, however, according to his own calibration an increase of 20 per cent from the minimum in the center at the ends of the 5 cm range used in

Fig. 5

Fig. 8. Lowering of the field in the zero line.

Fig. 9. Lowering of the field above the zero line.

measurements. It has, therefore, by no means the necessary homogeneity. Furthermore, in the present author's apparatus the sensitiveness of the arrangement for measuring the relative change of resistance, dw/w , was one hundred times as great as that of Vilbig. Readings were taken with a Thomson double bridge. As null instrument a mirror galvanometer of Siemens and Halske with magnetic shunt having a current sensitivity of about 10^{-9} amp. deg. -1 at 450 degrees distance was used. For more details regarding the apparatus, especially the temperature protection of the wire and its arrangement and centering in the magnetic field, see the paper of the author referred to above.³ The samples tested measured 50–70 cm in length.

Figs. 5 to 9 show in analogy to Vilbig's work measurements of the change of resistance in low fields. The wire always had a residual magnetism at the

beginning of the measurements. Regarding the resistance, we shall term this state the "zero state." On increasing the field at the beginning of the readings from $H=0$ to $H=100-150$ gauss and subsequently decreasing it to $H=0$, now on another increase of the field in the opposite direction, there were found *apparent* negative changes of resistance, which showed a minimum and a subsequent increase of resistance, i.e., the resistance becomes smaller at the minimum than in the zero state.

These are the negative changes of resistance observed and investigated by Vilbig. Of course, differences in the course of the curves are to be expected here, so-called "stable" and "labile" curves, when the field is lowered, e.g., before or after reaching the minimum or the zero line. But then it would be equally justifiable to speak of stable and labile parts in the curve of magnetization.

Figs. 10 and 11. Apparent negative changes of resistance of nickel.

The observed effects are not, therefore, to be considered as anomalies of the change of resistance, but as inherent in the process of magnetization. On visualizing the course of magnetization for each variation of field in Figs. 5-9, one readily sees that with these low fields the relative change of resistance and the magnetization are quite analogous. The very marked, broad loop of the curves has its origin in the strong residual magnetism with nickel, notably in weak fields, which is by far greater than with all other ferromagnetics. With iron these phenomena are therefore much less developed and not so easy to observe although they appear quite in the same form and corresponding to the curve of magnetization.

Figs. 10 and 11 demonstrate two other phenomena observed by the author and referred to in the paper of Vilbig as characteristic yet inexplicable.

Fig. 10 shows the gradual stabilization of the curves after a single or repeated passing of the minimum range. Fig. 11 shows that the value of the negative minimum of change of resistance depends on the strength of the magnetic field applied before in the reverse direction. A detailed discussion of these phenomena in connection with the process of magnetization appears unnecessary after the preceding demonstration.

It can therefore be stated quite generally that regarding the change of resistance of iron and nickel in longitudinal magnetic fields, there is always an increase of electrical resistance, which may be marked by the existence of coercive force H . This generalization, however, is only clear after complete demagnetization of the wire before each measurement. These considerations

Fig. 12. Resistance hysteresis of annealed iron with carbon content.

show, that it is the neglect of this fact which accounts for a number of earlier observations which demonstrate a reversal in sign of the effect in low fields.

These statements are, however, not valid for high temperatures. W. Gerlach⁴ found that with rising temperature the value of the magnetic change of resistance decreases steadily and finally, above the Curie point, turns into a decrease, while a loop is no longer formed. It is true, however, that for a temperature of as high as $+200^{\circ}\text{C}$, Gerlach finds an example with quite a normal curve of resistance hysteresis.

In the paper referred to above³ the present author emphasized that apart from incomplete demagnetization of the wires there are still other causes which may to a certain degree account for the change of sign described, e.g. soldering of the leads to the wire sample. In the magnetic field such contacts may give rise to thermomagnetic and thermoelectric effects, causing anoma-

⁴ W. Gerlach, *Zeits. f. Physik* 59, 847 (1930); *Ann. d. Physik* 6, 772 (1930).

lous shapes of the curve, and in particular as observed, a change of sign. The superposition of such effects on the purely magnetic effects, described above, may considerably distort the form of the curve under certain conditions and therefore render difficult the unambiguous interpretation of the phenomena. On carefully avoiding all sources of error, there is invariably a normal curve of resistance hysteresis to be obtained, as shown for nickel in Fig. 4 and for iron in Fig. 12. According to these, the inner magnetization is invariably the factor which principally determines the resistance and not the outer magnetic field.

On the basis of this statement, the change of resistance, considered over the whole magnetic cycle need not necessarily show a loop as Figs. 4 and 12, unless the curve of magnetization of the material shows hysteresis. Gerlach⁴ confirmed these results for nickel at high temperatures. The author showed on the other hand with pure electrolytic iron that the loop sensibly disappears.

Fig. 13. Change of resistance of electrolytic iron: I untreated, II annealed.

Fig. 13 demonstrates this for two samples of electrolytic iron. Curve I is for a hard drawn, non-recrystallized wire. Curve II is for a sample, recrystallized in the usual way by two tempering processes and one drawing process between. For the whole magnetic cycle, the relative change of resistance is determined unambiguously by the strength of the magnetic field applied. A detailed report is given in a paper "Zur Frage der Widerstandsänderung von reinem Elektrolyteisen in longitudinalen Magnetfeldern."⁵

With material of so high a degree of purity (impurities amounting to only 1/1000 percent, contrary to ordinary technical iron) a very great influence of any mechanical stress and of the size of crystal grain on the relative change of resistance was found. Investigation of these influences is being carried on in the Laboratory of Applied Electricity of Goettingen University and will be reported elsewhere.

PART II

In the paper cited above,¹ McKeehan expressed the need for solution of another problem, viz., the question as to the "early saturation of the magneto-resistance effect." The following considerations may help to throw some light on the solution of this problem.

With non-ferromagnetic substances saturation of the change of resistance begins only in very strong fields of an order of magnitude of 10^5 – 10^6 gauss. With the ferromagnetic substances, however, the beginning of saturation of the change of resistance and of the magnetization coincide very nearly; with nickel and iron at $B=6000$ – 8000 and $20,000$ – $25,000$ gauss respectively. In these cases, of course, the internal fields are to be considered and not the external fields. With the ferromagnetic bodies, therefore, the values for the strength of field for saturation are by the factor 10 or 100 lower than with para- and diamagnetic bodies.

In the latter group P. Kapitza⁶ made extended measurements which have only recently been theoretically explained by the work of N. H. Frank.⁷ In an extension of Sommerfeld's theory of the magnetic change of resistance, Frank derives a formula which represents correctly the change for all field strengths. Frank's formula is

$$\frac{dR}{R} = \frac{b \cdot H^2}{1 + c \cdot H^2} \quad (1)$$

where b and c are individual atomistic constants, characteristic of each material, of the following form:

$$b = \frac{\pi^2}{3} (emlkT)^2 \left(\frac{\lambda}{h} \right)^6, \quad (2)$$

$$c = (e\lambda/h)^2; \quad (3)$$

where e is the elementary electrical charge, m the mass of the electron, l the mean free path of the electron, k Boltzmann's constant, T the absolute temperature, λ deBroglie's wave-length of conducting electrons, and h is Planck's constant.

By means of Eq. (1) the change of resistance in the magnetic field may be determined for any material when its characteristic constants are known. Frank made such a determination for some substances investigated by Kapitza and found excellent agreement, notably for the saturation value b/c as calculated from Eq. (1) for strong fields.

Figure 14 shows the general course of the function (1) $dR/R=f(H)$ for any value of b and c (in the case plotted $b=c=1$): for small fields the ascent varies with the square, for the medium fields there is a fairly linear part near the point of inflection, and for very strong fields an approach to saturation. Deviations from this course are as yet shown only by the ferromagnetic sub-

⁶ P. Kapitza, Proc. Roy. Soc. A123, 292 (1929).

⁷ N. H. Frank, Zeits. f. Physik 60, 682 (1930); 64, 650 (1930).

stances in small fields, because here permeability $\mu \gg 1$. The ascent goes here, where the internal field plays an important part, not with the second but with the third, fourth or even fifth power of B^3 . When the value of μ approaches unity, however, according to the measurements available, the theory seems to hold for ferromagnetic bodies as well.

Fig. 14. Change of resistance in the magnetic field according to Frank-Sommerfeld.

Now, for an electron which has the velocity v perpendicular to the direction of the field, the following relation holds for the radius of curvature of its orbit:

$$\frac{1}{r} = \frac{eH}{mv} = \frac{eH\lambda}{h}, \quad (4)$$

where λ is defined by the wave equation:

$$mv = h/\lambda; \quad (5)$$

the other symbols meaning the same as explained above. On comparing, according to Frank, Eq. (4) with (3) equation

$$cH^2 = (l/r)^2 \quad (6)$$

results. Therefore the denominator of Eq. (1) differs from unity only when l becomes of the order of r or greater. When $l < r$, the electron passes only a small part of its orbit in the magnetic field between two collisions. For $l > r$, however, it travels through several full circles before a collision with an atom occurs, in which case the change of resistance dR/R approaches the saturation value b/c .

Therefore, when according to Eqs. (4) and (6), the values of l and λ or l and v respectively are known for any substance its behavior in the magnetic field is sufficiently known, in particular the beginning of saturation of the change of resistance. An investigation based on such considerations is being carried on in our laboratory, especially for ferromagnetic bodies. In particular

the attempt is being made to demonstrate whether on the bases of the electron theory the abnormally low value of field strength at which magnetic saturation of resistance occurs with ferromagnetic bodies emphasized by McKeehan is to be expected.

In this way probably the great differences between the saturation values obtained by different observers, quoted in McKeehan's paper, may find an explanation. It will be readily understood that particularly with very pure materials minute quantities of impurities or slight mechanical stresses may have a very marked influence on the lattice structure and consequently on the constants mentioned above. For this reason, measurements on materials, the properties of which are not exactly defined are useless for the establishment of quantitative relations.

Fig. 15. Change of resistance of annealed iron with carbon content (Fig. 12) as a function of magnetization.

Finally, an interesting analogy may be mentioned between the curves of resistance hysteresis previously published by the author,³ and the curves recently observed by McKeehan and published in his paper referred to above.¹ These curves represent the magnetic change of resistance under tensile stress and are unexplained as yet.

On representing the relative change of resistance dw/w not as a function of the external field H , but by means of the curve of magnetization $B=f(H)$ as a function of the magnetic induction B , again a loop is obtained, the individual parts of which intersect in a very striking way once or repeatedly. Fig. 15 demonstrates this fact, representing the function $dw/w=f(B)$ for the iron wire, the curve of resistance hysteresis $dw/w=f(H)$ of which is already shown above in Fig. 12. The origin of these intersections and their reality re-

main still quite uncertain and at the time of his publication the author suspected the possibility of some error. Meanwhile, however, McKeehan has found very similar curves in the course of his experiments on the change of resistance by tension in the magnetic field (compare the paper¹ e.g. page 970).

A striking analogy between these curves and those of the type of Fig. 15 is evident. A closer examination of these phenomena has not yet been undertaken. Such measurements might be comparatively easy with nickel and at first in not too strong fields, the residual magnetism being very high in this case and the formation of the loop very marked. Further extended research work, which might help to solve this problem, appears very desirable.

SUMMARY

The special phenomena, found in the investigation of the change of electrical resistance of ferromagnetic bodies in magnetic fields dealt with in the present paper, may be summarized as follows:

(1) In low applied fields the change of resistance presents no anomalies. The deviations from the normal curves, as frequently observed, are caused by errors, the most important of which is an incomplete demagnetization of the sample. By measurements made with this error purposely introduced it was demonstrated that the anomalous curves of change of resistance actually have their origin in incomplete demagnetization.

(2) The saturation of the change of electrical resistance of ferromagnetic bodies which invariably occurs in magnetic fields of a lower order of magnitude than those for saturation with non-ferromagnetic bodies appears to present a problem soluble on the basis of the Frank-Sommerfeld theory of magnetic change of resistance. This question will be discussed in greater detail elsewhere.

LETTERS TO THE EDITOR

Prompt publication of brief reports of important discoveries in physics may be secured by addressing them to this department. Closing dates for this department are, for the first issue of the month, the twenty-eighth of the preceding month; for the second issue, the thirteenth of the month. The Board of Editors does not hold itself responsible for the opinions expressed by the correspondents.

The Molecular Scattering of Light from Ammonia Solutions

During the course of an investigation of the molecular scattering of light from substances in their pure and dissolved states, solutions of ammonia have given such interesting results that it seems advisable to communicate them

by Carelli, Pringsheim and Rosen.⁵ Their data with those of the writers, are given in Table I.

The excitation was by means of a quartz mercury arc. The instrument used was a Steinheil glass spectrograph. The plates were

at once. Results have previously been given for gaseous ammonia by Wood,¹ and Dickinson, Dillon and Rasetti;² for liquid ammonia by Daure,³ Bhagavantam⁴ and Dickinson, Dillon and Rasetti;² and for water solutions

photometered using a Moll microphotometer, kindly loaned by the Department of Physics. Lines corresponding to the frequency differences 1073, 3219, 3311, and 3394 have been found to be excited by both Hg 4046 and Hg. 4358. The line corresponding to 3311 appears to have been excited by Hg 4078 as well. The line corresponding to 1615 could be observed when excited by Hg 4358 after the exciting line Hg 4046 had been filtered out. Even under these conditions it is extremely faint and an exact determination of its position has not as yet been possible. The relative intensities of the lines can be judged from the accompanying microphotograph. (Fig. 1).

It is interesting to note that all the lines which have been reported from gaseous and

⁴ Bhagavantam, Ind. J. Physics 5, 59 (1930).

⁵ Carelli, Pringsheim and Rosen, Zeits. f. Physik 51, 511 (1928).

liquid ammonia have now been found in the concentrated solution (16 normal) as well. The times of exposure necessary to observe the ammonia frequencies, $\Delta\nu_3$, $\Delta\nu_4$, and $\Delta\nu_5$ were short enough to avoid difficulty due to the excitation of the water bands, although the latter could not be entirely avoided.

One can hardly decide from the figures given in the table whether or not there is a change in the characteristic frequencies when ammonia is dissolved in water from those observed for the pure substance. It appears that it will always be difficult to make a decision concerning this point because the frequency

differences may depend upon the concentration of the scattering substance in the solution and other factors.

Complete details of the experimental work and a critical discussion of the data particularly with regard to changes taking place in solution will be given at a later date.

Capture of Electrons by Swiftly Moving Alpha-Particles

Capture of electrons by α -particles when the kinetic energy of the electron with respect to the α -particle was equal to that of an energy level of the helium atom were reported by Bergen Davis and A. H. Barnes (Phys. Rev. July 1929) and by A. H. Barnes (Phys. Rev. Feb. 1930).

The results reported depended on observations made by counting scintillations visually. The scintillations produced by α -particles on a zinc sulphide screen are a threshold phenomenon. It is possible that the number of counts may be influenced by external suggestion or autosuggestion to the observer. The possibility that the number of counts of scintillation might be greatly influenced by suggestion had been realized, and a test of their reliability had been made by two methods: (a) The voltage applied to the electrons was altered without the knowledge of the observer (Barnes); (b) the direction of the electron stream with respect to the α -particle path was altered by a small electro-magnet. Such changes in voltage and direction of electron stream were noted at once by the observer. These checks were thought at the time to be entirely adequate.

In examining the data of observation made in our laboratory Dr. Irving Langmuir concluded that the checks applied had not been sufficient, and convinced us that the experiments should be repeated by wholly objective methods. Accordingly we have investigated the matter by means of the Geiger counter. Four additional experimental electron α -ray tubes have been constructed for this purpose.

Capture of the kind reported was often observed over a considerable period of time, but following prolonged observation the effect seemed to disappear. The results deduced from visual observations have not been confirmed. If such capture of electrons does take place, it must depend on unknown critical conditions which we were not able to reproduce at will in the new experimental tubes.

We wish in particular to acknowledge our obligations to Mr. J. R. Dunning who has improved the Geiger counter to such an extent that it is almost an instrument of precision.

The Results of a Least-Square Adjustment of Cosmic-Ray Observations

Millikan and Cameron have recently published¹ a new series of depth-ionization measurements on the cosmic-rays, from which they conclude that there are four components or "bands" of widely varying intensity and absorption coefficient, the latter probably increasing at first with depth on account of the Compton effect. In a paper read before the Physical Society in December, 1929, the writer showed how least-squared adjustment

may be adapted to the analysis of such a combination of rays, provided they obey the assumed absorption law, and provided also that approximate values of the initial intensity and absorption coefficient of each component, such as Millikan and Cameron have estimated, are available. The method uses, as the unknowns

¹ Millikan and Cameron, Phys. Rev. 37, 235 (1931).

to be adjusted, not the cosmic-ray constants themselves, but the small, unknown corrections to be applied to the approximate values, in order to give the most probable values derivable from the observations. If the above provisions were fulfilled, and if the method were applied to a series of measurements of such precision as those of Millikan and Cameron, the small corrections would certainly appear as a matter of routine calculation.

Through a research grant from the Iowa Academy of Science, the writer has made such an analysis of Millikan and Cameron's latest data. The adjustment was, however, confined to the lower three-fourths of the depth range, in order to avoid the Compton effect as far as possible; and this, incidentally, eliminates the assumed most absorbable fourth component from the calculation. It was found necessary to prepare and use a more extended and more accurate table of the Gold integral than that employed by Millikan and Cameron. The numerical work was performed on a calculating machine by an experienced computer, and carefully checked at every stage. The resulting adjusted values of the corrections were found to satisfy the normal equations exactly, and to give a smaller sum of squared residuals than if the corrections were zero.

It is therefore somewhat disconcerting to have to report that these adjusted values, if applied as corrections, would yield a set of altogether meaningless and physically impossible absorption coefficients and intensities; some of which would even turn out negative.

The writer can arrive at only one interpretation of this, namely, that the assumptions upon which the analysis was made are not justified. Whether the discrepancy arises from insufficiently accurate tentative values of the constants, from the assumption of the wrong number of components, from the persistence of the Compton effect at great depths, or from an altogether erroneous interpretation of the whole phenomenon, it seems necessary to look with serious reserve upon any such sweeping conclusions as to "atom building" as Millikan and Cameron have deduced from the results of their splendid experimental work.

A more detailed account of this investigation will duly appear in the Proceedings of the Iowa Academy of Science for 1931.

Mutual Impedance of Grounded Wires on the Surface of a Two-Layer Earth

Mr. R. M. Foster's formula¹ for the mutual impedance of any thin grounded wires lying on the surface of the earth has been generalized by us, following his basic assumptions and method of derivation, to cover the case of a horizontally stratified earth having the conductivities λ_1 and λ_2 at depths which are less than or greater than b respectively. We find:

$$Z_{12} = \iint \left\{ \frac{d^2 Q}{dS ds} + i\omega \cos \epsilon N \right\} dS ds$$

with

$$Q = \frac{1}{2\pi\lambda_1} \int_0^\infty \left\{ 1 + \frac{4\alpha_1^2(u + \alpha_2)(\lambda_1 - \lambda_2)e^{-2b\alpha_1}}{\Delta[\alpha_1\lambda_2 + \alpha_2\lambda_1 + (\alpha_1\lambda_2 - \alpha_2\lambda_1)e^{-2b\alpha_1}]} \right\} J_0(ru) du$$

$$N = 2 \int_0^\infty \frac{u}{\Delta} [\alpha_1 + \alpha_2 + (\alpha_1 - \alpha_2)e^{-2b\alpha_1}] J_0(ru) du$$

$$\omega = 2\pi f = \text{radian frequency}$$

$$\Delta = (\alpha_1 + \alpha_2)(u + \alpha_1) + (\alpha_1 - \alpha_2)(u - \alpha_1)e^{-2b\alpha_1}$$

$$\alpha_j = (u^2 + i4\pi\omega\lambda_j)^{1/2}, j = 1 \text{ and } 2$$

$$J_0 = \text{Bessel function of first kind, zero order.}$$

The integrations are extended in the double integral over the two wires S and s whose elements dS and ds are separated by distance r and include the angle ϵ between their directions. This general formula includes as special cases:

(1) One wire straight and doubly infinite as given by H. P. Evans.²

¹ Bulletin of the American Mathematical Society, May 1930, Abstract 289, pp. 367-368. ² Evans, Phys. Rev. 36, 1584 (1930) Eq. (30).

(2) The mutual resistance of any wires at frequency zero, that is, for direct current as given by F. Ollendorff.³

(3) One wire straight and doubly infinite with finite earth surface conductivity, as given by G. Haberland.⁴

(4) One wire straight and doubly infinite

with finite earth surface conductivity and zero earth volume conductivity as given by Otto Mayr.⁵

FIG. 3

BOOK REVIEWS

Physics, A Textbook for Colleges. Revised Edition. O. M. STEWART. Pp. 770, figs. 492. Ginn and Co. Boston. Price \$4.00.

In reading this College Physics, the reviewer gets the impression that the author has attempted to put in a single volume, everything that has ever been included in a college text on physics. There are a number of rather well-written chapters on "modern physics" of the sort so much in demand today but which are probably omitted by most classes. If such material must be included, a bit more might have been included about the Bohr atom and energy levels so as to give the student a more definite picture of the atom. In those places where modern ideas really help in giving an elementary explanation, the author has made good use of them.

The main part of the book is not very different from many college texts. Certain features are however noticeable. An extra large number of topics are mentioned, some more briefly than usual. For example, the Carnot cycle, magnetic circuits and methods of combining vectors are mentioned but not really discussed. A great many formulae are given without even a suggestion as to how they were obtained. This is perhaps partly due to the total avoidance of all use of calculus. It does seem however, as if fewer formulae worked out in more detail would teach the student more physics. The more detailed discussions given and most of the diagrams are very good. The chapter on meteorology is particularly good—if it belongs in the book.

The accuracy of the book, particularly as to definitions, seems to be very high although the indeterminate expressions "calories per gram per degree" and "cm per sec per sec" are used. There is included an unusually large number of problems and answers. Since there is no perfect text on college physics, the reviewer believes that many teachers will find this book very satisfactory and that they will get good results from its use.

NIEL F. BEARDSLEY

Principles of Engineering Thermodynamics. PAUL J. KIEFER AND MILTON C. STUART. Pp. 545, figs. 135. John Wiley and Sons, Inc. New York, 1930. Price \$4.50.

It is strictly an engineering thermodynamics in that it treats of the subject in relation to all power plant problems, such as the steam engine, steam turbine, gas engine, compressor, refrigerating machine etc. It is a successful endeavor to tie the fundamental principles taught in a good course in physics with the theory and technical application of thermodynamics in the various types of power machinery. The treatise is divided in five parts. Part I, composed of three chapters, considers the first law of thermodynamics and the division of energy into different forms, as stored and transient energy in relation to flow and non-flow processes. Part II, which contains four chapters, takes up the second law of thermodynamics, the Carnot principle and makes a particular effort to give more of a physical significance to entropy, i.e., as a measure of the unavailability of energy. The latter point is to be especially commended. In the three chapters constituting Part III are treated the properties of the various media in which these thermodynamic processes must operate when applied to practical devices. The assumption of certain ideal conditions to establish a fundamental relation and then the institution of other factors to admit the introduction of other superposed physical effects as one passes from the theoretical to the practical case is well demonstrated in this treatment. There are eight chapters in Part IV, each devoted to a different type of motive power machinery. Each illustrates how certain accessories are instituted to make the special type of machine operative and the corresponding diversion from the theoretically ideal device. A working relation is obtained for each case.

The principles of thermodynamics are so general, that there are many other problems in physics and chemistry which may be solved by their application. Part V is used to develop additional thermodynamic equations such as are required in this large field of work that lies outside of this text.

Probably one of the most commendable features about this treatise is the summary, review

questions and the problems accompanying each chapter. Not only has it high pedagogical value but there is nothing that systematizes information and gives one a perspective of the subject like a summary. It inspires a feeling of mastery. Apparently there was no sparing of effort for clarity in the text.

L. F. MILLER

Algebraic Charts. EDGAR DEHN. Columbia Press, New York, 1930. 14 cards in an envelope.

These charts consist of six fundamental cards, each accompanied by a card giving an illustrative solution. The curves and auxiliary formulas provided permit the approximate solution of any quadratic or cubic equation, and of a certain type of bi-quadratic equation. The charts furnish interesting simple illustrations of nomographical methods and give applications of certain fundamental notions of analytic geometry and the theory of equations. Teachers of mathematics, particularly in colleges of engineering, would probably find the charts appropriate for supplementary work in certain of their courses.

Any graphical method for solving a quadratic equation is largely of theoretical interest, because of the ease with which the algebraic solution can be performed. Hence, from the practical standpoint, the charts are of interest mainly as they apply to cubics and bi-quadratics. For such equations, it appears to the reviewer that Mr. Dehn's methods could be applied efficiently only by one with a good knowledge of the theory of equations, and then only after considerable practice. If used efficiently, however, these charts would be very useful aids in problems where the degree of approximation of the chart-solutions would be satisfactory.

WILLIAM L. HART

Wave Mechanics. LOUIS DEBROGLIE. Translated by H. T. Flint. Pp. 249+vi, figs. 13. Methuen and Company, London, 1930. Price 12/6.

The number of good books on the quantum mechanics is rapidly increasing, so the student now has the choice of numerous styles and modes of exposition. In most of these texts the emphasis is on the "how"; i.e. the technique of the theory and its application to numerous problems. In the present volume, by the originator of the wave mechanics, the emphasis is placed on the "why"; in particular on the comparison of the ideas underlying the classical (Newton-Hamilton) and the modern (deBroglie-Schroedinger) view-points. Professor deBroglie here, as in his other works, builds up his argument starting from the dynamical equations of Newton and of the restricted principle of relativity. This makes a very compact and elegant argument, incidentally furnishing the student with a good chance to renew his acquaintance with general dynamical principles. The transition to waves is very clearly set forth, and there is a wealth of illustrative material on the motion of the waves and of probability packets in special cases. The average American student may find the treatment rather mathematical for a first trial, but after he has learned, from other sources, how to "quantize" a few things, he may return to this book and derive considerable pleasure and profit from it. The reviewer cannot help but record his enjoyment at the open-minded and considered manner in which Professor deBroglie treats his subject. Unfortunately there is a considerable tendency toward dogmatic statement among many writers on quantum mechanics, a tendency which the reviewer believes leads only to an unnecessary confusion and uncertainty on the part of many who are sincerely trying to understand something about the theory. This book should do much to help the situation and the translator is to be thanked for making it available to the English-speaking public.

E. L. HILL

Lecons Sur Le Calcul Vectoriel. T. A. RAMOS. Pp. 119. Librairie Scientifique A. Blanchard, Paris, 1930. Price, fr. 25.

Despite its numerous good points, this book probably will not make much appeal to American physics students, principally because of the choice of notation. The notation of Gibbs has become so standard in the physical literature that it scarcely seems worth while for a beginning student to learn any other. Considered on its own merits, however, this book gives a pleasing presentation of the subject. Vector algebra and calculus are developed in detail, the applications being mainly of a purely mathematical nature; e.g. to space curves and surfaces and to curvi-

linear coordinates. The treatment throughout is of a better grade than in most texts with which the student is apt to make contact, but might have been helped in places by the addition of simple figures. The last chapter, of a more advanced character, gives a treatment of tensor calculus as a direct generalization of vector analysis.

E. L. HILL

Principles of Electrical Engineering (Second Edition). W. H. TIMBIE AND V. BUSH. Pp. 595, figs. 270. McGraw-Hill Book Company, New York, 1930, Price \$4.50.

In this edition of the well-known text most of the articles and figures remain as in the first edition except those in the last four of the thirteen chapters. Many of the articles in these last chapters have been rewritten and valuable material added. Nearly all of the 600 problems are new or entirely rewritten.

The text is a substantial first course designed to train students in the principles of applied electricity and is the outgrowth of the experience in teaching the subject to electrical engineering students at the Massachusetts Institute of Technology. Some training in the use of calculus is presupposed. It is assumed that the student has completed or is pursuing the first college course in physics, including the subject of electricity as treated therein.

The outstanding feature of the text is its many exceptionally valuable problems which are improved in this edition and which give information concerning the basic practical aspects of electrical engineering and excellent training in analytical thinking. The magnetic circuit and dielectrics are stressed and the electron theory is used freely. The subjects of thermionic emission, conduction through gases, electrolytic conduction and some high frequency phenomena are included in addition to the standard subjects. The summary at the end of each chapter of the main facts and laws treated in that chapter is commendable.

Historical relationships are disregarded. The text, aside from secondary statements, defines ampere as the rate of flow of a coulomb per second. The volt is defined only in terms of the difference of potential produced by a standard cell, while the difference of potential itself can hardly be said to have been defined. The maxwell is defined as "the amount of flux which, when established in a magnetic circuit, will produce one abvolt-second in a coil of one turn wound on the magnetic circuit." The generated electromotive force is a circuit is then referred only to this. Such treatment, notwithstanding its practical simplicity, gives an inadequate picture of the units and tells nothing concerning how the electromotive force is produced by the change in flux. This treatment may be permissible in a text of this nature only on the assumption that the student has had previous training in the theoretical aspects of the subject and in the systems of units.

While minor details and the definitions may be criticized and some mis-statements still appear, the text on the whole is excellent and gives substantial training from the practical point of view in the basic principles on which modern electrical engineering is founded.

ANTHONY ZELENY

Constitution et Thermochimie des Molecules. ALBERT GOSSELIN AND MARCEL GOSSELIN. Pp. vii+231. Les Presses Universitaires de France, Paris, France.

The authors propose a new theory of chemical combination based on the hypothesis that: first, there exist within molecules other molecules and groupings, as for example a H_2 molecule exists within a methane molecule, and second there exist two kinds of chemical bonds, the polar and nonpolar bond which may produce a semi-polar bond. The molecule is furthermore conceived as a dynamic structure with a central atom around which the other atoms, groups or constituent molecules gravitate. The ideas that are new are certainly different from the usual notions and it appears to the reviewer, they are quite unnecessary and based on insufficient evidence. The four hydrogen atoms in methane are surely equivalent as far as we have experimental knowledge of this situation, and there is no need to introduce the idea that a H_2 molecule exists within the methane structure. To be sure some such notion is presented by writers on molecular structure who attempt to study molecules on the basis of molecular wave mechanics, but the present authors do not mention these newer concepts at all. Their new structures are sometimes quite remarkable: A central oxygen atom of mass 16 has a bromine molecule

of mass 160, a HBr molecule of mass 81, a couple of hydrogen atoms and two ethylene groups gravitating around itself! The authors think that they can claim their new structures to be correct because they are able to set up a scheme of thermochemistry for their new formulae which checks when used for predicting the heats of formation of compounds. But this only means that they were consistent in their changes of formulae and is no proof for their ideas.

The book is written in a clear style as all French books are and it has been an interesting pastime to review the book, for it served to compare the "new" ideas with the current notions held by the reviewer, and it is felt that the new theories presented are quite unnecessary. It is hoped that the book will be available to mature students only who can judge for themselves and who have been instructed in the well-tried ideas of modern valency theory.

GEORGE GLOCKLER

Telephone Theory and Practice; Theory and Elements. KEMPSTER B. MILLER. Pp. xiv+486, figs. 272. McGraw-Hill Book Company, New York, 1930.

This is the first volume of a three volume work by an author who has long been an authority in this field.

Part I, consisting of four chapters, is mainly historical, tracing in a highly interesting manner the developments in communication up to the present time. The history of the electric speaking telephone is accurately presented.

Part II includes a discussion of the nature of sound and hearing, the conversion of sound waves into electric waves, the functions of vacuum tubes in the transmission of these waves, and concludes with a chapter on magnetism and magnetic materials.

The three chapters on sound are of particular interest. The first shows the physical meaning of the properties, loudness, pitch, and quality. The second deals with the sensation of sound showing the manner of operation of the ear, and giving the evidence for the "maximum amplitude" theory of determination of pitch. The significance of the auditory sensation area, and the meaning of the units of pitch and loudness are clearly presented. Subjective tones are discussed and illustrations of their rather startling effects given. The phenomenon of masking, so important when extraneous noise is present, is competently treated. The third of these chapters on sound describes simply and clearly the operation of the vocal organs in speech. The relative importance of various frequencies in articulation, and in good musical reproduction is shown.

The chapter on vacuum tubes gives good physical pictures of the operation of these devices in their various functions, and the chapter on magnetic materials discusses principally the iron-cobalt-nickel alloys used in modern telephone apparatus.

The third part of the volume discusses the construction and use of the elements of telephone apparatus such as wires, coils, condensers, contacts, which play such important roles in the modern telephone system.

The volume is ably and interestingly written, well referenced to primary sources, and excellently printed and illustrated. The almost non-mathematical treatment of voice waves and alternating currents is ingenious and makes it easily readable to the layman as well as to the technician.

RALPH D. BENNETT

The Metallic State. Electrical Properties and Theories. W. HUME-ROTHERY. Pp. 372+xx, figs. 66. Clarendon Press, Oxford, 1931. Price \$9.00.

The general problem with which this book is finally concerned is the understanding of the properties of metals, including not only ordinary pure metals, but also intermetallic compounds and alloys in general. The problem is therefore one which by tradition has been associated, in certain broad aspects, with the metallurgist, and the author has indeed had the training of a metallurgist, and at the time of writing held the position of Armourers' and Brasiers' Company Research Fellow in Metallurgy. The subject is, however, preëminently one for the physicist, and the book is throughout almost exclusively devoted to the purely physical aspects of the problem.

In order not unduly to expand the book, attention is confined to those aspects of the

problem about which most is known and in which the most significant theoretical progress has been made, and this restricts the book almost entirely to the electrical properties of metals. The book is divided into two parts, the first experimental and the second theoretical. The experimental part does not deal at all with such conventional metallurgical matters as methods of fixing the phase diagrams, or even with the phase diagrams themselves to any large extent, but it is concerned with electrical and thermal conductivity, some of the galvano-magnetic and thermo-magnetic effects, thermo-electric effects, and emission and contact potential difference phenomena. The dependence of these properties on composition, temperature, and mechanical stress is discussed, and constitutes a valuable summary of data which has not before been collected into one place.

In the theoretical part most of the theories of historical or present day importance are discussed, starting with the electron gas theory of Drude and its mathematical elaboration by Lorentz. The discussion of the theories now discarded is most skillfully done, both in pointing out the weaknesses of the theories and in emphasizing the way in which many of the physical aspects of the present wave mechanics pictures were being anticipated as the only possible solution consistent with the complex experimental situation. The discussion of the Sommerfeld theory and its later modifications presents the very valuable and revolutionary achievements of the theory, but also does not fail to emphasize the features in which the theory is weak or unsatisfactory—a welcome antidote to the attitude of too many recent writers that electrical phenomena in metals are now, again, an essentially closed chapter, and that only details remain to be filled in. There is a concluding section dealing with correlations between electrical properties, position in the periodic table, and the structure of the atom according to recent ideas, which is most interesting. This includes a full discussion of a number of most curious and undoubtedly significant empirical correlations discovered by Hume-Rothery himself which will be most welcome.

As a whole, the book is exceedingly stimulating and suggestive, and cannot be too highly recommended to the careful study of any one working in this field. It is unusual in the emphasis that it puts on unsolved problems, and in its suggestions as to possible programs for their solution. One point repeatedly emphasized, namely that the physicist in making measurements in the field of alloys almost always deals with specimens which no metallurgist would tolerate because they have not been sufficiently annealed to reach a condition of equilibrium, would in itself justify the book if the warning is heeded.

P. W. BRIDGMAN

Albert A. Michelson

THE PHYSICAL REVIEW

ALBERT A. MICHELSON, 1852-1931

AT ONE o'clock on Saturday afternoon, May 9, 1931, death came very quietly in his home in Pasadena to the most illustrious of the American physicists of our generation, at the age of seventy-eight years and five months. Six weeks earlier he had taken to his bed, after having made with his associates, Messrs. Pease and Pearson, enough observations to assure himself that his last experiment on the speed of light as measured in an evacuated pipe a mile long and three feet in diameter buried in the earth on the Irvine ranch near Santa Ana, California, was going to yield results as satisfactory as he had anticipated. This experiment had been planned for the sake of obtaining a check by a method entirely free from atmospheric effects of all kinds upon the accuracy of his next preceding determination made over a twenty-one mile stretch between California mountain peaks. He did not expect by these new experiments to exceed the accuracy previously obtained, but rather to add something to the *reliability* of the previous determination.

More than a month before his death, Mr. Michelson had known that he would never get up again, for a creeping paralysis was coming over him of which he himself was altogether conscious. His mind was quite clear until two days before the end, when a lesion occurred which brought on unconsciousness within an hour, an unconsciousness from which he never again awoke.

As one of the men who has had the most enduring and most intimate association with Mr. Michelson and his work, I esteem it a privilege now to make a few additions to my former appreciation of him and his achievement.

Under the caption, "Michelson's Economic Value," now published as Chapter VII in a volume by Scribner's entitled "Science and the New Civilization," I have attempted to appraise in broad lines the significance for our times of measurements of the highest skill and accuracy of the sort which Michelson has done and for which his name stands the world over, and I should like to refer to that appraisal and merely supplement it here by adding some details both of a scientific and of a personal sort.

Practically all of Mr. Michelson's work in physics centered about determinations for increasing the precision of measurement. He has been called an extremely skillful and intelligent instrument designer, but while he was that

he was much more than that, for his attention was always on the problem to be solved, not primarily on the instrument for solving it, and he was always seeking for problems incapable of solution save by improvements in the accuracy of measurement. Ten different times in the fifty-one years of his activity, extending from 1880 when at the age of twenty-eight he became the best known American physicist by virtue of his new speed-of-light measurement up to 1931 when he died, still trying to prove the certainty of his determination and precision of that most fundamental constant, he made major outstanding advances, which I list as follows:

1. Measurements of the speed of light, 1880-1931.
2. Development of the Michelson interferometer, 1882 et seq.
3. Ether-drift experiments, 1887-1928.
4. The first analysis of the fine structure of spectral lines, 1894-1900.
5. Development of the Michelson-Stratton harmonic analyzer, 1897.
6. Development of the principle of the Echelon spectrograph, 1898.
7. Perfection and increase in resolution of the line grating, 1902-1917.
8. First accurate measurement of the rigidity of the earth, 1916.
9. Development of the U. S. Naval Range Finder, 1918.
10. Direct interferometer measurement of the diameter of stars, 1921.

Of these ten five, namely the second, third, fourth, and tenth, have to do primarily with the interferometer or its application to various sensitive measurements. It was in measurements relating to the interference of light and speed of light that he was by far the greatest expert that the world has yet seen. He spent his scientific life largely in these two fields. He was not an omnivorous reader of the literature of physics, and did not try to follow closely the developments of the theoretical fields of electronics and quantum theory. He was essentially a classical physicist, but any one who ever heard him conduct a Ph.D. examination in physics, and any one who ever attended his lectures or heard him speak knows that his grasp of classical physics was penetrating and precise. His lectures and his papers were masterpieces of elegance and conciseness. He used a few words, but they were just the ones he wanted. Indeed, the precision of his mind was its dominating characteristic, which showed even in his sports. I have played tennis with him all my life, and his calling of balls, for example, was never generous either to himself or to his opponent. It was simply exact and just. Closely allied to this characteristic was his altogether extraordinary honesty. Pretense of any kind was utterly foreign to his make up. Indeed, he was one of those very rare persons who would not even tolerate fooling himself with respect to his own motives, as so many of us do. If his conduct was ever ungenerous he knew it and frankly admitted it, whether he thought it wise to change it or not. Before I became intimately associated with him I had heard that he was considered by his pupils to be somewhat unapproachable, occasionally arbitrary, and at times dictatorial, if not unreasonable, but in the twenty-five years in which we worked together I could not have been treated with greater courtesy and consideration, even in the few cases in which we differed in judgment. His dignity and courtesy of bearing were altogether striking characteristics, and as the

years passed he grew to be a man of great mellowness, kindness, and affability.

Like many a scientist, Mr. Michelson was also an artist, with a keen feeling for form and color, as well as for music. He painted well, played the violin well, and did well at tennis, chess, and billiards.

American Science and the American nation have lost in his death one of their finest and greatest figures.

APPLICATION OF SPINOR ANALYSIS TO THE MAXWELL AND DIRAC EQUATIONS

BY OTTO LAPORTE AND GEORGE E. UHLENBECK
DEPARTMENT OF PHYSICS, UNIVERSITY OF MICHIGAN

(Received February 24, 1931)

ABSTRACT

With the spinor analysis developed by B. van der Waerden which comprises all representations of the Lorentz group, even those not contained in ordinary tensor calculus, one is able to write all derivations and equations in an *automatically covariant form*. For the convenient translation into spinor language of the Maxwell equations, it becomes important to introduce three self-dual tensors, one representing the electromagnetic field, one corresponding to the Hertzian vector, and one representing a kind of current potential. These correspond to symmetric spinors of the 2nd rank. Many spinor equations thus become simpler than the corresponding tensorial equations, especially the expression for the stress energy tensor. From the 1st order Dirac equations in spinor form, as given by v.d. Waerden, we derived the 2nd order equation, which agrees with the Gordon-Klein form but for a correction term which again contains the self-dual field tensor. Further the expression for the current was derived, and its decomposition into conduction and polarization currents, and both Maxwell and Dirac equations were derived from a spinorial variation principle, analogous to the results of Gordon and Darwin. In addition to the divergence condition for the current three new invariant relations between the wave functions which are independent of the potentials were obtained (Chapter III, Eqs. (11), (12) and (13)).

INTRODUCTION

THE Dirac equations of the electron have for the first time furnished an example of a system of equations, which show an invariance of form when subjected to a Lorentz transformation, but which only very artificially could be written with tensors. This difficulty was felt especially by Darwin¹ when he wrote: "The relativity theory is based on nothing but the idea of invariance, and develops from it the conception of tensors as a matter of necessity; and it is rather disconcerting to find that apparently something has slipped through the net, so that physical quantities exist, which it would be, to say the least, very artificial and inconvenient to express as tensors."

The Dirac equation is

$$[(\Gamma^k p_k) + mc]\psi = 0 \quad (1)$$

where p_k represents the 4-vector²

$$p_k = \frac{h}{i} \frac{\partial}{\partial x^k} + \phi_k \quad (2)$$

¹ C. G. Darwin, Proc. Roy. Soc. **118**, 657 (1928).

² We use the Dirac h , which is $1/2\pi$ times the Planck constant, and write here; and in Ch. III, ϕ_k for e/c times the ordinary four potential.

and Γ^k are four four-row matrices, given by:³

$$\begin{aligned}\Gamma^1 &= \begin{pmatrix} 0 & 0 & 0 & -1 \\ 0 & 0 & -1 & 0 \\ 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{pmatrix} & \Gamma^2 &= \begin{pmatrix} 0 & 0 & 0 & i \\ 0 & 0 & -i & 0 \\ 0 & -i & 0 & 0 \\ i & 0 & 0 & 0 \end{pmatrix} \\ \Gamma^3 &= \begin{pmatrix} 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \end{pmatrix} & \Gamma^4 &= \begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \end{pmatrix}\end{aligned}\quad (3)$$

ψ is a function of two kinds of variables, of x^i and an inner variable, which can only assume four discrete values; the p_k act upon the x^k while the Γ^k operate on the inner variable. This way of describing Eq. (1) is of course equivalent to regarding Eq. (1) as *four* equations containing 4 ψ 's, each of them a function of x^k only.

There are *two* points of view possible, with regard to the transformation properties of the Dirac equation: The *first* of these regards the Γ^k as a matrix four vector, and the ψ as constant. According to the *second* point of view, the Γ^k are constants and the ψ are being transformed.

One can easily show that these two methods are equivalent. For if we subject the coordinates x^k to a Lorentz transformation,

$$x = x' L$$

then the p_k will be transformed like

$$p = L^{-1} p'.$$

If we consider Γ^k as a four vector, it will transform like x^k , and the scalar product

$$(\Gamma p) = (\Gamma' L L' p') = (\Gamma' p')$$

will remain invariant. On the other hand, we can always find a matrix S such that

$$p = L^{-1} p' = S^{-1} p' S. \quad (4)$$

Now the Γ^k are kept constant, and since they act on the inner variable only, they are exchangeable with S , so that

$$(S^{-1} \Gamma p' S) \psi + m c \psi = 0$$

or

$$(\Gamma p') (S \psi) + m c (S \psi) = 0.$$

Putting

$$\psi' = S \psi \quad (5)$$

³ When written out, Eq. (1) agrees with the form given by Weyl, Gruppentheorie und Quantenmechanik, Leipzig 1928, page 171, Eq. (45'). If the above given matrices for Γ^1 , Γ^2 , Γ^3 are divided by i , they become identical to Weyl's Γ_1 , Γ_2 , Γ_3 ; our Γ^4 is equal to his Γ_0 .

we regain (1), now with transformed ψ . This point of view regards the Γ^k simply as determining the coefficients $0, \pm 1, \pm i$ in the four wave equations.

For special two dimensional Lorentz transformations, Darwin has written out the transformation (5). They have the peculiar character that the coefficients contain the angle $\theta/2$, when the coordinates are rotated by the angle θ . We can see already from (4) that S is something like a square root of L .⁴ This shows that ψ cannot be a tensor, and that there are equations, which defy translation into tensor language and yet fulfill the relativity principle. Now it has been known to the mathematicians that the ordinary tensor language does not comprise all possible representations of the Lorentz group as had always been assumed tacitly by the physicists.⁵ The necessary extension of the tensor calculus, the *spinor calculus*, was given by B. van der Waerden,⁶ upon instigation of Ehrenfest, and indeed gives all possible representations.

These two points of view correspond in a certain way to the particle and wave description of the electron. The first may give additional information concerning the particle velocity,⁷ the second, however, is necessary for the consideration of the Dirac equations as field equations. In this case the ψ must naturally be transformed to a new coordinate system just as E and H in Maxwell's equations. We shall restrict ourselves to this point of view.

CHAPTER I. THE MATHEMATICAL APPARATUS OF THE SPINOR ANALYSIS

§1. Since van der Waerden's article is not very easily accessible, and in order to make the spinor analysis more popular, we shall briefly develop the few necessary theorems and formulae here, following van der Waerden closely.

Consider the following binary transformation

$$\begin{aligned}\xi_1' &= \alpha_{11}\xi_1 + \alpha_{12}\xi_2 \\ \xi_2' &= \alpha_{21}\xi_1 + \alpha_{22}\xi_2\end{aligned}\tag{1}$$

and its complex conjugate:

$$\begin{aligned}\bar{\xi}_1' &= \bar{\alpha}_{11}\bar{\xi}_1 + \bar{\alpha}_{12}\bar{\xi}_2 \\ \bar{\xi}_2' &= \bar{\alpha}_{21}\bar{\xi}_1 + \bar{\alpha}_{22}\bar{\xi}_2\end{aligned}\tag{2}$$

with the determinant

$$\begin{vmatrix} \alpha_{11} & \alpha_{12} \\ \alpha_{21} & \alpha_{22} \end{vmatrix} = 1.\tag{3}$$

All these transformations form a group of $8-2=6$ parameters. Any two numbers transforming like the ξ_1, ξ_2 in (1), we shall call a spinor of the 1st rank, and denote by

⁴ Landau therefore calls ψ a half vector.

⁵ Compare especially Hermann Weyl, *Gruppentheorie und Quantenmechanik*, Leipzig, 1928. Kap. III.

⁶ B. van der Waerden, *Göttinger Nachrichten* 1929, page 100. The spinor formalism is already implicitly contained in the book of Weyl, and in a paper by V. Fock, *Zeits. f. Physik* 57, 261 (1929).

⁷ V. Fock, *Zeits. f. Physik* 55, 127 (1929); G. Breit, *Proc. Natl. Acad.* 14, 553 (1928); E. Schrödinger, *Sitzungsber. Berliner Akad.* 24, 418 (1930).

$$a_k \quad k = 1, 2$$

whereas any two quantities transforming like (2) will be written

$$b_{\dot{r}} \quad \dot{r} = \dot{1}, \dot{2}.$$

Any four quantities transforming like the products $\xi_1\xi_1$, $\xi_1\xi_2$, $\xi_2\xi_1$, $\xi_2\xi_2$ we call a spinor of the 2nd rank and write

$$a_{kl} \quad k, l = 1, 2.$$

Correspondingly 4 quantities transforming like the products of $\bar{\xi}_1$ and $\bar{\xi}_2$ we denote by

$$b_{\dot{r}\dot{s}} \quad \dot{r}, \dot{s} = \dot{1}, \dot{2}.$$

There are also "mixed" spinors of the 2nd rank transforming like a product of a barred ξ and an unbarred ξ , denoted by

$$c_{\dot{r}k} \quad \dot{r} = \dot{1}, \dot{2}; \quad k = 1, 2.$$

Analogously we can define spinors of higher rank, like $a_{\dot{r}ml}$.

One can show easily, that because of (3) the area of the parallelogram formed by two spinors ξ_k and η_l

$$\xi_1\eta_2 - \xi_2\eta_1$$

is invariant under transformation (1). This enables us to introduce *contravariant* spinors a^k or $b^{\dot{r}}$, according to

$a^1 = a_2$	$b^{\dot{1}} = b_{\dot{2}}$
$a^2 = -a_1$	$b^{\dot{2}} = -b_{\dot{1}}$

(4)

because in this way the scalar products

$$a_1c^1 + a_2c^2 = a_\lambda c^\lambda$$

$$b_{\dot{1}}d^{\dot{1}} + b_{\dot{2}}d^{\dot{2}} = b_{\dot{\rho}}d^{\dot{\rho}}$$

are invariant.⁸ When we establish the usual connection between covariant and contravariant indices by means of a spinor ϵ^{kl} according to

$$a^k = \epsilon^{k\lambda} a_\lambda \quad (5)$$

we find

$$\epsilon^{kl} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \quad \epsilon_{kl} = \begin{pmatrix} 0 & +1 \\ -1 & 0 \end{pmatrix}$$

and

$$\epsilon^{k\lambda}\epsilon_{l\lambda} = -\delta_l^k \quad (6)$$

where

⁸ Summation signs are as usual suppressed; dummy indices are always given Greek letters, free indices Latin letters.

$$\delta_l^k = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}.$$

As in the usual tensor algebra, the only covariant operations are also here *multiplication* and *contraction*. For instance from the spinors a_{rs}^l and $b^{\dot{m}}_{kt}$ we can form the spinor of the 6th rank

$$c_{rs}^{l\dot{m}}{}_{kt} = a_{rs}^l b^{\dot{m}}_{kt}$$

or the spinor of 4th rank

$$c_s^{l\dot{m}}{}_{kt} = a_{rs}^l b^{\dot{m}}_{kt}$$

or the spinor of the 2nd rank

$$c_{st} = a_{rs}^{\lambda} b^{\dot{\mu}}_{\lambda t}.$$

The following two rules are essential in calculations. According to (6) we have

$$a_{\lambda} b^{\lambda} = - a^{\lambda} b_{\lambda} \quad (7)$$

An immediate consequence of this is that any spinor of odd rank has absolute value zero

$$a_{\lambda} a^{\lambda} = 0; \quad a^{\lambda\mu\nu} a_{\lambda\mu\nu} = 0. \quad (7a)$$

Similarly we have

$$a^{\lambda} b_{\lambda} c_m + a_{\lambda} b_m c^{\lambda} + a_m b^{\lambda} c_{\lambda} = 0. \quad (8)$$

Of course this rule may also be applied to the product $a^{\lambda} c_{\lambda m}$. It also holds for three dotted indices.

There are two more rules concerning the relations of dotted and undotted indices.

1° It is not necessary to fix the position of dotted and undotted indices belonging to the same spinor. Thus, for instance

$$a_{\dot{r}lt} = a_{l\dot{r}t} = a_{l\dot{t}r}.$$

On the other hand two dotted or two undotted indices are not necessarily interchangeable; if they are, the spinor in question has special symmetry properties.

2° The complex conjugate of any spinor equation is obtained by replacing all undotted indices by dotted ones and *vice versa*.

§2. We will now establish the connection between spinors and world tensors. We assert that the following combinations of components of a second rank spinor a_{ii} are to be associated with the components of a world vector A^1, A^2, A^3, A^4 as follows

$$\left. \begin{aligned} \frac{1}{2}(a_{\dot{2}1} + a_{i2}) &= A^1 = A_1 \\ \frac{1}{2i}(a_{\dot{2}1} - a_{i2}) &= A^2 = A_2 \\ \frac{1}{2}(a_{i1} - a_{\dot{2}2}) &= A^3 = A_3 \\ \frac{1}{2}(a_{i1} + a_{\dot{2}2}) &= A^4 = -A_4 \end{aligned} \right\} \quad (9)$$

These combinations are real, and after a transformation (1) and (2) they will still be real; thus their transformation coefficients are real also. To prove that it is a Lorentz transformation we solve (9) for the $a_{\dot{a}i}$ and obtain using (4)

$$\left. \begin{aligned} a_{\dot{2}1} &= -a^{i2} = A^1 + iA^2 = A_1 + iA_2 \\ a_{i2} &= -a^{\dot{2}1} = A^1 - iA^2 = A_1 - iA_2 \\ a_{i1} &= +a^{\dot{2}2} = A^3 + A^4 = A_3 - A_4 \\ -a_{\dot{2}2} &= -a^{i1} = A^3 - A^4 = A_3 + A_4 \end{aligned} \right\} \quad (10)$$

Now it is easily verified that

$$-\frac{1}{2}a_{\dot{a}r}a^{\dot{a}r} = A_\gamma A^\gamma. \quad (11)$$

To every transformation (1) there corresponds one Lorentz transformation; *vice versa*, since the connection formulae between the transformation coefficients of A and the α 's of eq. (1) are quadratic, there are two transformations (1) differing in sign, corresponding to one Lorentz transformation.⁹ Therefore (1) and (2) form a representation of the Lorentz group. It can be proved, and this is the fundamental theorem of the spinor analysis, that one obtains all representations of the Lorentz group by transforming all possible spinors according to (1) and (2). It follows that the true "quantities" belonging to the Lorentz group are spinors, of which tensors form only a special class. Analogous to (10) spinors of the fourth rank with two dotted and two un-

⁹ For example using the transformation formulae (1) and (2) for a spinor $a_{\dot{a}i}$ we find that for a Lorentz transformation

$$\begin{aligned} ct' &= ct \cosh \theta + z \sinh \theta \\ z' &= ct \sinh \theta + z \cosh \theta \end{aligned}$$

there correspond the two transformation matrices

$$\alpha_{kl} = \begin{pmatrix} \pm e^{\theta/2} & 0 \\ 0 & \pm e^{-\theta/2} \end{pmatrix}$$

and with a special rotation

$$\begin{aligned} x' &= x \cos \theta + y \sin \theta \\ y' &= -x \sin \theta + y \cos \theta \end{aligned}$$

there correspond the two matrices

$$\alpha_{kl} = \begin{pmatrix} \pm e^{-i\theta/2} & 0 \\ 0 & \pm e^{+i\theta/2} \end{pmatrix}$$

For general spacial rotations we see that because of the invariance of i , that is to say of $\xi_1\xi_1 + \xi_2\xi_2$ the corresponding binary transformation (1) will be unitarian. For more information compare especially H. Weyl, *Gruppentheorie und Quantentheorie*, Leipzig 1928, p. 106-114.

dotted indices correspond to world tensors of the second rank. The formulae connecting them are obtained from (10) by multiplication. For instance

$$\left. \begin{aligned} a_{\dot{2}\dot{2}11} &= a^{ii22} = A^{11} - A^{22} + i(A^{12} + A^{21}) = A_{11} - A_{22} + i(A_{12} + A_{21}) \\ - a_{\dot{2}\dot{2}21} &= a^{ii12} = A^{31} - A^{41} + i(A^{32} - A^{42}) = A_{31} + A_{41} + i(A_{32} + A_{42}) \end{aligned} \right\} \quad (12)$$

In the following table all possible kinds of spinors of the 5 lowest ranks are written down and those corresponding to world tensors are underscored.

<u>a</u>				
<u>a_k</u>		<u>a_{m̄}</u>		
<u>a_{kl}</u>	<u>a_{m̄l}</u>	<u>a_{m̄n̄}</u>		
a _{kl̄l}	a _{m̄l̄t}	a _{m̄n̄t}	<u>a_{m̄n̄i}</u>	
a _{kl̄t̄v}	a _{m̄l̄t̄v}	<u>a_{m̄n̄t̄v}</u>	a _{m̄n̄r̄v}	a _{m̄n̄r̄i}

§3. Although the underscored spinors correspond *directly* to tensors of half their rank, the *spinors of even rank* can be related to tensors of higher rank, which possess certain symmetry properties. Let us consider the simplest spinors of this kind a_{kl} and its complex conjugate $a_{\bar{m}\bar{n}}$. We decompose a_{kl} into a symmetric and antisymmetric spinor, according to

$$a_{kl} = \frac{1}{2}(a_{kl} + a_{lk}) + \frac{1}{2}(a_{kl} - a_{lk}) = \sigma_{kl} + \alpha_{kl}. \quad (13)$$

The antisymmetric part α_{kl} has only one "Kennzahl"

$$\begin{aligned} \alpha_{12} &= -\alpha_{21} = \frac{1}{2}(a_{12} - a_{21}) = \frac{1}{2}(a_1^1 + a_2^2) \\ &= \frac{1}{2}a_\rho{}^\rho \end{aligned}$$

which is an invariant. The symmetric part σ_{kl} has three "Kennzahlen" and can be shown to correspond to an *antisymmetric self-dual tensor*. Consider a real antisymmetric world tensor F^{kl} . The dual tensor to this is obtained by means of

$$F_{kl}^* = \pm \frac{i}{2} \delta_{kl\alpha\beta} F^{\alpha\beta} \quad (14)$$

where $\delta_{klmn} = 0$ when any two indices are equal and $= \pm 1$ according to whether the indices form an even or odd permutation of the numbers 1234. Thus two dual tensors F^{*kl} are possible to an originally real tensor F^{kl} ; they differ only by the sign, so that one is the complex conjugate of the other. Obviously the dual to F^{*kl} is again the original F^{kl} without asterisk. The self-dual tensor G^{kl} is the sum of the two¹⁰

$$\begin{aligned} G^{kl} &= F^{kl} + F^{*kl} \\ \bar{G}^{kl} &= F^{kl} - F^{*kl}. \end{aligned} \quad (15)$$

Calling the three Kennzahlen k_1, k_2, k_3 , G^{kl} may be written

¹⁰ We note the theorem, that for any two self-dual tensors G^{kl} and H^{kl} the product

$$G^{k\lambda} \bar{H}_{k\lambda} = 0$$

$$G^{kl} = \begin{pmatrix} 0 & k_3 & -k_2 & -ik_1 \\ -k_3 & 0 & k_1 & -ik_2 \\ k_2 & -k_1 & 0 & -ik_3 \\ ik_1 & ik_2 & ik_3 & 0 \end{pmatrix} \quad (15a)$$

or taking the lower sign in (14)

$$\bar{G}^{kl} = \begin{pmatrix} 0 & \bar{k}_3 & -\bar{k}_2 & i\bar{k}_1 \\ -\bar{k}_3 & 0 & \bar{k}_1 & i\bar{k}_2 \\ \bar{k}_2 & -\bar{k}_1 & 0 & i\bar{k}_3 \\ -i\bar{k}_1 & -i\bar{k}_2 & -i\bar{k}_3 & 0 \end{pmatrix}. \quad (15b)$$

Then we form the spinor of the fourth rank g_{ikl} according to (12) which using G^{kl} can be written

$$g_{ik}{}^l = g_{i\dot{s}}\delta_k{}^l \quad (16a)$$

and which using \bar{G}^{kl} can be written

$$g_{\dot{i}}{}^{\dot{s}}{}_{kl} = \delta_{\dot{i}}{}^{\dot{s}}g_{kl}. \quad (16b)$$

Here the spinors $g_{i\dot{s}}$ and g_{kl} are *symmetric*. Solving (16) and (16a) we obtain

$$\left. \begin{aligned} g_{i\dot{s}} &= \frac{1}{2}g_{i\dot{s}\lambda}{}^{\lambda} \\ g_{kl} &= \frac{1}{2}g_{\dot{s}}{}^{\dot{s}}{}_{kl} \end{aligned} \right\}. \quad (17)$$

The formulae connecting the components of the symmetric spinors with those of the antisymmetric, self-dual world-tensor are

$$\left. \begin{aligned} g_{11} &= 2(k_2 + ik_1) \\ g_{22} &= 2(k_2 - ik_1) \\ g_{12} &= g_{21} = -2ik_3 \end{aligned} \right\} \quad (18)$$

and using (16a) we simply obtain the complex conjugate

$$\left. \begin{aligned} g_{11} &= 2(\bar{k}_2 - i\bar{k}_1) \\ g_{22} &= 2(\bar{k}_2 + i\bar{k}_1) \\ g_{12} &= g_{21} = 2i\bar{k}_3 \end{aligned} \right\}. \quad (18a)$$

§4. Corresponding to the introduction of a covariant gradient vector we now define a gradient spinor $\partial_{i\dot{s}}$ according to the connection formulae (10) as follows

$$\left. \begin{aligned} \partial^1{}_{\dot{1}} &= \partial_{\dot{2}1} = \frac{\partial}{\partial x^1} + i\frac{\partial}{\partial x^2} \\ -\partial^{\dot{2}}{}_{\dot{2}} &= \partial_{12} = \frac{\partial}{\partial x^1} - i\frac{\partial}{\partial x^2} \\ -\partial^{\dot{2}}{}_{\dot{1}} &= \partial_{11} = \frac{\partial}{\partial x^3} - \frac{\partial}{\partial x^4} \\ -\partial^{\dot{1}}{}_{\dot{2}} &= -\partial_{22} = \frac{\partial}{\partial x^3} + \frac{\partial}{\partial x^4} \end{aligned} \right\} \quad (19)$$

where the contravariant vector (x^1, x^2, x^3, x^4) corresponds to (x, y, z, ct) . Analogously to (11) we may now translate the familiar vector analytical operations like Div or \square into the spinor language. We have

$$\frac{\partial \phi^\alpha}{\partial x^\alpha} = -\frac{1}{2} \partial_{\sigma\tau} \phi^{\sigma\tau} \quad (20)$$

and

$$\frac{\partial^2 S}{\partial x_\alpha \partial x^\alpha} = -\frac{1}{2} \partial_{\sigma\tau} \partial^{\sigma\tau} S. \quad (21)$$

CHAPTER II. MAXWELL EQUATIONS IN SPINOR FORM

§5 α . To facilitate the comparison, we shall briefly recapitulate the Maxwell equations in the ordinary tensor form. As usual we define the antisymmetric field tensor

$$F^{kl} = \begin{pmatrix} 0 & H_z & -H_y & -E_x \\ & 0 & H_x & -E_y \\ & & 0 & -E_z \\ & & & 0 \end{pmatrix} \quad (1)$$

then the dual tensor according to (14) is

$$F^{*kl} = -i \begin{pmatrix} 0 & E_z & -E_y & H_x \\ & 0 & E_x & H_y \\ & & 0 & H_z \\ & & & 0 \end{pmatrix} \quad (2)$$

The two Maxwell equations are

$$\begin{aligned} \frac{\partial F^{k\lambda}}{\partial x^\lambda} &= S^k \\ \frac{\partial F^{*k\lambda}}{\partial x^\lambda} &= 0 \end{aligned} \quad (3)$$

where S^k is the four-current $(\rho v_x/c, \rho v_y/c, \rho v_z/c, \rho)$ obeying the continuity equation

$$\frac{\partial S^\lambda}{\partial x^\lambda} = 0. \quad (5)$$

We can embody these two equations into one

$$\frac{\partial G^{k\lambda}}{\partial x^\lambda} = S^k \quad (6)$$

by using the self-dual tensor

$$G^{kl} = F^{kl} + F^{*kl} \quad (7)$$

which has the form (15), with¹¹

$$\vec{k} = \vec{H} - i\vec{E}. \quad (8)$$

We can derive G^{kl} from the four-potential $\phi^k = (A_x, A_y, A_z, \phi)$ by means of

$$G^{kl} = \frac{\partial \phi^l}{\partial x_k} - \frac{\partial \phi^k}{\partial x_l}. \quad (9)$$

The ϕ^k are subjected to the accessory condition

$$\frac{\partial \phi^\lambda}{\partial x^\lambda} = 0. \quad (10)$$

Introducing (9) into (6), using (10) we get the wave equation for ϕ^k

$$\frac{\partial^2 \phi^k}{\partial x_\lambda \partial x^\lambda} = S^k. \quad (11)$$

§5β. To free ourselves from the condition (10) imposed on the potentials, we express ϕ^k in terms of a self-dual antisymmetric tensor Z^{kl} , the analogue to the Hertzian vector in three dimensions by means of¹²

$$\phi^k = \frac{\partial Z^{k\lambda}}{\partial x^\lambda}. \quad (12)$$

Introducing this in (11), we get for Z^{kl} a third order differential equation

$$\frac{\partial}{\partial x^\lambda} \frac{\partial^2 Z^{k\lambda}}{\partial x_\alpha \partial x^\alpha} = S^k.$$

In the three dimensional form one reduces this to a second order differential equation by an integration of the current $\rho v/c$ with respect to the time.¹³ The analogue of this is the derivation of S^k from a stream potential Q^{kl} , which is again an antisymmetric self-dual tensor, according to

¹¹ Comp. Riemann-Weber, Die partiellen Differentialgleichungen der Physik, Braunschweig 1901, Vol. II, 348. L. Silberstein, Ann. d. Physik **22**, 579 (1907). See also F. Zerner, Handbuch der Physik vol. XII, p. 93.

¹² When we represent Z^{kl} by the scheme

$$Z^{kl} = i \begin{pmatrix} 0 & Z_z & -Z_y & iZ_x \\ & 0 & Z_x & iZ_y \\ & & 0 & iZ_z \\ & & & 0 \end{pmatrix}$$

then the three dimensional form of (12) is

$$A = i \operatorname{curl} Z - \frac{1}{c} \frac{\partial Z}{\partial t}$$

$$\phi = \operatorname{div} Z.$$

¹³ See e.g. Madelung, Die mathematischen Hilfsmittel des Physikers, Berlin 1922, p. 196.

$$S^k = \frac{\partial Q^{k\lambda}}{\partial x^\lambda}. \quad (13)$$

This causes the continuity equation (5) to be identically satisfied. For Z^{kl} we then get the wave equation

$$\frac{\partial^2 Z^{kl}}{\partial x_a \partial x^a} = Q^{kl}. \quad (14)$$

§5γ. The stress-energy tensor $T_k{}^l$ whose divergence is equal to the components of the four force can be written

$$T_k{}^l = \frac{1}{2}(F_{k\alpha}F^{l\alpha} - F^*_{k\alpha}F^{*\alpha l}).$$

This can be written in terms of our tensor G_{kl}

$$T_k{}^l = \frac{1}{4}(G_{k\alpha}\bar{G}^{l\alpha} + \bar{G}_{k\alpha}G^{l\alpha}) \quad (15)$$

where the conjugate tensor is to be formed according to Eq. (15) of Chapter I. As is well known this tensor has a diagonal sum which is zero

$$T_\alpha{}^\alpha = 0 \quad (16)$$

as one sees using the theorem of footnote 10. Consequently $T_k{}^l$ has only nine linearly independent "Kennzahlen."

§5δ. It is important for the sequel briefly to discuss the phenomenological form of the Maxwell equations in matter. Since the dielectric displacement D and the magnetic induction B are connected with E and H through

$$\begin{aligned} D &= E + P \\ B &= H + I \end{aligned} \quad (17)$$

where P and I are the electric and magnetic polarization respectively, we can write the Maxwell equations

$$\left. \begin{aligned} \operatorname{div} E &= \rho' \\ \operatorname{curl} B - \frac{1}{c} \frac{\partial E}{\partial t} &= \frac{J}{c} \end{aligned} \right\} \quad \left. \begin{aligned} \operatorname{div} B &= 0 \\ \operatorname{curl} E + \frac{1}{c} \frac{\partial B}{\partial t} &= 0 \end{aligned} \right\} \quad (18)$$

where

$$\begin{aligned} \rho' &= \rho - \operatorname{div} P \\ \frac{J}{c} &= \frac{\rho v}{c} + \operatorname{curl} I + \frac{1}{c} \frac{\partial P}{\partial t}. \end{aligned} \quad (19)$$

If ρ , $(\rho v/c)$, P and I are given, the above system agrees formally with the equations in vacuo. To write (18) and (19) in four dimensional form we introduce the two self-dual tensors G'^{kl} and M^{kl} . They have the form (15a) where

$$\begin{aligned} \vec{k}_{G'} &= \vec{B} - i\vec{E} \\ \vec{k}_M &= \vec{I} + i\vec{P}. \end{aligned} \quad (20)$$

We then write (18) and (19)

where

$$\left. \begin{aligned} \frac{\partial G'^{k\lambda}}{\partial x^\lambda} &= J^k \\ J^k &= S^k + \frac{1}{2} \left(\frac{\partial M^{k\lambda}}{\partial x^\lambda} + \frac{\partial \bar{M}^{k\lambda}}{\partial x^\lambda} \right) \end{aligned} \right\} \quad (21)$$

§6α. Having been able to write the entire formalism of Maxwell equations with the help of the self-dual world tensor G^{kl} and its complex conjugate, we can now introduce by means of formulae (18) and (18a) two symmetric spinors $g_{\dot{m}\dot{n}}$ and g_{kl} of the second rank, and thus avoid the introduction of fourth-rank spinors altogether. It is obvious that the spinor g_{kl} , just like the tensor \bar{G}^{kl} , will only be needed in the formulation of the stress-energy tensor.

We know from Chapter II, that the four-current S^k becomes a spinor $s_{\dot{m}l}$, the gradient $\partial/\partial x^k$ according to (19) a spinor operator $\partial_{\dot{m}l}$; we see now that the simplest way of connecting $\partial_{\dot{m}l}$ and $s_{\dot{m}l}$ in a manner analogous to (6), is by letting $\partial_{\dot{m}l}$ act on a spinor with two dotted or two undotted indices. We choose the former and write Maxwell equations¹⁴

$$\partial^{\dot{p}l} g_{\dot{p}\dot{m}} = 2s_{\dot{m}l}. \quad (6a)$$

The continuity equation for the four current reads

$$\partial^{\dot{m}\lambda} s_{\dot{m}\lambda} = 0. \quad (5a)$$

The identity of this with (5) was already noted in Chapter I formula (20).

The analogue of the four potential ϕ^k will be the spinor $\phi_{\dot{m}l}$. It is connected with the field spinor $g_{\dot{r}\dot{s}}$ by the following curl-like operation, which, however, in this case is symmetrical:

$$g_{\dot{r}\dot{s}} = \partial_{\dot{r}\lambda} \phi_{\dot{s}}^{\lambda} + \partial_{\dot{s}\lambda} \phi_{\dot{r}}^{\lambda} \quad (9a)$$

The $\phi_{\dot{m}l}$ are subjected to the divergence condition

$$\partial^{\dot{m}\lambda} \phi_{\dot{m}\lambda} = 0. \quad (10a)$$

Introducing (9a) into (6a) we have

$$\partial^{\dot{p}l} (\partial_{\dot{p}\alpha} \phi_{\dot{m}}^{\alpha} + \partial_{\dot{m}\alpha} \phi_{\dot{p}}^{\alpha}) = 2s_{\dot{m}l}.$$

Using (8) Chapter I, we can transform each term according to

$$\begin{aligned} \partial^{\dot{p}l} \partial_{\dot{p}\alpha} \phi_{\dot{m}}^{\alpha} &= -\partial^{\dot{p}}_{\alpha} \partial_{\dot{p}}^{\alpha} \phi_{\dot{m}l} - \partial^{\dot{p}\alpha} \partial_{\dot{p}\alpha} \phi_{\dot{m}l} \\ \partial^{\dot{p}l} \partial_{\dot{m}\alpha} \phi_{\dot{p}}^{\alpha} &= -\partial_{\dot{m}l} \partial_{\dot{p}\alpha} \phi^{\dot{p}\alpha} - \partial_{\dot{p}l} \partial^{\dot{p}\alpha} \phi_{\dot{m}\alpha}. \end{aligned}$$

¹⁴ For $l=1, \dot{m}=\dot{1}$ and for $l=2, \dot{m}=\dot{2}$ we have

$$\begin{aligned} \partial^{\dot{1}}_{1g\dot{1}\dot{1}} + \partial^{\dot{2}}_{1g\dot{2}\dot{1}} &= 2s_{\dot{1}1} \\ \partial^{\dot{1}}_{2g\dot{1}\dot{2}} + \partial^{\dot{2}}_{2g\dot{2}\dot{2}} &= 2s_{\dot{2}2} \end{aligned}$$

With (4), (10), (19), (18) of Ch. I, and (8) Chapter II, this becomes:

$$\begin{aligned} \left(\text{curl}_z H - \frac{1}{c} \dot{E}_z + \text{div } E \right) - i \left(\text{curl}_z E + \frac{1}{c} \dot{H}_z - \text{div } H \right) &= \frac{\rho v_z}{c} + \rho \\ \left(-\text{curl}_z H + \frac{1}{c} \dot{E}_z + \text{div } E \right) + i \left(\text{curl}_z E + \frac{1}{c} \dot{H}_z + \text{div } H \right) &= \frac{\rho v_z}{c} + \rho \end{aligned}$$

from which follow four of the eight Maxwell equations.

Adding these, the last two terms cancel because of (7) Chapter I, and due to (10a), we get

$$\partial_{\rho\alpha}\partial^{\rho\alpha}\phi_{\dot{m}l} = 2s_{\dot{m}l}. \quad (11a)$$

§6β. The analogue of the self-dual Hertzian tensor Z^{kl} is the symmetric Hertzian spinor $z_{\dot{r}\dot{s}}$. The potential spinor $\phi_{\dot{m}l}$ is derived from this according to

$$\phi_{\dot{m}l} = \partial^{\dot{\sigma}}_l z_{\dot{m}\sigma}. \quad (12a)$$

By this operation the divergence condition (10a) is identically fulfilled, for we obtain, introducing (12a) into (10a)

$$\partial^{\dot{\mu}\lambda}\phi_{\dot{\mu}\lambda} = \partial^{\dot{\mu}\lambda}\partial^{\dot{\sigma}}_{\lambda} z_{\dot{\mu}\sigma}$$

using the symmetry of $z_{\dot{\mu}\sigma}$ we have

$$\partial^{\dot{\mu}\lambda}\phi_{\dot{\mu}\lambda} = \frac{1}{2}\{\partial^{\dot{\mu}\lambda}\partial^{\dot{\sigma}}_{\lambda} + \partial^{\dot{\sigma}\lambda}\partial^{\dot{\mu}}_{\lambda}\} z_{\dot{\mu}\sigma} \equiv 0.$$

This vanishes applying (7) Chapter I to the index λ . Analogous to the stream potential Q_{kl} , a self-dual tensor we now derive the stream spinor $s_{\dot{m}l}$ from

$$s_{\dot{m}l} = \partial^{\dot{\sigma}}_l q_{\dot{m}\sigma} \quad (13a)$$

where $q_{\dot{m}\sigma}$ is again a symmetric spinor of the second rank. Introducing (12a) and (13a) into (11a), and dropping a ∂ operator on both sides, we obtain the wave equation for $z_{\dot{m}\dot{s}}$

$$\partial_{\rho\alpha}\partial^{\rho\alpha}z_{\dot{m}\dot{s}} = 2q_{\dot{m}\dot{s}}. \quad (14a)$$

§6γ. The spinor analogue of the stress-energy tensor T_{kl} will be a spinor of the fourth rank with two dotted and two undotted indices. Its divergence will have to be equal to the spinor $f_{\dot{m}l}$ which corresponds to the four vector of the Lorentz force density and the action density. To derive this expression we write down the Maxwell equations and their conjugates according to (6a), using (7) Chapter I

$$\partial_{\dot{\rho}l}g^{\dot{\rho}\dot{m}} = -2s^{\dot{m}}_l$$

$$\partial_{r\lambda}g^{\lambda k} = -2s_r^k.$$

Then we multiply the upper equation with g^{lk} and the lower with $g^{i\dot{m}}$ and contract with respect to r and l . After adding we can write this

$$\partial_{\dot{\rho}\lambda}\{g^{\dot{\rho}\dot{m}}g^{\lambda k}\} = -2\{g^{\dot{\rho}\dot{m}}s_{\dot{\rho}}^k + g^{\lambda k}s^{\dot{m}}_{\dot{\rho}}\}.$$

Introducing

$$i^{\dot{r}\dot{m}lk} = \frac{1}{4}g^{\dot{r}\dot{m}}g^{lk} \quad (15a)$$

we have

$$\partial_{\dot{\rho}\lambda}i^{\dot{r}\dot{m}lk} = 2f^{\dot{m}k} \quad (15b)$$

where the force spinor

$$f^{\dot{m}k} = -\frac{1}{4}\{g^{\dot{\rho}\dot{m}}s_{\dot{\rho}}^k + g^{\lambda k}s^{\dot{m}}_{\dot{\rho}}\}. \quad (15c)$$

It follows from the symmetry of the spinors $g^{r\dot{m}}$ and g^{lk} that $t^{\dot{m}lk}$ has only nine "Kennzahlen." Thus relation (16) is already embodied in the structure of the stress-energy spinor.

§6δ. Analogous to the developments of §5δ we introduce two symmetric spinors $g'_{r\dot{s}}$ and $m_{r\dot{s}}$ which correspond to the self-dual tensors G'^{kl} and M^{kl} . We then write the spinor analogue of (21)

$$\partial^s_l g'_{s\dot{r}} = 2j_{r\dot{l}}$$

where

$$j_{r\dot{l}} = \dot{s}_{r\dot{l}} + \frac{1}{2}(\partial^s_l m_{s\dot{r}} + \partial_r^s m_{s\dot{l}}) \quad (21a)$$

where the first term on the right side is due to conduction and the second term to electric and magnetic polarization.

CHAPTER III. THE DIRAC EQUATIONS IN SPINOR FORM

§7. Van der Waerden has shown how to write the Dirac equations in spinor form. The four wave functions ψ of Dirac correspond to two spinors of the first rank $\psi_{\dot{m}}$ and χ_l , and his equations become

$$mc\chi_l - \left(\frac{\hbar}{i}\partial^s_l + \phi^s_l\right)\psi_{\dot{s}} = 0 \quad (1a)$$

$$mc\psi_{\dot{m}} + \left(\frac{\hbar}{i}\partial_m^{\dot{\lambda}} + \phi_m^{\dot{\lambda}}\right)\chi_{\dot{\lambda}} = 0 \quad (1b)$$

where ϕ^s_l is the potential spinor as according to (9a) Chapter II. We shall also need the complex conjugate equations which read

$$mc\chi_{\dot{m}} - \left(-\frac{\hbar}{i}\partial_m^{\dot{\lambda}} + \phi_m^{\dot{\lambda}}\right)\psi_{\dot{\lambda}} = 0 \quad (2a)$$

$$mc\psi_l + \left(-\frac{\hbar}{i}\partial^s_l + \phi^s_l\right)\chi_{\dot{s}} = 0. \quad (2b)$$

We now wish to obtain the second order Dirac equations. Introducing the abbreviation

$$p^s_l = \frac{\hbar}{i}\partial^s_l + \phi^s_l \quad (3)$$

we eliminate χ_l from (1) and get

$$m^2c^2\psi_{\dot{m}} + p_m^{\dot{\lambda}}p^s_{\dot{\lambda}}\psi_{\dot{s}} = 0.$$

We apply the identity (8) Chapter I to the second term and have, using also identity (7) Chapter I,

$$p_m^{\dot{\lambda}}p^s_{\dot{\lambda}}\psi_{\dot{s}} = -\frac{1}{2}p^{\dot{\lambda}\dot{s}}p_{\dot{s}\dot{\lambda}}\psi_{\dot{m}} + \frac{1}{2}p_{\dot{s}\dot{\lambda}}p_m^{\dot{\lambda}}\psi^{\dot{s}} - \frac{1}{2}p_m^{\dot{\lambda}}p_{\dot{s}\dot{\lambda}}\psi^{\dot{s}}.$$

Taking (3) into account we see that

$$\begin{aligned} p_{\sigma\lambda} p_{\dot{m}}^{\lambda} \psi^{\dot{\sigma}} - p_{\dot{m}}^{\lambda} p_{\sigma\lambda} \psi^{\dot{\sigma}} &= \frac{\hbar}{i} \psi^{\dot{\sigma}} (\partial_{\sigma\lambda} \phi_{\dot{m}}^{\lambda} + \partial_{\dot{m}\lambda} \phi_{\sigma}^{\lambda}) \\ &= \frac{\hbar}{i} \psi^{\dot{\sigma}} g_{\dot{m}\sigma}, \end{aligned}$$

the latter because of (9a) Chapter II. Thus the second-order wave equation becomes

$$-\frac{1}{2} \left(\frac{\hbar}{i} \partial^{\sigma\lambda} + \phi^{\sigma\lambda} \right) \left(\frac{\hbar}{i} \partial_{\sigma\lambda} + \phi_{\sigma\lambda} \right) \psi_{\dot{m}} + m^2 c^2 \psi_{\dot{m}} = -\frac{\hbar}{2i} g_{\dot{m}\sigma} \psi^{\dot{\sigma}}. \quad (4)$$

Correspondingly one obtains

$$-\frac{1}{2} \left(\frac{\hbar}{i} \partial^{\sigma\lambda} + \phi^{\sigma\lambda} \right) \left(\frac{\hbar}{i} \partial_{\sigma\lambda} + \phi_{\sigma\lambda} \right) \chi_k + m^2 c^2 \chi_k = \frac{\hbar}{2i} g_{k\lambda} \chi^{\lambda}. \quad (5)$$

The left side is identical with the Gordon wave equation written in spinor form, whereas the right side represents the spin correction. It is satisfactory, that the field only occurs in the form of our symmetric spinor $g_{\dot{m}i}$ resp. g_{kl} .

§8. To derive the expression for the current we multiply (1a) with ψ^i , (1b) with $-\chi^{\dot{m}}$, (2a) with $-\psi^{\dot{m}}$, (2b) with χ^i , and add all four equations. Using repeatedly identity (7) Chapter I all terms containing the mass and the potentials cancel and we can write the result

$$\partial^{\dot{m}\lambda} j_{\dot{m}\lambda} = 0 \quad (6)$$

where

$$j_{\dot{m}l} = \psi_{\dot{m}} \psi_l + \chi_{\dot{m}} \chi_l. \quad (7)$$

§9. We shall split up the above expression after the fashion of Eq. (1a) Chapter II. We replace $\psi_{\dot{m}}$ and χ_l in (7) by their expressions following from (1a) and (1b) and have, using identity (8) Chapter I

$$\begin{aligned} mcj_{\dot{m}l} &= -\psi_l \left(\frac{\hbar}{i} \partial_{\dot{m}}^{\alpha} + \phi_{\dot{m}}^{\alpha} \right) \chi_{\alpha} + \chi_{\dot{m}} \left(\frac{\hbar}{i} \partial_{\sigma l} + \phi_{\sigma l} \right) \psi^{\dot{\sigma}} \\ &= +\psi^{\alpha} \left(\frac{\hbar}{i} \partial_{\dot{m}\alpha} + \phi_{\dot{m}\alpha} \right) \chi_l - \chi^{\dot{\sigma}} \left(\frac{\hbar}{i} \partial_{\sigma l} + \phi_{\sigma l} \right) \psi_{\dot{m}} \\ &\quad + \psi_{\alpha} \left(\frac{\hbar}{i} \partial_{\dot{m}l} + \phi_{\dot{m}l} \right) \chi^{\alpha} - \chi_{\dot{\sigma}} \left(\frac{\hbar}{i} \partial_{\dot{m}l} + \phi_{\dot{m}l} \right) \psi^{\dot{\sigma}}. \end{aligned}$$

We then replace in (7) ψ_l and $\chi_{\dot{m}}$ by the expressions following from (2a) and (2b) and transform the equations by means of (8) Chapter I in a completely analogous fashion. We thus obtain four expressions for $mcj_{\dot{m}l}$. Adding all of them we have after a few elementary transformations

$$j_{\dot{r}l} = s_{\dot{r}l} + \frac{1}{2} (\partial^{\dot{\sigma}} m_{\dot{\sigma}\dot{r}} + \partial_{\dot{r}}^{\alpha} m_{\alpha l}) \quad (8)$$

where

$$s_{\dot{i}l} = \frac{\hbar}{4imc} (\psi_{\alpha} \partial_{\dot{i}l} \chi^{\alpha} + \chi_{\alpha} \partial_{\dot{i}l} \psi^{\alpha} + \psi^{\dot{\sigma}} \partial_{\dot{i}l} \chi_{\dot{\sigma}} + \chi^{\dot{\sigma}} \partial_{\dot{i}l} \psi_{\dot{\sigma}}) \quad (9)$$

$$+ \frac{1}{2mc} \phi_{\dot{i}l} (\psi_{\alpha} \chi^{\alpha} + \psi_{\dot{\sigma}} \chi^{\dot{\sigma}})$$

$$\left. \begin{aligned} m_{\dot{i}\dot{s}} &= \frac{\hbar}{imc} (\psi_{\dot{i}} \chi_{\dot{s}} + \psi_{\dot{s}} \chi_{\dot{i}}) \\ m_{kl} &= \frac{-\hbar}{imc} (\psi_k \chi_l + \psi_l \chi_k) \end{aligned} \right\} \quad (10)$$

Equations (8) (9) and (10) are the spinor form for the decomposition of the current first given independently by Gordon¹⁵ and Darwin.¹⁶ Similarly to the correction terms on the right side of (4), the spinor (10) expresses the existence of a spin.

§10. The multiplication process described in §8 is not the only process by means of which the potentials $\phi_{\dot{m}l}$ may be eliminated from the Dirac equations. In fact, besides the one leading to the continuity Eq. (6), it is possible in three more ways to eliminate the $\phi_{\dot{m}l}$ each of which lead to an invariant relation between the ψ and χ .

For the sake of convenience we write down the four Dirac equations, but using only covariant ∂ -operators. In four columns at the right side of the equations, the various factors, with which we multiply are given.

$mc\chi_l + \frac{\hbar}{i} \partial_{\dot{s}l} \psi^{\dot{\sigma}} + \phi_{\dot{s}l} \psi^{\dot{\sigma}} = 0$	a	b	c	d
	$+ \psi^l$	$+ \psi^l$	$+ \chi^l$	$+ \chi^l$
$mc\psi_{\dot{m}} - \frac{\hbar}{i} \partial_{\dot{m}\lambda} \chi^{\lambda} - \phi_{\dot{m}\lambda} \chi^{\lambda} = 0$	$- \chi^{\dot{m}}$	$+ \chi^{\dot{m}}$	$+ \psi^{\dot{m}}$	$+ \psi^{\dot{m}}$
$mc\chi_{\dot{m}} - \frac{\hbar}{i} \partial_{\dot{m}\lambda} \psi^{\lambda} + \phi_{\dot{m}\lambda} \psi^{\lambda} = 0$	$- \psi^{\dot{m}}$	$- \psi^{\dot{m}}$	$+ \chi^{\dot{m}}$	$- \chi^{\dot{m}}$
$mc\psi_l + \frac{\hbar}{i} \partial_{\dot{s}l} \chi^{\dot{\sigma}} - \phi_{\dot{s}l} \chi^{\dot{\sigma}} = 0$	$+ \chi^l$	$- \chi^l$	$+ \psi^l$	$- \psi^l$

We obtain

$$(a) \quad \partial_{\dot{s}\lambda} (\psi^{\dot{\sigma}} \psi^{\lambda} + \chi^{\dot{\sigma}} \chi^{\lambda}) = 0. \quad (6)$$

This is Eq. (6) for the current.

$$(b) \quad \partial_{\dot{s}\lambda} (\psi^{\dot{\sigma}} \psi^{\lambda} - \chi^{\dot{\sigma}} \chi^{\lambda}) + 2i \frac{mc}{\hbar} (\psi^{\lambda} \chi_{\lambda} + \psi_{\dot{\sigma}} \chi^{\dot{\sigma}}) = 0 \quad (11)$$

(c) (d) Adding and subtracting the results of process (c) and (d) we have, using (7) and (7a) Chapter I

¹⁵ W. Gordon, Zeits. f. Physik 50, 630 (1928).

¹⁶ G. Darwin, Proc. Roy. Soc. A120, 621 (1928).

$$\chi^\lambda \partial_{\delta\lambda} \psi^\delta - \psi^\delta \partial_{\delta\lambda} \chi^\lambda = 0 \quad (12)$$

$$\chi^\delta \partial_{\delta\lambda} \psi^\lambda - \psi^\lambda \partial_{\delta\lambda} \chi^\delta = 0. \quad (13)$$

It is clear, that these are the only relations between the wave functions which are independent of the potentials $\phi_{\delta\lambda}$, because we have eight equations (the four Dirac equations and their complex conjugates) in which only four potentials $\phi_{\delta\lambda}$ occur.¹⁷ It is curious, that three of these relations are also independent of the mass.

A few words may be added concerning the quadratic invariants which do not involve differentiation. Due to (7a) Chapter I the only two invariants are:

$$\left. \begin{aligned} \Delta &= \psi_\lambda \chi^\lambda \\ \bar{\Delta} &= \psi_\delta \chi^\delta \end{aligned} \right\}. \quad (14)$$

It is easily verified¹⁸ that the square of the current

$$j_{\delta\lambda} j^{\delta\lambda} = 2\Delta\bar{\Delta} \quad (15)$$

and the square of the polarization spinor (10):

$$\left. \begin{aligned} m_{\delta\sigma} m^{\delta\sigma} &= 2 \left(\frac{h}{mc} \right)^2 \bar{\Delta}^2 \\ m_{\alpha\beta} m^{\alpha\beta} &= 2 \left(\frac{h}{mc} \right)^2 \Delta^2 \end{aligned} \right\} \quad (16)$$

Introducing the abbreviation

$$k_{\delta\lambda} = \psi_\delta \psi_\lambda - \chi_\delta \chi_\lambda$$

for the spinor whose divergence occurred in (11), it is readily seen that

$$\left. \begin{aligned} k^{\delta\lambda} m_{\delta\sigma} &= - \frac{h}{imc} j_{\delta\lambda} \bar{\Delta} \\ j^{\delta\lambda} m_{\delta\sigma} &= - \frac{h}{imc} k_{\delta\lambda} \bar{\Delta}. \\ k_{\delta\lambda} j^{\delta\lambda} &= 0 \end{aligned} \right\} \quad (17)$$

§11. Darwin¹⁹ has shown how to derive both the Maxwell and the Dirac equations from a variation principle. The analogous development using spinor analysis runs as follows. We start with the Lagrangian function

¹⁷ Relations (11), (12) and (13) were found more or less accidentally by the authors. The point of view described in the text was supplied by Professor G. Y. Rainich, who found them independently. Professor Rainich further communicated to us a rigorous proof of the fact that the Dirac equations possess only two algebraic quadratic invariants, which are simply our Δ and $\bar{\Delta}$. Also relations (17) are due to him. The authors are greatly indebted to Professor Rainich for several discussions on the subject.

¹⁸ Compare C. G. Darwin, Proc. Roy. Soc. A120, 621 (1928). See esp. p. 627.

¹⁹ C. G. Darwin, Proc. Roy. Soc. A118, 654 (1928).

$$L = \frac{\hbar}{i} \{ \psi^\mu \partial_\mu^\lambda \psi_\lambda - \chi^\mu \partial_\mu^\lambda \chi_\lambda - \psi^\lambda \partial_\lambda^\mu \psi_\mu + \chi^\lambda \partial_\lambda^\mu \chi_\mu \} \\ + 2mc(\Delta + \bar{\Delta}) + \phi^{\dot{\mu}\lambda} j_{\dot{\mu}\lambda} - \frac{1}{2} g^{\dot{\mu}\dot{\rho}} g_{\dot{\mu}\dot{\rho}} \quad (18)$$

where the meaning of Δ , $\bar{\Delta}$, $j_{\dot{m}i}$ and $g_{\dot{m}\dot{n}}$ in terms of ψ , χ , and ϕ are given in Eq. (14) (7) Chapter III and (9a) Chapter II respectively. L is to be considered a function of ψ , χ , ϕ and their derivatives.

1°. Varying ψ_i we obtain as Euler-Lagrange equation

$$\partial_\mu^i \left\{ \frac{\partial L}{\partial (\partial_\mu^\alpha \psi_\alpha)} \right\} - \frac{\partial L}{\partial \psi_i} = 0$$

which is identical with (1a).

2°. Varying $\chi_{\dot{m}}$ we obtain

$$\partial_{\dot{\lambda}}^{\dot{m}} \left\{ \frac{\partial L}{\partial (\partial_{\dot{\lambda}}^\sigma \chi_\sigma)} \right\} - \frac{\partial L}{\partial \chi_{\dot{m}}} = 0$$

which is identical with (1b).

3°. Varying $\psi_{\dot{m}}$ we get (2a) and varying χ_i we get (2b).

4°. Varying $\phi_{\dot{m}i}$ we obtain

$$\partial_\sigma^i \left\{ \frac{\partial L}{\partial (\partial_{\sigma\alpha} \phi_{\dot{m}\alpha})} \right\} - \frac{\partial L}{\partial \phi_{\dot{m}i}} = 0$$

that is to say

$$\partial_\sigma^i g^{\dot{\sigma}\dot{m}} = 2j^{\dot{m}i} = 2(\psi^{\dot{m}} \psi^i + \chi^{\dot{m}} \chi^i)$$

which are the Maxwell equations with the Dirac current.

A TENSOR FORM OF DIRAC'S EQUATION

BY BORIS PODOLSKY*

CALIFORNIA INSTITUTE OF TECHNOLOGY

(Received April 8, 1931)

ABSTRACT

In this paper a simple tensor form of Dirac's equation is obtained. This is accomplished by considering ψ_s and $\gamma^\alpha(rs)$ of the usual equations as being related to a set of n -beins as invariants corresponding to true tensors ψ_μ and $\Gamma^\alpha_\beta{}^\sigma$. The results are, however, independent of the choice of the n -beins. It is thus shown that the introduction of the idea of half-vectors in the quantum mechanics, while undoubtedly desirable when dealing exclusively with cartesian coordinates, is unnecessary.

1. MUCH work was done in attempting to find a generalization of Dirac's wave equation to general relativity. Of this the most important is probably the work of Fock.¹ In nearly all these, however, ψ is regarded as a half-vector. It is interesting, therefore, to see to what extent it is possible to achieve this generalization using only the ordinary tensors.

It became quite clear, as the result of other investigations, that the extension of Dirac's equations to general relativity necessitates the introduction of n -beins, i.e. a local cartesian coordinate system at each point. This, however, does not spoil the generality of equations obtained, as they turn out to be independent of the particular choice assumed.

2. For our purpose it is convenient to write Dirac's equation in the following form:

$$\sum_s e_s \left\{ \Gamma^\alpha_{rs} \left(p_\alpha + \frac{e}{c} \Phi_\alpha \right) + mc \Gamma_{rs} \right\} \psi_s = 0 \quad (1)$$

where all subscripts take the values 1, 2, 3, and 4. As is done in the work of Fock, summations with respect to doubled Greek indices are always implied, while summations with respect to Latin indices are explicitly indicated. The matrices are taken to be the following:

$$\begin{aligned} \Gamma^1 &= \begin{pmatrix} 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix}; & \Gamma^2 &= \begin{pmatrix} 0 & -i & 0 & 0 \\ i & 0 & 0 & 0 \\ 0 & 0 & 0 & i \\ 0 & 0 & -i & 0 \end{pmatrix}; & \Gamma^3 &= \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix} \\ \Gamma^4 &= I = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}; & \Gamma &= \begin{pmatrix} 0 & 0 & 0 & -1 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ -1 & 0 & 0 & 0 \end{pmatrix}. \end{aligned} \quad (2)$$

* This work was started at the Leipzig Physikalisches Institut while the author was there on a National Research Fellowship.

¹ Fock, Journ. de Phys. 10, 392 (1929) in which other references are given. See also Tetradé, Zeits. f. Physik 50, 336 (1928), and Wigner, Zeits. f. Physik 53, 592 (1929).

Here $p_\alpha = (\hbar/2\pi i)\partial/\partial x^\alpha$; $x^\alpha = (x, y, z, ct)$; $\Phi_\alpha = (A_x, A_y, A_z - \phi)$, where ϕ is the scalar and (A_x, A_y, A_z) the vector potential. Also, the quantities $e_1 = e_2 = e_3 = -1$, $e_4 = 1$, are introduced for later convenience.

3. We now introduce a set of n -beins by means of sixteen parameters h_s^ν and their corresponding moments $h_{s\nu}$ as is done by Fock. Designating local components of vectors, i.e. ordinary cartesian projections on the vectors constituting the n -beins at each point, by Latin indices and their tensor components by Greek indices, we have the following relations:

$$\begin{aligned} A_\sigma &= \sum_k e_k A_k h_{k\sigma} \\ A^\sigma &= \sum_k e_k A_k h_k^\sigma. \end{aligned} \quad (3)$$

The quantities e_k are introduced to make the components A_4 , A^4 , and $h_{4\sigma}$ real and are $e_1 = e_2 = e_3 = -1$, $e_4 = 1$, as in Eq. (1).

With this notation² the h 's satisfy the following relations:

$$\begin{aligned} e_k h_k^\sigma h_{l\sigma} &= e_l h_l^\sigma h_{k\sigma} = \delta_{kl} \\ \sum_k e_k h_{k\sigma} h_k^\rho &= \delta_\sigma^\rho. \end{aligned} \quad (4)$$

Equations (3) can be immediately generalized to any tensor. Thus, for example:

$$A^{\alpha\beta}_\gamma = \sum_{r,s,t} e_r e_s e_t A_{rst} h_r^\alpha h_s^\beta h_{t\gamma} \quad (5)$$

or, solving for A_{rst} with the help of (4)

$$A_{rst} = A^{\alpha\beta}_\gamma h_{r\alpha} h_{s\beta} h_t^\gamma.$$

The quantities A_{rst} are invariants, i.e. they do not change with the change of the coordinate system, although they, of course, change with the change of the set of n -beins.

We may also have quantities such as

$$A^{\alpha}_{st} = A^{\alpha\beta}_\gamma h_{s\beta} h_t^\gamma, \quad (6)$$

which are in part invariants of a set of n -beins and in part tensors.

4. We extend Dirac's equation to general relativity by regarding the Latin indices occurring in Eq. (1) as the n -bein system indices. Thus, Γ_{rs} and ψ_s are invariants, and Γ^α_{rs} are the mixed quantities of the type of Eq. (6).

We will now rewrite Eq. (1) in a tensor form. First we observe that

$$\sum_s e_s \Gamma_{rs} \psi_s = \sum_{s,t} e_s \Gamma_{rs} \delta_{st} \psi_t = \sum_{s,t} e_s e_t \Gamma_{rs} h_s^\sigma h_{t\sigma} \psi_t, \text{ by (4)}$$

thus, by (3)

$$\sum_s e_s \Gamma_{rs} \psi_s = \Gamma_r^\sigma \psi_\sigma. \quad (7)$$

² The notation throughout this paper is that of Fock.

Similarly

$$\begin{aligned}\sum_s e_s \Gamma^{\alpha}_{rs} \left(p_{\alpha} + \frac{e}{c} \Phi_{\alpha} \right) \psi_s &= \left(p_{\alpha} + \frac{e}{c} \Phi_{\alpha} \right) \sum_s e_s \Gamma^{\alpha}_{rs} \psi_s \\ &= \left(p_{\alpha} + \frac{e}{c} \Phi_{\alpha} \right) \Gamma^{\alpha}_{r\sigma} \psi_{\sigma}.\end{aligned}\tag{8}$$

In place of the ordinary partial derivative in the interpretation of p_{α} as an operator we now use

$$p_{\alpha} = \frac{h}{2\pi i} (\dots)_{;\alpha} \tag{9}$$

where; α is the covariant derivative in the sense of Einstein.³ This operator acting on a tensor gives again a tensor of one rank higher in covariant indices. It is defined with the help of the quantities

$$\Delta^{\sigma}_{\alpha\beta} = \sum_s e_s h_s^{\sigma} \frac{\partial h_{s\alpha}}{\partial x^{\beta}}. \tag{10}$$

In constructing Einstein's covariant derivatives one uses $\Delta^{\sigma}_{\alpha\beta}$ like $\{\alpha\beta, \sigma\}$ in ordinary covariant differentiation. Thus, for example,

$$(A_{\beta}^{\alpha})_{;\gamma} = \frac{\partial A_{\beta}^{\alpha}}{\partial x^{\gamma}} + A_{\beta}^{\sigma} \Delta^{\alpha}_{\sigma\gamma} - A_{\sigma}^{\alpha} \Delta^{\sigma}_{\alpha\beta}.$$

For us the important property of; α is

$$(h_s^{\nu})_{;\alpha} = (h_{s\nu})_{;\alpha} = (g_{\mu\nu})_{;\alpha} = 0. \tag{11}$$

From this follows:

$$\begin{aligned}p_{\alpha} \Gamma^{\alpha}_{r\sigma} \psi_{\sigma} &= \frac{h}{2\pi i} (\Gamma^{\alpha}_{r\sigma} \psi_{\sigma})_{;\alpha} \\ &= \frac{h}{2\pi i} \left(\sum_s \Gamma^{\alpha}_{rs} e_s h_s^{\sigma} \psi_{\sigma} \right)_{;\alpha} \\ &= \frac{h}{2\pi i} \sum_s \Gamma^{\alpha}_{rs} e_s h_s^{\sigma} (\psi_{\sigma})_{;\alpha}\end{aligned}$$

since Γ^{α}_{rs} are constants and by Eq. (11). Hence

$$\begin{aligned}p_{\alpha} \Gamma^{\alpha}_{r\sigma} \psi_{\sigma} &= \left(\sum_s \Gamma^{\alpha}_{rs} e_s h_s^{\sigma} \right) \cdot \frac{h}{2\pi i} (\psi_{\sigma})_{;\alpha} \\ &= \Gamma^{\alpha}_{r\sigma} p_{\alpha} \psi_{\sigma}\end{aligned}\tag{12}$$

i.e., p_{α} and the Γ 's commute.

³ Einstein, Math. Ann. 102, 685 (1930).

Using Eqs. (7), (8), and (13) we can rewrite Eq. (1) in the form

$$\left\{ \Gamma_{r^{\sigma}}^{\alpha} \left(p_{\alpha} + \frac{e}{c} \Phi_{\alpha} \right) + mc \Gamma_{r^{\sigma}} \right\} \psi_{\sigma} = 0.$$

Multiplying by $e_r h_{r\beta}$ and summing with respect to r , we obtain the desired equation:

$$\left\{ \Gamma_{\beta^{\sigma}}^{\alpha} \left(p_{\alpha} + \frac{e}{c} \Phi_{\alpha} \right) + mc \Gamma_{\beta^{\sigma}} \right\} \psi_{\sigma} = 0. \quad (13)$$

5. The adjoint to Eq. (1) by a similar transformation becomes

$$\left\{ \Gamma_{\beta^{\sigma}}^{\alpha} \left(p_{\alpha} - \frac{e}{c} \Phi_{\alpha} \right) - mc \Gamma_{\beta^{\sigma}} \right\} \psi^{\dagger\beta} = 0. \quad (14)$$

Multiplying Eq. (13) by $\psi^{\dagger\beta}$, Eq. (14) by ψ_{α} and adding we obtain

$$\psi^{\dagger\beta} \Gamma_{\beta^{\sigma}}^{\alpha} p_{\alpha} \psi_{\sigma} + \psi_{\alpha} \Gamma_{\beta^{\sigma}}^{\alpha} p_{\alpha} \psi^{\dagger\beta} = 0$$

or

$$(\psi^{\dagger\beta} \Gamma_{\beta^{\sigma}}^{\alpha} \psi_{\sigma})_{;\alpha} = 0. \quad (15)$$

We may interpret the expression in parenthesis as the current-density vector

$$J^{\alpha} = \Gamma_{\beta^{\sigma}}^{\alpha} \psi^{\dagger\beta} \psi_{\sigma}; \quad (16)$$

then Eq. (15) becomes a generalization of the equation

$$\text{div} J^{\alpha} = 0.$$

Using Eqs. (3) and (5), Eq. (16) may be also written as follows:

$$J^{\alpha} = \sum_{r,s} e_r e_s \psi_r^{\dagger} \Gamma_{rs}^{\alpha} \psi_s, \quad (17)$$

which is what one obtains directly from Eq. (1) and its adjoint.

6. The energy is given by the relation

$$-\frac{E}{c} = p_4 = \frac{h}{2\pi i} (\dots)_{;4}. \quad (18)$$

Of course, we can speak of energy of an electron only in a flat space-time in which one of the coordinates is singled out as time. Thus, if $x_4 = ct$, Eq. (18) reduces to the usual

$$E = -\frac{h}{2\pi i} \frac{\partial}{\partial t}$$

which must of course be interpreted to mean that the numerical value of the energy is given by

$$E' = -\frac{h}{2\pi i} \int \psi^{\dagger\alpha} \frac{\partial}{\partial t} \psi_{\alpha} dV.$$

In this case E' is $-c$ times the time component of a vector

$$p_{\beta'} = \frac{h}{2\pi i} \int \psi^\dagger{}^\alpha (\psi_\alpha)_{;\sigma} dV. \quad (20)$$

7. The angular momentum operator of Dirac

$$M^\alpha = m^\alpha + \frac{h}{4\pi} \sigma^\alpha, \quad (21)$$

where $m^1 = yp_z - zp_y$, etc. in our notation becomes

$$M_{rs}^\alpha = m_{rs}^\alpha + \frac{h}{4\pi} \sigma_{rs}^\alpha. \quad (22)$$

The Hamiltonian of Dirac is also a four-rowed square matrix H_{rs} , and the fact that M^α and H commute means

$$\sum_{s,t} M_{rs}^\alpha H_{st} \psi_t = \sum_{s,t} H_{rs} M_{st}^\alpha \psi_t. \quad (23)$$

The operator (22) has a meaning only in flat space-time. In that case, however, our Eq. (13) can be written in the form

$$\sum_s e_s \left\{ H_{rs} + \frac{h}{2\pi i} \delta_{rs} \frac{\partial}{\partial t} \right\} \psi_s = 0 \quad (24)$$

where H_{rs} is the Dirac Hamiltonian. The relation (23) then holds, so that operator (22) is still a constant of the motion.

8. The invariance of Eq. (13) with respect to Lorentz transformations does not follow immediately from the tensor form of the equation. In Eq. (2) Γ_{rs}^α are assumed constants associated with a particular coordinate system. By a Lorentz transformation they change to Γ'^α_{rs} given by

$$\Gamma'^\alpha_{rs} = \Gamma_{rs}^\beta a_{\beta\alpha}, \quad (25)$$

where $a_{\beta\alpha}$ is a set of coefficients satisfying the relation

$$\begin{aligned} a_{\mu\nu} a_{\mu\rho} &= \delta_{\nu\rho} \\ a_{\mu\rho} a_{\nu\rho} &= \delta_{\mu\nu}. \end{aligned} \quad (26)$$

Now, since the original and the new coordinate systems are physically indistinguishable, we may have started with the new Γ 's and the old coordinate system; i.e. we have no way of knowing to which coordinate system the originally assumed Γ 's belong. Thus, we may have written instead of Eq. (1)

$$\sum_s e_s \left\{ \Gamma'^\alpha_{rs} \left(p_\alpha + \frac{e}{c} \Phi_\alpha \right) + mc \Gamma_{rs} \right\} \psi'_s = 0. \quad (27)$$

We must now show that Eq. (27) leads to the same physical results as Eq. (1). It has been shown⁴ that Eq. (25) may be put in the form

⁴ See for example Moglich, *Zeits. f. Physik* **48**, 852 (1928) and Neumann, *Zeits. f. Physik* **48**, 868 (1928).

$$\Gamma'^{\alpha}_{rs} = \sum_{t,u} S^{\dagger}_{rt} \Gamma^{\alpha}_{tu} S_{us}, \quad (28)$$

where S and S^{\dagger} are matrices of the form

$$S = \begin{pmatrix} \alpha & \beta & 0 & 0 \\ \gamma & \delta & 0 & 0 \\ 0 & 0 & \bar{\alpha} & \bar{\beta} \\ 0 & 0 & \bar{\gamma} & \bar{\delta} \end{pmatrix}, \quad S^{\dagger} = \begin{pmatrix} \bar{\alpha} & \bar{\gamma} & 0 & 0 \\ \bar{\beta} & \bar{\delta} & 0 & 0 \\ 0 & 0 & \alpha & \gamma \\ 0 & 0 & \beta & \delta \end{pmatrix}$$

and $\alpha\delta - \beta\gamma = 1$. Furthermore

$$\Gamma_{rs} = \sum_{t,u} S^{\dagger}_{rt} \Gamma_{tu} S_{us}. \quad (29)$$

Using Eqs. (28) and (29), Eq. (27) may be written as follows:

$$\sum_{s,t,u} e_s S_{rt} \left\{ \Gamma^{\alpha}_{tu} \left(p_{\alpha} + \frac{e}{c} \Phi_{\alpha} \right) + mc \Gamma_{tu} \right\} S_{us} \psi'_s = 0.$$

Thus, if ψ'_s satisfies Eq. (27), ψ_u given by

$$e_u \psi_u = \sum_s e_s S_{us} \psi'_s \quad (30)$$

will satisfy Eq. (1). Similarly

$$e_u \psi_u^{\dagger} = \sum_s e_s \psi'^{\dagger}_s S_{su}^{\dagger}. \quad (30')$$

Thus Eq. (17) becomes

$$\begin{aligned} J^{\alpha} &= \sum_{r,s} \left(\sum_t e_t \psi'^{\dagger}_t S_{tr} \right) \Gamma^{\alpha}_{rs} \left(\sum_u e_u S_{su} \psi'_u \right) \\ &= \sum_{t,u} e_t e_u \psi'^{\dagger}_t \Gamma'^{\alpha}_{tu} \psi'_u, \text{ by (28)} \end{aligned}$$

This is just what would have been obtained directly from Eq. (27).

9. Similarly, the invariance of Eq. (13) with respect to rotation of n -beins must be tested by investigating what would have happened if the original set of Γ 's became associated with another set of n -beins. Our original equation would then be

$$\sum_s e_s \left\{ \Gamma''^{\alpha}_{rs} \left(p_{\alpha} + \frac{e}{c} \Phi_{\alpha} \right) + mc \Gamma''_{rs} \right\} \psi''_s = 0 \quad (31)$$

where Γ''^{α}_{rs} and Γ''_{rs} are obtained from the given Γ 's by a rotation of n -beins.

We will now show that the physical consequences of Eq. (31) are the same as of Eq. (1). In order to show this we must first find the relation between Γ'' and Γ . This is given by the condition that tensors $\Gamma^{\alpha}_{\beta\sigma}$ must be independent of the n -beins. Thus,

$$\Gamma_{\beta}^{\alpha} = \sum_{r,s} e_r e_s h_{r\beta} h_s^{\sigma} \Gamma_{rs}^{\alpha} = \sum_{r,s} e_r e_s h''_{r\beta} h''_s{}^{\sigma} \Gamma''_{rs}{}^{\alpha}. \quad (32)$$

Using the laws of transformation of the n -beins

$$\begin{aligned} h_{r\beta} &= \sum_t a_{tr} h''_{t\beta} \\ h_s{}^{\sigma} &= \sum_t a_{ts} h''_t{}^{\sigma} \end{aligned} \quad (33)$$

where $\sum_t a_{rt} a_{st} = \sum_t a_{tr} a_{ts} = \delta_{rs}$, we obtain

$$e_r e_s \Gamma''_{rs}{}^{\alpha} = \sum_{t,u} e_t e_u a_{rt} \Gamma_{tu}^{\alpha} a_{su} \quad (34)$$

and a similar equation for Γ''_{rs} . With the help of Eq. (34) we may rewrite Eq. (31) as follows

$$\sum_{s,t,u} e_t e_u a_{rt} a_{su} \left\{ \Gamma_{tu}^{\alpha} \left(p_{\alpha} + \frac{e}{c} \Phi_{\alpha} \right) + mc \Gamma_{tu} \right\} \psi''_s = 0. \quad (35)$$

If the a 's are constants, which is the case if we have distant parallelism, Eq. (35) becomes

$$\sum_r e_t a_{rt} \left[\sum_u e_u \left\{ \Gamma_{tu}^{\alpha} \left(p_{\alpha} + \frac{e}{c} \Phi_{\alpha} \right) + mc \Gamma_{tu} \right\} \sum_s a_{su} \psi''_s \right] = 0. \quad (36)$$

Thus, if ψ''_s satisfies Eq. (31),

$$\psi_u = \sum_s a_{su} \psi''_s \quad (37)$$

will satisfy Eq. (1). Similarly

$$\psi_t \dagger = \sum_r \psi''_r \dagger_r a_{rt}. \quad (38)$$

The current-density vector which we would have constructed using ψ''_s would be

$$\begin{aligned} J''^{\alpha} &= \sum_{r,s} e_r e_s \Gamma''_{rs}{}^{\alpha} \psi''_r \dagger \psi''_s \\ &= \sum_{r,s} \left(\sum_{t,u} e_t e_u a_{rt} \Gamma_{tu}^{\alpha} a_{su} \right) \psi''_r \dagger \psi''_s, \text{ by (34)} \\ &= \sum_{t,u} e_t e_u \Gamma_{tu}^{\alpha} \left(\sum_r \psi''_r \dagger a_{rt} \right) \left(\sum_s a_{su} \psi''_s \right) \\ &= \sum_{t,u} e_t e_u \Gamma_{tu}^{\alpha} \psi_t \dagger \psi_u, \text{ by (37) and (38)} \\ &= J^{\alpha}, \text{ by (17).} \end{aligned}$$

10. Thus we were able to find a tensor equation, Eq. (13), which is invariant with respect to the Lorentz transformation and with respect to the

n -bein rotations. It satisfies all the conditions which a correct generalization of the Dirac equation should satisfy.

As for the physical or geometrical interpretation of the tensors $\Gamma^{\alpha}_{\beta}{}^{\sigma}$ and $\Gamma_{\beta}{}^{\sigma}$ we can only say that their introduction required the use of covariant differentiation in Einstein's sense and a true distant parallelism. In this we approach Einstein's unified field theory. However, a complete transition cannot be achieved as long as we are compelled to introduce potentials Φ_{α} in our equations as something externally given.

REPULSIVE ENERGY LEVELS IN BAND SPECTRA

BY JOSEPH KAPLAN

UNIVERSITY OF CALIFORNIA AT LOS ANGELES

(Received April 20, 1931)

ABSTRACT

An explanation is given for many cases of anomalous intensity distribution in the band spectra of diatomic molecules. Use is made of an interaction between the known energy levels of molecules and energy levels which are produced by the repulsive interaction of pairs of atoms in their normal and metastable energy levels. The chief types of anomalies which are discussed are those corresponding to the sudden cutting off of a group of bands at some low value of v' , the initial vibrational quantum number, and the failure of bands to agree with the Franck-Condon theory. Use is made of these ideas to explain the long life of active nitrogen.

WHILE there have been some very unusual cases of intensity distribution in the band spectra of diatomic molecules, they have been the exception rather than the rule and for that reason very little attention has been paid to them. The writer has made use of some of these cases to calculate the heats of dissociation of nitrogen¹ and of carbon monoxide² and until recently nothing more was done with them. Recent experiments on some very unusual band spectrum intensities in nitrogen-oxygen mixtures, combined with the increased interest in the purely repulsive potential energy levels of Heitler and London,³ have led the writer to what is believed to be a satisfactory explanation of many of the unusual examples of band spectrum excitation which have arisen. The recent paper by Turner⁴ on the effect of magnetic fields on the fluorescence radiation of iodine, suggested the direction in which an explanation was to be sought for the above-mentioned cases. In this note we will only mention these cases and make brief remarks about their explanations.

As a typical example we will consider the second positive group of nitrogen. These bands correspond to transitions from the C level to the B level. No bands of this system are known whose initial levels are higher than $v'=4$, in spite of the fact that the total energy of the " C " level is about 15 volts, corresponding to dissociation into a 2D and a 2P metastable atom.⁵ The energy in the C_4 level is about 13.9 volts and this is exactly equal to the dissociation energy of nitrogen into two metastable 2D atoms. Therefore, unless the products of dissociation are assumed to be two 2D atoms rather than a 2D and a 2P atom, one cannot explain the non-appearance of the higher vibrational levels by saying the $v'=4$ is the highest vibrational quantum number that

⁵ Mulliken, Phys. Rev. **32**, 186 (1928).

can be associated with the *C* level. An alternative explanation presents itself if one assumes that all vibrational states above $v'=4$ are quenched by transitions from the *C* level to the Heitler and London level which corresponds to the coming together of two metastable 2D atoms. The probability of transitions from the stable molecular level to a Heitler and London level is undoubtedly governed by the same rules as those which govern the usual molecular transitions e.g. by the Franck-Condon principle. Thus one can in general study the shape of the potential energy curve corresponding to a Heitler and London level, from the way it combines with known potential energy curves. The writer proposes to make a careful study of this in the future.

There are two possible explanations for the case which was just discussed, so that we propose now to discuss some more convincing examples of interaction between repulsive and attractive potential energy curves. The fourth positive bands of nitrogen are developed with but one initial vibrational state, corresponding to the transition D_0-B_v . The writer has used this fact as a means of calculating the heat of dissociation of nitrogen, making the postulate that the reason for the non-appearance of higher vibrational states was that the molecule spontaneously dissociated when an attempt was made to excite the higher vibrational states. At the time the calculation was made this was thought to indicate an extreme anharmonicity of the *D* level and consequently a very small heat of dissociation for this level. The value of $\omega_0 x$ necessary to yield the extremely small value of D^0 that this explanation demanded was so large as to be without precedent among band spectra. The present explanation will be seen to be much more reasonable. A purely repulsive potential energy curve corresponding to the coming together of a 2D and a 2P atom would cross the potential energy curve of the *D* level at just about the energy corresponding to its first or second vibrational states. Even if the *D* level does possess some vibrational states, a strong intercombination with the Heitler and London level might either prevent the excitation of these higher vibrational states or if they were excited, it might quench them. Probably both of these effects must be considered, but once again it is seen that a Heitler and London level is useful in explaining an unusual spectroscopic phenomenon.

Similar considerations may be applied to the third positive group, the *3A* bands and the *5B* bands of carbon monoxide.⁶ All three of these groups possess but one initial vibrational level and the writer has used the lowest one of these electronic levels, the *b* level, as a means of calculating the heat of dissociation of CO, making the same assumption as was made for the *D* level in nitrogen. The generally accepted value for the heat of dissociation of CO is around 10.3 volts and the energy values of the initial levels of the third positive and the *5B* bands are 10.34 and 10.61 volts respectively. Thus it is gain highly probable that the repulsive energy level which corresponds to the coming together of a normal carbon atom and a normal oxygen atom, will so combine with these two electronic levels as to prevent the excitation of higher

⁶ J. Kaplan, Phys. Rev. 36, 784 (1930).

vibrational states. The repulsive interaction of a normal oxygen atom and a carbon atom in the 1S_0 state will yield an energy level in the vicinity of 11.5 volts, and this will account for the absence of vibrational states higher than $v'=0$ in the $3A$ bands of CO.

Returning to the consideration of the nitrogen molecule we call attention to several other cases of anomalous intensity distribution in band spectra, which seem to be examples of interaction between attractive and repulsive levels in the molecule. A system of nitrogen bands, discovered by Birge and Hopfield,⁷ and having but a single initial vibrational state at 12.8 volts, shows a very unusual intensity distribution among the bands of the progression. Now 12.8 volts corresponds very closely to the energy of recombination of a normal nitrogen atom and a metastable atom in the 2P level. Once again therefore we can blame the peculiar development of the bands on an interaction between an attractive and a repulsive energy state. In the same report, Birge and Hopfield call attention to many irregularities in the bands which make up the ultraviolet system $^1S-^1P$. Since the electronic energy of this system is 8.5 volts and most of the irregularities are connected with the progressions arising on $v'=4, 5$ and 6 , the explanation is given that these irregularities arise from interactions between this level and the repulsive level which is formed when two normal nitrogen atoms come together. The heat of dissociation of nitrogen is about 9.1 volts⁸ and the energy of the $v'=4$ level is 9.3 volts. By comparison with the previous examples it is certainly reasonable to assume that the above explanation is correct.

The experiments which first called the writer's attention to the possibilities of the ideas presented here, were designed to reproduce some of the peculiar intensity phenomena which arise in the first positive bands of nitrogen as produced in the aurora borealis. Without attempting a detailed discussion of the experiment, we can say that as far as the intensity distribution among the bands is concerned, especially when the relative intensities of the bands in a single v' progression are considered, the first positive bands are surprisingly sensitive to excitation conditions, more so in fact than any other band system with which the writer has had experience. Elsewhere⁹ the present writer has called attention to the violent variation in intensities which arises when inert gases are mixed with active nitrogen. This variation in intensities, which is a variation of intensities in v' progressions, must be looked on as a variation in transition probabilities, because the relative intensities of bands within a v' progression are fixed by the relative transition probabilities, which can be determined by the Franck-Condon principle. In practically all discussions of band spectra it is assumed that the predictions of the above principle hold and in general they do apply. The anomalous cases presented here are those which arise either under unusual excitation conditions or in the case of energy levels which are very sensitive to excitation conditions and thus yield exceptional intensities even under normal dis-

⁷ Birge and Hopfield, *Astrophys. J.* **68** 257 (1928).

⁸ Birge, *Trans. Faraday Soc.* **25** 718 (1929).

⁹ J. Kaplan, *Phys. Rev.* **36**, 778 (1930).

charge conditions. A few more remarks about the first positive bands will soon convince us that it is partly an example of the very sensitive energy state rather than that of unusual excitation conditions.

It is easy to see, from only a casual inspection of the spectrum, some of the unusual features of the first positive bands. One unusual feature is, that while most of the first positive bands possess four heads, the bands whose initial levels correspond to $v'=13, 14, 15, 16$ and sometimes $v'=17$, as well as those with $v'=19, 20, 21$, possess only strong single heads. In some discharges even $v'=3, 4$ and 5 showed this characteristic. Under some conditions there are remarkable variations in the relative intensities of the four heads and sometimes only one strong head appears where four appeared under normal conditions. Furthermore the intensities of the bands which possess these single-heads under normal conditions, are less than those originating on higher vibrational states, which is in itself an exceptional occurrence, and in agreement with the idea that the vibrational states corresponding to the single-headed bands are quenched by some mechanism in the molecule. In some of the experiments on the spectra of oxygen-nitrogen mixtures it was possible to produce the first positive bands with a sharp cut-off at $v'=12$. The vibrational states higher than $v'=12$ were almost completely missing thus giving here an excitation similar to some of the examples discussed above for NO, N₂ and CO.

A calculation of the energies corresponding to the range of vibrational states from which single-headed bands arise shows them to be in regions of the potential energy curve where one might quite reasonably postulate interaction with repulsive energy levels of the molecule. The vibrational levels associated with the initial electronic state of the first positive group lie between 9.35 and 13.9 volts. In this range there are four possible Heitler and London levels corresponding to the coming together of two normal atoms, or one normal and one ²D metastable atom or one normal and one ²P atom or two ²D atoms. We therefore readily see why this group of bands should be so highly sensitive to changes in conditions of excitation. The energies of recombination corresponding to the above modes of interaction are 9.1, 11.47, 12.66 and 13.84 volts. The observation in some experiments of single headedness around $v'=3$ probably corresponds to the 9.1 volt level, the $v'=13$ to 17 correspond to both 11.47 and 12.66 since their energies lie just between these two values and finally the single headed bands around $v'=20$ or 21 can correspond to either 12.66 or 13.84.

The most interesting application of the idea of interaction between attractive and repulsive levels is to the problem of the afterglow of active nitrogen. Here the question has often been asked as to the reason why the afterglow persists for such a long time. What is the mechanism in the nitrogen molecule which regenerates metastable atoms, normal atoms and metastable molecules and keeps the afterglow visible for what is a very long time when one considers the degree of metastability of the energy states involved. If we postulate that many of the molecules in the initial states of the first positive bands interact with Heitler and London levels and dissociate

instead of radiating, then we have a direct mechanism for sustaining the afterglow. We literally allow the molecule to waste its time during the process of the decay of the afterglow. It may be that only a very small number of excited nitrogen molecules lose their energy by radiation, most of them simply redissociating due to interaction with one of the repulsive levels. Thus if the walls of the afterglow tube are such as to allow the persistence of atoms, and it is well known that the walls are of paramount importance here, then one can expect a very long duration for the glow. Until further investigation has been made, it is not possible to say which of the two factors governs the life of the glow. It will be an interesting problem to study the effect of this new factor on the life of the nitrogen afterglow.

One final example will be discussed because of the good numerical agreement with heats of dissociation to which it leads. It has been known for a long time to spectroscopists that the beta bands of nitric oxide possess a very exceptional intensity distribution.¹⁰ These bands were first discovered in active nitrogen and the intensity distribution to which we refer is the one which is observed there. The writer has reported two experiments in which the beta bands were observed in the discharge but no careful study of intensity distribution has been made there. The two main anomalies in the intensity distribution in active nitrogen are the failure of the bands to fit the Franck-Condon theory and the absence of progressions higher than $v'=4$ even though $v'=5$ has been observed in absorption. The energy of the $v'=4$ level of the *B* band system is 6.15 volts and about three years ago the writer made some calculations of heats of dissociation of N_2 and O_2 , using this as the heat of dissociation of NO. The success of this method in N_2 and CO was the reason for these calculations. The resulting value for O_2 was so low that it was not considered at the time. In view of the recent revisions of the heats of dissociation of N_2 and O_2 , it is now possible to calculate a new value for NO,¹¹ using 9.1 volts for N_2 and 5.06 volts for O_2 . The heat of dissociation of NO is found to be 6.15 volts so that the explanation is immediately apparent. We have here an example exactly like that of the second positive bands of nitrogen. The fact that in this case the phenomenon is observed in active nitrogen, where the interaction between attractive and repulsive levels is probably rather strong, makes the explanation more interesting. Here again we postulate an interaction between the excited states on which the beta bands arise and the Heitler and London level corresponding to the coming together of a normal oxygen and a normal nitrogen atom. The failure of the beta bands to obey the Franck-Condon rule for band intensities is added evidence that the proposed explanation is correct, since that also occurred in some other cases mentioned earlier in this paper.

We have seen that the interaction between a repulsive and an attractive level will account for the sudden curtailing of band systems and that many such examples are accompanied by a failure of the bands to obey the Franck-Condon rule. This latter phenomenon can be referred to as a variation of

¹⁰ Barton, Jenkins and Mulliken, *Phys. Rev.* 30, 175 (1927).

¹¹ Birge and Sponer, *Phys. Rev.* 28, 259 (1926).

intensity within a progression, because a little consideration will show that the Franck-Condon rule predicts very definitely only the relative intensities within a single progression. Without going into much detail at this time it can be shown how the interactions which account for the curtailing of band systems will also account for a variation of intensities within a progression. The Franck-Condon theory is usually applied in a qualitative manner by drawing the two potential energy curves which are involved and noticing what lower states result when vertical lines are drawn through the two extreme values for the separation of the two atoms in the vibrating molecule. This procedure is correct provided the initial state radiates to, or in any other way goes to, only a single lower electronic state. The relative intensities of the bands which arise on a single initial vibrational state are then definitely fixed. If however the upper state finds itself in a position to interact with another lower state, the transition probabilities can be fixed now only by a consideration of both lower potential energy curves. It is obvious that one might readily expect large variations in the intensity distribution in progressions in this way. In the present paper we have shown how a third lower level, namely the Heitler and London level, may be brought in to the picture. From the nature of the observations it appears that this third level is sensitive to conditions and thus the intensity of interaction with normal levels will vary a great deal.

The present paper has been written mainly to bring out the one idea which is presented here. For that reason we have not published any spectra. This will be done in other publications which can be brought out with more leisure and in more detail, since this work is now being extended.

NOTE ON THE VISIBLE HALOGEN BANDS, WITH SPECIAL
REFERENCE TO ICl

BY ROBERT S. MULLIKEN

RYERSON PHYSICAL LABORATORY, UNIVERSITY OF CHICAGO

(Received April 9, 1931)

ABSTRACT

It is pointed out that the dissociation of excited ICl molecules, after absorption of light in the visible bands, into normal atoms is in harmony with theory. In analogy with the other halogens, these bands probably belong to a ${}^3\Pi \leftarrow {}^1\Sigma^+$ transition. The upper level of the bands is, however, doubtless not just the 0^+ part of the ${}^3\Pi_0$ as in the homonuclear halogen molecules, but is probably the whole ${}^3\Pi_0$, or else the ${}^3\Pi_1$. Detailed arguments against the possibility that the upper state of the halogen bands may be ${}^3\Sigma$ are given. Conclusions drawn in previous papers from the behavior of the I_2 bands in magnetic fields are revised.

IN TWO previous papers,^{1,2} the writer has shown that the well-known visible absorption bands of the molecules Cl_2 , Br_2 , and I_2 probably correspond to the transition $0^+_u({}^3\Pi) \leftarrow {}^1\Sigma^+_g$. The object of the present note is to supplement these papers by extending their application to such molecules as ICl, and by revising two or three doubtful or erroneous statements made in them.

INTERPRETATION OF ICl BANDS

In molecules like ICl, relations between molecular and atomic electron states somewhat different from those in I_2 or Cl_2 are to be expected. This is obvious from the fact that we have four combinations $I({}^2P_{1/2}) + Cl({}^2P_{1/2})$, $I({}^2P_{3/2}) + Cl({}^2P_{1/2})$, $I({}^2P_{3/2}) + Cl({}^2P_{3/2})$, and $I({}^2P_{1/2}) + Cl({}^2P_{3/2})$, where with I_2 we have only three. Besides, it can hardly be taken for granted that the electronic states of the molecule ICl should show any close analogy to those of I_2 or Cl_2 . Nevertheless, experience with other molecules shows that such an analogy may be expected (cf. analogies of SO to S_2 and O_2 , CS and SiO to CO, AlO to BO, etc.).

A clearer understanding can be obtained by attempting to assign electron configurations. It has been assumed² that the normal and excited states of the visible absorption bands of chlorine are . . . $4d\sigma^2 3p\pi^4 4d\pi^4$, ${}^1\Sigma^+_g$ and . . . $4d\sigma^2 3p\pi^4 4d\pi^3 5f\sigma$, ${}^3\Pi_u$ (inverted) and that the corresponding states of I_2 are . . . $6d\sigma^2 5p\pi^4 6d\pi^4$, ${}^1\Sigma^+_g$ and . . . $6d\sigma^2 5p\pi^4 6d\pi^3 7f\sigma$, ${}^3\Pi_u$. It seems likely that the normal and excited states of the visible ICl bands have exactly the same configurations of outer electrons as I_2 , the outer Cl electrons being promoted to equality with those of the I atom. Such a promotion appears necessary, since all the orbits which the outer electrons would occupy in Cl_2 are already filled in the I atom of ICl. This argument then supports the analogy already men-

¹ R. S. Mulliken, Phys. Rev. 36, 699 (1930).² R. S. Mulliken, Phys. Rev. 36, 1440 (1930).

tioned. The $^3\Pi$ excited state of ICl, like those of the other halogens, should in view of its electron configuration be *inverted*. The triplet width should probably be about the same as in the $^3\Pi$ of Br₂, for which 2400 cm⁻¹ seems a reasonable estimate.

It has been shown¹ that in I₂ the upper state of the visible bands is probably a 0^+_u state and that on theoretical grounds such a state cannot possibly be derived from $I(^2P_{1/2}) + I(^2P_{1/2})$ or $^2P_{1/2} + ^2P_{1/2}$, but that it can be derived from $^2P_{1/2} + ^2P_{3/2}$, as is observed. It was also shown to be likely that this 0^+_u belongs to a $^3\Pi$ state (mentioned in the preceding paragraph) of which the 0^-_u , 1_u , and 2_u components theoretically can and probably do dissociate into unexcited atoms. In the case of ICl, however, because of the absence of the property indicated by *g* or *u*, there is no theoretical reason why the 0^+ component of a $^3\Pi$ state analogous to that of I₂ should not dissociate, like the 0^- , 1 , and 2 components, into normal atoms. In fact the theory makes this probable,—although it does not require it.

For according to the rules giving the relations between case *c* molecular and atomic states,² we may expect the following correlations: case *c* states 3 , 0^+ , 0^- , 2 , 1 , 2 , 1 , 1 , 0^+ , 0^- from $I(^2P_{1/2}) + Cl(^2P_{1/2})$; 2 , 1 , 1 , 0^+ , 0^- from $I(^2P_{1/2}) + Cl(^2P_{3/2})$ and a similar set from $I(^2P_{3/2}) + Cl(^2P_{1/2})$; 1 , 0^+ , 0^- from $I(^2P_{3/2}) + Cl(^2P_{3/2})$. These are the same sets of states that one gets from $2I(^2P_{1/2})$; $I(^2P_{1/2}) + I(^2P_{3/2})$; and $2I(^2P_{3/2})$, respectively, except for the fact that no indices *g* or *u* are assigned here. It will be seen that all the case *c* states 2 , 1 , 0^+ , and 0^- necessary to give a $^3\Pi$ state in case *a* can be obtained from two normal atoms I + Cl. Now there has been a good deal of discussion as to whether the upper state of the visible ICl bands gives two normal atoms on dissociation or whether it gives an excited chlorine atom.³ The experimental evidence³ strongly favors the latter alternative, which is here seen to be in harmony with theory. (It also negatives the possibility that an excited iodine atom is formed on dissociation.)

Assuming that the ordinary visible ICl bands give two normal atoms on dissociation, the question may still be raised as to whether their upper level is really the 0^+ component of a $^3\Pi_0$ as in I₂. First it should be noted that, if 0^+ is stable, it should be accompanied by 0^- , forming a complete $^3\Pi_0$, since if 0^+ dissociates into normal atoms, the corresponding 0^- almost certainly does too. Next comes the question whether this $^3\Pi_0$ should be a stable molecular state. If one examines Fig. 2 of Ref. 2, it will be seen that the fact that 0^+_u of I₂ is a reasonably stable molecular state (dissociation energy 0.55 volts) is due largely to the fact that it gives an excited atom on dissociation. Fig. 2 indicates that the 0^- and even the $^3\Pi_1$ and $^3\Pi_2$ components of the $^3\Pi_u$ should be much less stable in I₂ than the 0^+ , or perhaps not be real molecular states at all. In view of these relations, one may question whether the $^3\Pi_0$ state of ICl should be stable, since it dissociates giving normal atoms. It therefore seems worth while,—although of course the quantitative relations may be considerably different than in Cl₂, Br₂, and I₂,—to consider the possibility that the upper level of the ICl bands may be $^3\Pi_1$ or even $^3\Pi_2$, and that the $^3\Pi_0$ state gives rise only to a continuum. [It is, however, also theoretically possible, although im-

probable, that both components of the ${}^3\Pi_0$ state might give excited atoms on dissociation, so that ${}^3\Pi_0$ would be a higher but stable state.] A possible indication that the upper level of the ICl bands is not ${}^3\Pi_0$ as in the other halogens is the fact that its energy (1.69 volts above the ground state)³ is lower than that of any of the other halogens, while its dissociation energy (0.47 volts³) is nearly as large as that of I_2 . If, however, it should turn out after all to be ${}^3\Pi_0$, then one should probably find at longer wave-lengths other bands leading to ${}^3\Pi_1$ and perhaps also to ${}^3\Pi_2$.

ADDITIONS AND CORRECTIONS TO PREVIOUS PAPERS

Possibility that the upper level of the halogen bands is ${}^3\Sigma$. A possible interpretation of the visible halogen bands which was not entirely disposed of in Refs. 1 and 2 was that they belong to a ${}^3\Sigma^+_u$ (case b), ${}^1\Sigma^+_g$ transition with $\Delta K = \pm 1$ in which only those combinations having $\Delta J = \Delta K = \pm 1$ are observed, the other possible combinations $\Delta J = 0$ being for some unknown reason very weak. This reason might possibly be found in the intersystem character of ${}^3\Sigma \leftarrow {}^1\Sigma$, for whose intensity relations we have no reliable guiding theory. [But as was mentioned in Ref. 1 (p. 701), we know that in the ${}^1\Sigma \leftarrow {}^3\Sigma$ atmospheric oxygen bands, the transitions with $\Delta J = 0$ are as strong as those with $\Delta J = \pm 1$, and there seems no reason why the same should not be true here. Nevertheless since it is likely^{4,5} that the atmospheric bands are ${}^1\Sigma^+_g \leftarrow {}^3\Sigma^-_g$, the argument may not hold, since this is a quadrupole transition.] A rather strong argument is that there is no theoretical necessity here for a ${}^3\Sigma^+_u$ state (which becomes 0^-_u plus 1_u in case c) to give ${}^2P_{1/2} + {}^2P_{1/2}$ on dissociation, as the upper levels of the halogen bands are empirically known to do, whereas in the case of a 0^+_u state such a necessity does exist. [There is, to be sure, no theoretical proof that such a ${}^3\Sigma^+_u$ state could *not* give ${}^2P_{1/2} + {}^2P_{1/2}$ here, although the theory strongly favors ${}^2P_{1/2} + {}^2P_{1/2}$ as dissociation products.²] A consideration of electron configurations also strongly favors a 0^+_u state (belonging to a ${}^3\Pi_0$) as against a ${}^3\Sigma^+_u$ state.²

Granting that the upper level of the halogen bands is 0^+_u , this might still conceivably be a 0^+_u which, together with a 1_u , would go over for small r into a case b ${}^3\Sigma^-_u$ state.² But a consideration of possible electron configurations makes this very improbable; at least two excited electrons would be required. Everything considered, it seems very probable that the identification of the upper state of the halogen bands as a 0^+_u belonging to a ${}^3\Pi_0$ is correct.

Magnetic behavior of iodine bands. In Ref. 1 the fact that a ${}^3\Pi_0$ molecular gas should be paramagnetic was taken as an explanation of the Faraday effect

⁴ R. S. Mulliken, Phys. Rev. **32**, 880 (1928).

⁵ R. S. Mulliken, Phys. Rev. 1931 (Abstract, Washington Meeting, Spring, 1931). Recent work of Childs and Mecke (Zeits. f. Physik **68**, 344, 1931) gives extremely low absorption coefficients in the atmospheric bands, and so favors ${}^1\Sigma^+_g$ rather than the possible alternative ${}^1\Sigma^-_u$ as the upper state of these bands.

observed in the iodine bands. Unfortunately, however, the fact was overlooked that the observed Faraday effect indicates that the normal state of iodine ($^1\Sigma_g^+$) is magnetically rather more sensitive than the upper (0^+_u) state.⁶ The fact was also overlooked that, although a $^3\Pi_0$ molecular gas should be paramagnetic (less so, however, if the $^3\Pi_0$ is widely split into 0^+ and 0^-), this does not imply a first-order Zeeman effect. In fact, the 0^+ and 0^- states belonging to a $^3\Pi_0$ state should behave, if well-separated, very much like $^1\Sigma$ states in respect to the Zeeman or Faraday effect; but if the separation of the 0^+ and 0^- states should be small and if, as is the case for low K values in I_2 , the separations of the rotational levels should be less than the spacing of the components of a normal Zeeman triplet, a magnetic field should produce a Paschen-Back effect in the $^3\Pi_0$ levels.⁷

But unless there is an error in Kemble's conclusion that the normal more than the excited state is responsible for the observed Faraday effect, we should probably return to Kemble's explanation⁶ of this effect in the iodine bands, namely, that it is caused by the development of a small magnetic moment through the rotation of the molecule. Its existence would then really give no evidence either for or against the $^3\Pi_0$ nature of the upper electron level in the iodine bands. Nevertheless a renewed investigation of the matter would be of interest.

The quenching of the fluorescence of the iodine bands in a magnetic field, emphasized in Ref. 1, seems to indicate a special sensitiveness of the upper level to magnetic fields. The most promising suggestion as to the cause of the magnetic quenching of fluorescence seems to be Turner's idea⁸ that it is due to a magnetically induced predissociation.

Indeed Van Vleck has now found, in a paper soon to be published, that a magnetic field may be expected to induce predissociation in the 0^+ state belonging to a $^3\Pi_0$ when the 0^+ and 0^- components dissociate as shown in Fig. 2 of Ref. 2. Thus the existence of magnetic quenching gives strong evidence in favor of the designation $0^+_u(^3\Pi_0)$.

PICTORIAL REPRESENTATIONS OF THE ELECTRON CLOUD FOR HYDROGEN-LIKE ATOMS

By H. E. WHITE

UNIVERSITY OF CALIFORNIA, BERKELEY

(Received April 21, 1931)

ABSTRACT

It is well known that the solutions of the wave-equation for hydrogen-like atoms may be represented graphically by interpreting $\Psi\Psi^*$ as a *probability density*. The *probability density factors* $\Phi_m\Phi_m^* \cdot [\Theta_{m,l}]^2 \cdot [R_{n,l}]^2 = \Psi\Psi^*$ are represented graphically and briefly discussed and compared with the electron orbits of four classical models. Graphs for *s*, *p*, *d*, *f*, *g*, and *h* electrons are given. An attempt to combine the *probability density factors* and form some graphical representation of $\Psi\Psi^*$ has resulted in the construction of a mechanical device or model, see Fig. 5, which when photographed, gives very closely the desired result. Photographs for the magnetic states $m=0, \pm 1, \pm 2, \pm 3, \dots$ are given for 1*s*, 2*p*, 3*d*, 4*f*, 2*s*, 3*p*, 4*d*, 5*f*, 3*s*, 4*p*, and 5*d* electrons, see Fig. 6.

WITH all of the successes of the quantum mechanics one still hears on every hand, for want of an atomic model, the terms *electron orbits*, *penetrating orbits*, *non-penetrating orbits*, etc. This is of course due to the fact that in many cases one may think in terms of the simpler electron orbits and be led to a result which is the same or very nearly the same as that given by the quantum mechanics. In going over some of the correlations very often made between the two theories several interesting graphical comparisons have been forthcoming.

It is well known that for a non-relativistic, conservative dynamical system of one nucleus and one electron (that is a hydrogen-like atom) Schroedinger's wave-equation

$$\Delta^2\Psi + \frac{8\pi^2\mu}{h^2}(W - V)\Psi = 0 \quad (1)$$

expressed in polar coordinates ϕ , θ , and r , see Fig. 1 may be solved by replacing Ψ by the product of a function of ϕ alone, another of θ alone, and another of r alone,

$$\Psi = \Phi_m \cdot \Theta_{m,l} \cdot R_{n,l}. \quad (2)$$

With this substitution the equation is separated into three total differential equations the well-known solutions of which are,

$$\Phi_m = (2\pi)^{-1/2} e^{im\phi}, \quad m = 0, \pm 1, \pm 2, \pm 3, \dots \pm l \quad (3)$$

$$\Theta_{m,l} = \left(\frac{(2l+1)(l-m)!}{2(l+m)!} \right)^{1/2} \sin^m \theta \cdot P_l^m(\cos \theta), \quad l = 0, 1, 2, 3, \dots (n-1) \quad (4)$$

$$R_{n,l} = \left[\frac{4(n-l-1)!Z^3}{[(n+l)!]^3 n^4 a_1^3} \right]^{1/2} \left(\frac{2Zr}{na_1} \right)^l e^{-Zr/na_1} L_{n-l}^{2l+1} \left(\frac{2Zr}{na_1} \right), \quad n = 1, 2, 3, \dots \quad (5)$$

involving in addition to the *normalizing factors*, the complex exponentials $e^{im\phi}$, the "*associated Legendre polynomials*," and derivatives of the "*Laguerre polynomials*," where m , l , and n , are to be associated with the *magnetic*, *azimuthal*, and *total quantum numbers* respectively. It is also well known that $\Psi\Psi^*dv$, which is interpreted as the *probability* of the electrons being found in a given element of volume dv is very small outside the region occupied by the corresponding classical electron orbits.

For descriptive purposes it has been convenient to think of the *probability density* $\Psi\Psi^* = P$ in terms of the angles ϕ and θ and of the distance r independently. From Eqs. (2), (3), (4), and (5) the *probability density*

$$\Psi\Psi^* = \Phi_m\Phi_m^* \cdot [\Theta_{m,l}]^2 \cdot [R_{n,l}]^2. \quad (6)$$

Fig. 1.

There are in general four classical models to be compared with these *probability density factors*. These four well-known models, which will here be called (a), (b), (c), and (d), have the same *total quantum number* n , and *azimuthal quantum numbers* as follows; (a) l (b) $[l(l+1)]^{1/2}$ (c) $l + \frac{1}{2}$, (d) $l + 1 = k$. It should be pointed out that none of these classical orbital models is correct and that, for want of an atomic model, any one of them may, with certain limitations, be used. In general (a) and (b) serve as vector models while (c) and (d) serve well as orbital models.

The $\Phi_m\Phi_m^*$ factor. For given m , Φ_m times its complex conjugate Φ_m^* is a constant, so that for any given state the probability of an electrons being found in any small element of angle $d\phi_1$ is the same as for any other equal angle $d\phi_2$. For all allowed electron states the *probability density* is therefore symmetrical about the ϕ (magnetic) axis. $\Phi_m\Phi_m^*$ plotted as a function of the angle ϕ (0 to 2π) would graphically be represented in rectangular coordinates by a straight line or in angular coordinates by a circle.

The $[\Theta_{m,l}]^2$ factor. For given m and l values the polynomials of Eq. 4 and consequently $[\Theta_{m,l}]^2$ are readily calculated from well known recursion formulas.¹

Values of the *probability density factor* $[\Theta_{m,l}]^2$ are given in Table I and plotted in rectangular coordinates in Fig. 2.

Unsold² has shown that for given n and l , the *probability density* summed over the states $m = +l$ to $m = -l$ presents spherical symmetry about the nucleus. Since $\Phi_m \Phi_m^*$ is constant for any state one has simply to show that

$$\sum_{m=-l}^{m=+l} [\Theta_{m,l}]^2 = \text{constant}. \quad (7)$$

This well-known theorem is seen to be true from the last column of Table I or graphically from the curves of Fig. 2. For example, the sum of the three

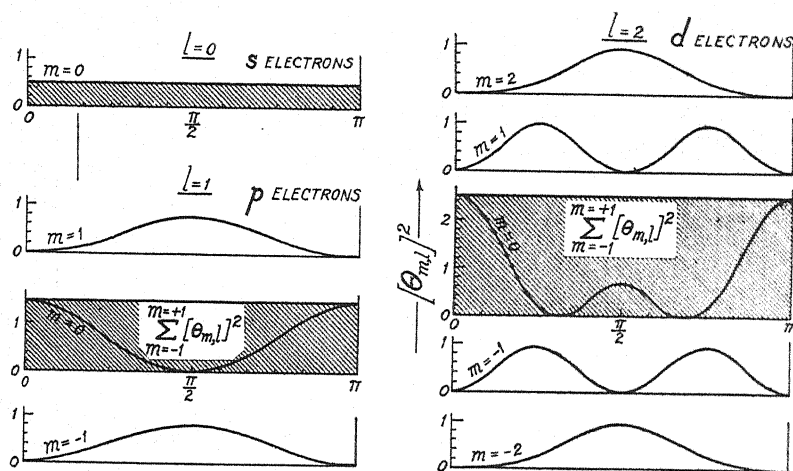

Fig. 2. The probability density factor $[\Theta_{m,l}]^2$ as a function of θ for s , p , and d electrons. The straight lines and the shaded areas represent spherical symmetry, the result of the summation of the curves from $m = +l$ to $m = -l$.

curves for the three p states $m = 1, 0, -1$ gives a straight line as indicated by The shaded area. Thus it is that in some of the complex spectra three similar p electrons five similar d electrons, or seven similar f electrons form spherical symmetry, that is an S term, as the most stable state.

If angular coordinates are used when plotting $[\Theta_{m,l}]^2$ a number of interesting correlations with the classical orbits may be made. Such curves are shown in Fig. 3 for s , p , d , f , g , and h electrons. Beneath each figure the corresponding classical orbit is given oriented in each case according to the vector model (a). In order to illustrate an orbit rather than its straight line projection the ϕ axis is tipped slightly out of the plane of the paper. It must be remembered that the electron is not confined to the shaded area in each

probability figure but that the magnitude of a line joining the center and any point on the curve is a measure of the electrons probability of being found in the direction of that line.

Since the plane in which each curve is drawn represents any plane through the ϕ axis symmetry of $\Phi_m \Phi_m^*$ is obtained by rotating each curve about the ϕ (or *magnetic*) axis. Corresponding to this axial symmetry there is the classical precession of each orbit around the ϕ axis producing a somewhat similar figure. For each $m=0$ curve the scale used is about $1/l+1$ times that of the other curves of the same l value.

For all $m=0$ states, excluding the spherically symmetrical s states, the *probability density* is greatest in the direction of the poles. With the exponent of $e^{im\phi}$ zero this distribution has been interpreted to mean³ that there is no motion in the ϕ coordinate and that correlated with this the motion of the electron (i.e. the orbital plane) is in some one meridian plane, all meridian planes being of equal probability. The end states $m = \pm l$ on the other hand take on their largest values in the direction of the equatorial plane. In this case one correlates the opposite signs in the exponents of $e^{\pm im\phi}$ with the opposite directions of rotation in the orbit. The way in which each classically oriented orbit follows the corresponding curves, from $m = +l$ to $m = -l$, especially for the states of higher l value, is quite remarkable. It should be mentioned that if the classical orbits are oriented according to models (b), (c), or (d) that their general agreement with the probability curves is not as good as with model (a), however, this may be a matter of personal opinion.

The $[R_{n,l}]^2$ factor. The factor $[R_{n,l}]^2$ which gives the *probability density* as a function of r alone has been discussed in detail by many investigators. For given values of n and l the Laguerre polynomials and hence $R_{n,l}$ (see Eq. (5)) and $[R_{n,l}]^2$ may be evaluated.¹ Plotting $[R_{n,l}]^2$ against r in units of the radius of the first Bohr circular orbit $a^1 = 0.528$ AU. give the heavy line curves of Fig. 4. Multiplying $[R_{n,l}]^2$ by $4\pi r^2$, the area of a sphere of radius r , one obtains the so called *probability density distribution* curves, D , indicated by the shaded areas in the figure. The classical orbits corresponding to each of these

³ See, Condon and Morse, "Quantum Mechanics."

curves, using model (c), are also shown. In each curve the *density distribution* differs greatly from zero only within the electron-nuclear distance of the corresponding classical orbits.

A more satisfactory correlation has been made by Pauling⁴ by comparing the average value of r as calculated on both theories. The method of evaluating r from the quantum mechanics has been given by Waller⁵ and is identical with the value obtained for the classical orbits if the *azimuthal quantum number* is taken to be $[l(l+1)]^{1/2}$, model (b). This average value of r is indicated in

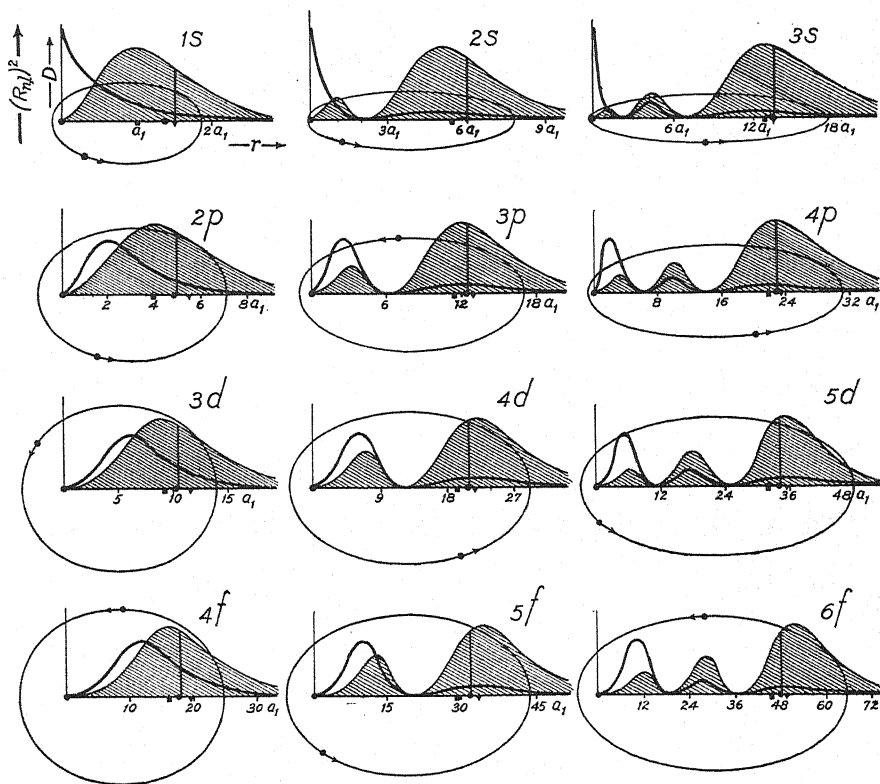

Fig. 4. The probability density factor $(R_{n,l})^2$ plotted as a function of the electron-nucleus distance r (r is measured in units of the first Bohr circular orbit). The density distribution curves $D = 4\pi r^2 \cdot (R_{n,l})^2$ the shaded areas, are to be compared with the electron-nucleus distance for the classical orbits, where the azimuthal quantum number is taken to be $l + \frac{1}{2}$.

each curve by a vertical line. The average value of r calculated for models (a), (c), and (d) are indicated on the r axis by triangular, circular, and square dots respectively.

For this radial comparison model (b) is to be preferred, however, a difficulty arises for the s states where the orbits reduce to straight lines with one

⁴ Pauling, Proc. Roy. Soc. 114, 181 (1927).

⁵ Waller, Zeits. f. Physik 38, 635 (1926).

end at the nucleus center. With model (c), the orbits shown in the figure, this difficulty does not arise and the agreement is practically the same.

THE PROBABILITY DENSITY $\Psi\Psi^*$

Attempts to bring together the *probability density factors* $\Phi_m\Phi_m^*$, $[\Theta_{m,l}]^2$, and $[R_{n,l}]^2$ into one single picture for $\Psi\Psi^*$, if we may call it a picture, have been somewhat successful. Langer and Walker⁶ using a method which is as yet unpublished, have produced *probability density* photographs which represent the spherically symmetrical *s* states and the *2p* states $m = +1$ and 0.

Preliminary attempts to produce a three dimensional model which will represent as closely as possible the *probability density* $\Psi\Psi^*$ has resulted in a mechanical device shown in Fig. 5. Spindles like the one shown in the center

Fig. 5. A mechanical device which when set in motion and photographed represents the electron cloud for the various states of the hydrogen-like atoms. The model shown in the figure is for a *3d* electron.

of the figure and in the last photograph of Fig. 6 are turned out on a lathe so that in projection they give the *density distribution* *D* curves of Fig. 4. Such a spindle is pivoted at its center by a small pin at *C*, and set in rotation about the vertical axis by means of a motor *M*. This motion gives the required symmetry about ϕ . At the same time that rotation about the ϕ axis is taking place, the angle θ is changed slowly from $\theta = 0$ to $\theta = \pi/2$ by means of a swivel *S* and a double cord *SHR* which passes through a hole in the table top to a roller *R*, the motion of which is confined to the slot as shown. Curves of thin wood, e.g. *A* in Fig. 5, are cut so that when they are moved slowly but with uniform speed along the table top in the direction indicated by the arrow the angular

⁶ See, "Atoms Molecules and Quanta," by Ruark and Urey, p. 565. Also Slater, Phys. Rev. 37, 482 (1931).

Fig. 6. Photographs of the electron cloud for various states of the hydrogen-like atoms as obtained from various models and the device shown in Fig. 5. The probability density $\Psi\Psi^*$ is symmetrical about the ϕ or magnetic axis which is vertical. The scale for each figure may be obtained from Fig. 4.

velocity $d\theta/dt$ is changed in the proper manner to give, as nearly as possible, the correct density when photographed. A time exposure started when $\theta=0$ and stopped when $\theta=\pi/2$ for the model shown yields the figure for the $3d$ state $m=0$. In constructing the various curves to be used at A , the changing angle of the cord IIR was taken into account and also the fact that as θ increases each point on the spindle moves in larger and larger circles and therefore faster. A small slot milled in the lower half of each spindle allows the angle $\theta=0$ to be reached. In projection each spindle should represent the *density distribution* curves, D of Fig. 5, in order that when rotating simultaneously about the ϕ and θ axes they give at each point in space the *density* $[R_{n,l}]^2$ curves of Fig. 5. It should be pointed out that there is a small amount of distortion due to the end on view of the spindle. This distortion is quite negligible, however, in that in this position the rapid motion as seen from the camera effects the photographic plates but little. Photographs for the states with negative m values are identical with those of positive m values. It may be seen by an examination of the figures that the addition of the $2p$ states $m=1, 0, -1$ or the sum of the $3d$ states $m=2, 1, 0, -1, -2$ will give spherical symmetry a figure like that of a $1s$ electron. Again the summation of the $4d$ states $m=2, 1, 0, -1, -2$ will give spherical symmetry resembling the $2s$ state. This may be considered as somewhat of a check on the figures in general and is quite as good as can be expected both from the standpoint of photographic reproduction of densities and the mechanical difficulties in the model.

The s states in Fig. 6 were made in a much simpler manner than the others and represent cross-sections only. Curves cut from white paper glued to the face of a blackened disk, and set rotating give the figures shown. Cross-section photographs have also been made for the nodal states by changing θ alone, ϕ remaining fixed. While these photographs are in general better, the more complete three dimensional reproductions are given in Fig. 6. The author wishes to take this opportunity to thank Professor Oppenheimer for his criticism of this paper.

NOTE ON THE CALCULATION OF VAN DER WAALS FORCES¹

BY HENRY MARGENAU

SLOANE PHYSICS LABORATORY, YALE UNIVERSITY

(Received April 28, 1931)

ABSTRACT

The general expression for the van der Waals energy arising from dipole interaction between atoms involves a summation over transition probabilities. These are in most cases difficult to calculate. It is here pointed out that since these transition probabilities obey the sum rule of Thomas and Kuhn, they may be evaluated in a manner which permits van der Waals' forces to be calculated with good approximation, provided that the polarizability is known. The method is outlined and illustrated by application to two examples: Na and He. The result in the case of He is in very good agreement with that obtained by the variational method.

THE methods proposed so far for a calculation of intermolecular forces depend on an (exact or approximate) knowledge either of the molecular wave functions² or of the oscillator strengths (dispersion f -values) associated with transitions from the ground state of the molecules in question.³ Occasionally, useful approximations were obtained in terms of polarizabilities and other known characteristics. In this note we wish to suggest a method, semi-empirical in character and not involving the use of wave functions, which in general, enables a calculation of van der Waals forces between atoms with greater accuracy than others of equal simplicity permit. It consists in expressing the perturbational energy of the second order as a sum over f -values, as was first done by London, and then determining these f -values by means of the sum rule of Thomas and Kuhn, and the relative intensities of spectral lines.

Suppose that the two interacting atoms, A_1 and A_2 , are similar and a distance R apart, R being so large that electron interchange does not take place. Let both A_1 and A_2 be in their lowest energy state which we take to be spherically symmetrical (s -state). α and β denumerate the various excited states of A_1 and A_2 respectively. If we restrict our consideration to the effects of the classical dipole interaction

$$V = \frac{e^2}{R^3}(y_1y_2 + z_1z_2 - 2x_1x_2) \quad (1)$$

¹ Part of the considerations here presented have been reported at the meeting of the Amer. Phys. Soc., Feb. 26-28. Hitherto we did not feel that they were of sufficient interest to be published more fully. Recently, however, Slater and Kirkwood (see ref. 2) have calculated a value for the attractive forces between He atoms differing widely from London's result. They attribute this discrepancy to the neglect of double electron jumps in London's theory. Aside from being applicable to many cases not of immediate interest at present, the method here outlined shows the correctness of the latter supposition.

² Eisenschitz and London, *Zeits. f. Physik* 60, 491 (1930); Slater and Kirkwood, *Phys. Rev.* 37, 682 (1931); Hassé, *Proc. Camb. Phil. Soc.* 27, 66 (1931).

³ F. London, *Zeits. f. phys. Chemie*, B, 11, 222 (1930).

which is proper for large separations only, the second order perturbation energy of $A_1 + A_2$ becomes

$$\Delta_2 E = - \sum'_{\alpha\beta} \frac{|V_{11,\alpha\beta}|^2}{E_\alpha + E_\beta - 2E_1}, \quad (2)$$

where

$$|V_{11,\alpha\beta}|^2 = \frac{e^4}{R^6} (y_{1\alpha}^2 y_{1\beta}^2 + z_{1\alpha}^2 z_{1\beta}^2 + 4x_{1\alpha}^2 x_{1\beta}^2 + 2y_{1\alpha} z_{1\alpha} y_{1\beta} z_{1\beta} - 4x_{1\alpha} y_{1\alpha} x_{1\beta} y_{1\beta} - 4x_{1\alpha} z_{1\alpha} x_{1\beta} z_{1\beta}) \quad (3)$$

$q_{1\alpha}$ is the coordinate matrix associated with a transition of A from the lowest state (1) to the state α , e.g. $x_{1\alpha} = \int R_{10}(r) x R_{n1}(r) P_l^m e^{im\phi} r^2 \sin \theta dr d\theta d\phi$; n, l , and m being the quantum numbers with their usual significance. (We are writing R_{10} for the radial function of the lowest state without meaning to imply that $n=1$ for this state.) It follows directly that

$$\sum_m x_{1\alpha} y_{1\alpha} = \sum_m x_{1\alpha} z_{1\alpha} = \sum_m y_{1\alpha} z_{1\alpha} = 0,$$

and that

$$\sum_m x_{1\alpha}^2 = \sum_m y_{1\alpha}^2 = \sum_m z_{1\alpha}^2 = \frac{1}{3} \delta_1 l_{1\alpha}^2.$$

Hence in summing (3) over the magnetic quantum numbers of both A_1 and A_2 we obtain $\frac{2}{3} \delta_1 l_{1\alpha} l_{1\beta} e^4 / R^6 r_{1\alpha}^2 r_{1\beta}^2$ so that (2) becomes

$$\Delta_2 E = - \frac{2}{3} \frac{e^4}{R^6} \sum'_{\alpha\beta} \frac{r_{1\alpha}^2 r_{1\beta}^2}{E_\alpha + E_\beta - 2E_1}, \quad (4)$$

where now the summation is no longer over magnetic quantum numbers and includes only states connected with the ground state by dipole radiation ($l_\alpha = l_\beta = 1$). But $r_{1\alpha}$ is related to the f -values appearing in the dispersion formula

$$n^2 - 1 = \frac{e^2 N}{\pi m} \sum_\alpha \frac{f_{1\alpha}}{\nu_\alpha^2 - \nu^2}$$

by the relation

$$r_{1\alpha}^2 = \frac{3}{2m} \left(\frac{h}{2\pi} \right)^2 \frac{f_{1\alpha}}{E_\alpha - E_1}. \quad (5)$$

Substituting this in (4) there results a formula meanwhile already obtained by London and used by him to compute intermolecular forces by means of a knowledge of a limited number of empirical f -values. We wish to propose a scheme permitting the f -values to be determined independently of spectroscopic dispersion formulae, which necessarily emphasize unduly the f 's in the vicinity of the spectral region for which the formulae were calculated.

Combining (5) and (4) and realizing that $\Sigma'_{\alpha\beta}$ includes an integration over the continuous region of the spectrum we may write

$$\Delta_2 E = -F \left\{ \sum_{\alpha\beta}' \frac{f_{1\alpha} f_{1\beta}}{v_\alpha v_\beta (v_\alpha + v_\beta)} + 2 \sum_{\alpha}' \int_0^\infty \frac{f_{1\alpha} (df_{1\alpha}/dE) dE}{v_\alpha (1+E)(v_\alpha + 1+E)} \right. \\ \left. + \int_0^\infty \int_0^\infty \frac{(df_{1E'}/dE')(df_{1E''}/dE'') dE' dE''}{(1+E')(1+E'')(2+E'+E'')} \right\}. \quad (6)$$

We are here using the abbreviations:

$$\epsilon_\alpha = -E_\alpha; v_\alpha = 1 - \frac{\epsilon_\alpha}{\epsilon_1}; F = \frac{1}{R^6} \frac{3}{2m^2 \epsilon_1^3} \left(\frac{he}{2\pi} \right)^4$$

E is the energy of any state beyond the series limit, measured in units equal to the energy of the series limit, ϵ_1 . (6) does not take explicit account of possible multiple electron transitions to discrete states beyond the series limit, the energy of which is frequently not known. They may be considered included in the integration, however, since the f -values will be adjusted in such a manner that their sum obeys the theorem of Kuhn and Reiche,⁴ which postulates:

$$\sum_{\alpha}' f_{1\alpha} + \int_0^\infty \frac{df_{1E}}{dE} dE = Z_0 \quad (7)$$

Z_0 being the number of dispersion electrons.

It becomes necessary to make some assumption about the distribution of the f_{1E} 's. Fortunately, the calculation of $\Delta_2 E$ is not very sensitive to this choice, provided that (7) is satisfied. We shall suppose, in conformity with what is known about H and x-ray spectra, that

$$\frac{df_{1E}}{dE} = \frac{\gamma}{(1+E)^3}, \quad (8)$$

γ being at present undetermined. Moreover, we shall consider that the relative intensities of the first few emission lines of the principal series are known. The accuracy of the calculation is not seriously impaired if this is not the case. Suppose these relative intensities to be J_α . Then one may easily verify that

$$f_{1\alpha} = \frac{\beta J_\alpha}{v_\alpha^3} \equiv \beta \phi_\alpha, \quad (9)$$

since $J_\alpha = \text{const.} (E_\alpha - E_1)^4 r_{1\alpha}^2$. β is another undetermined constant. To determine β and γ we have first (7), which may be written on account of (8) and (9):

$$\beta \sum_{\alpha}' \phi_\alpha + \frac{\gamma}{2} = Z_0 \quad (10)$$

and second the expression for the polarizability in a static field:

⁴ For complex structures, this sum rule is merely an approximation.

$$\alpha = \frac{1}{m} \left(\frac{eh}{2\pi} \right)^2 \sum_{\alpha}' \frac{f_{1\alpha}}{(E_{\alpha} - E_1)^2},$$

or, explicitly,

$$\alpha = \frac{1}{m\epsilon_1^2} \left(\frac{eh}{2\pi} \right)^2 \left\{ \sum_{\alpha}' \frac{f_{1\alpha}}{v_{\alpha}^2} + \int_0^{\infty} \frac{(df_{1E}/dE)dE}{(1+E)^2} \right\} \quad (11a)$$

whence

$$\beta \sum_{\alpha}' \frac{\phi_{\alpha}}{v_{\alpha}^2} + \frac{\gamma}{4} = m\epsilon_1^2 \left(\frac{2\pi}{eh} \right)^2 \alpha. \quad (11)$$

(10) and (11) supply the required numerical values of β and γ . If line intensities are not known, we may put the first $\phi = 1$ and all others equal to 0. The evaluation of (6) is now an easy matter.

In cases where $Z_0 = 1$ (no multiple jumps) the contribution of the region beyond the series limit is usually small. It may then be advisable to write (6)

$$\begin{aligned} \Delta_1 E = & -\frac{F}{2} \left\{ \sum_{\alpha\beta}' (1 + P_{\alpha\beta}) f_{1\alpha} f_{1\beta} + 2 \sum_{\alpha}' \int_0^{\infty} (1 + P_{\alpha E}) f_{1\alpha} \frac{df_{1E}}{dE} dE \right. \\ & \left. + \int_0^{\infty} \int_0^{\infty} (1 + P_{E'E''}) \frac{df_{1E'}}{dE'} \frac{df_{1E''}}{dE''} dE' dE'' \right\}, \end{aligned}$$

with the abbreviations

$$P_{\lambda\mu} = \frac{1 - v_{\lambda}v_{\mu}(v_{\lambda} + v_{\mu})/2}{v_{\lambda}v_{\mu}(v_{\lambda} + v_{\mu})/2},$$

v_E being $1+E$.

Using (7), this goes over into

$$\begin{aligned} \Delta_2 E = & -\frac{F}{2} \left\{ Z_0^2 + \sum_{\alpha\beta}' P_{\alpha\beta} f_{1\alpha} f_{1\beta} + 2 \sum_{\alpha}' P_{\alpha E} f_{1\alpha} \frac{df_{1E}}{dE} dE \right. \\ & \left. + \int_0^{\infty} \int_0^{\infty} P_{E'E''} \frac{df_{1E'}}{dE'} \frac{df_{1E''}}{dE''} dE' dE'' \right\}. \quad (12) \end{aligned}$$

Recalling the definition of the v 's we see that in some cases where the energy of all excited states is small compared with that of the lowest state they do not differ greatly from 1, which makes the P 's small. Then one may expect to attain a fair approximation to the polarization forces by retaining in the $\{$ of (12) only the term Z_0^2 . For hydrogen, the last 3 terms contribute about 8 percent of the total. If we make use of (8), (9), (10), and (11) expression (12) becomes:

$$\Delta_2 E = -\frac{F}{2} \left\{ Z_0^2 + \beta^2 \sum_{\alpha\beta}' P_{\alpha\beta} \phi_{\alpha} \phi_{\beta} + \beta\gamma \sum_{\alpha}' R_{\alpha} \phi_{\alpha} - 10.170\gamma^2 \right\}, \quad (13)$$

where

$$R_\alpha = \frac{4}{v_\alpha^2} \left[\frac{1}{3} - \frac{1}{2v_\alpha} + \frac{1}{v_\alpha^2} - \frac{1}{v_\alpha^3} \log(1 + v_\alpha) \right] - 1.$$

For hydrogen, this expression gives $\Delta_2 E$ to within 1 percent if only 4ϕ 's are used.

As an illustration, let us compute the polarization energy of two Na-atoms by the method here outlined. α can here be calculated since the f -values happen to be known.⁵ They will also afford a check on our β and γ . α turns out to be 24.2×10^{-24} . (We omit the details of the calculation, which is made with the aid of Eq. (11.) We shall use only ϕ_2 , corresponding to the resonance transition, and put it equal to 1. v_2 is then 0.409; $\epsilon_1 = 8.145 \times 10^{-12}$ ergs. Eqs. (10) and (11) give

$$\beta + \frac{\gamma}{2} = 1; \quad \frac{\beta}{0.409^2} + \frac{\gamma}{4} = 5.88,$$

so that $\beta = 0.888$ and $\gamma = 0.224$. From (13) one then obtains

$$\Delta_2 E = \frac{12.5}{R^6} \times 10^{-58} \text{ ergs} = \frac{790}{r^6} \text{ volts},$$

if r is measured in \AA . The correct value, which may be calculated from Sugiura's work, is

$$\Delta_2 E = \frac{14.5}{R^6} \times 10^{-58} \text{ ergs}.$$

It may be approximated as closely as desired, of course, by taking a greater number of ϕ 's into account. We note in passing that these results suggest the existence of very strong polarization forces and the formation of polarization molecules, such as were observed in K_2 by Kuhn.⁶

Another more interesting application is to He, where our calculations can be no longer controlled by a sufficiently accurate knowledge of the f -values. There exist intensity measurements on the emission lines of the "principal" series⁷ from which the ϕ_α 's may be obtained by (9). We have considered 10 of them, but it turns out that very few of them would have been sufficient, because the main contribution to the f 's seems to come from the region beyond the series limit. Taking α as 0.206×10^{-24} , Eqs. (10) and (11) become

$$\beta \sum_{\alpha} \phi_{\alpha} + \frac{1}{2} \gamma = 2$$

$$\beta \sum_{\alpha} \frac{\phi_{\alpha}}{v_{\alpha}^2} + \frac{1}{4} \gamma = 1.122.$$

If now we use the relative intensity data in Hopfield's arbitrary units $\Sigma_{\alpha} \phi_{\alpha} =$

⁵ Y. Sugiura, *Phil. Mag.* **4**, 495 (1927).

⁶ Kuhn, *Naturwissenschaften* **18**, 332 (1930). See also Oldenberg, *Zeits. f. Physik* **47**, 184 (1928) and **55**, 1 (1929).

⁷ Hopfield, *Astrophys. J.* **72**, 133 (1930).

293.7, and $\Sigma \phi_\alpha / v_\alpha^2 = 351.1$, whence $\beta = 5.97 \times 10^{-4}$ and $\gamma = 3.64$. The surprising magnitude of γ shows clearly, and probably over-emphasizes, the important rôle of the transitions to states beyond the ionization limit of one electron. That these states need not belong to the continuous spectrum, and that our integration (instead of summation) is dictated by convenience and lack of data to handle them more properly has already been pointed out. Substituting β and γ in (6), or more conveniently in (13) (where now, of course, on account of the size of γ only the second term in $\{ \}$ may be neglected) we find

$$\Delta_2 E = \frac{9.68}{R^6} \times 10^{-61} (1.49) \text{ ergs} = \frac{14.4}{R^6} \times 10^{-61} \text{ ergs} = \frac{0.91}{r^6} \text{ volts, if } r \text{ is in } \text{\AA}. \quad (14)$$

(The somewhat smaller value reported previously⁸ was obtained by considering only transitions of one electron, putting $Z_0 = 1$, which is not legitimate.) (14) agrees very well indeed with the result of Slater and Kirkwood, calculated with a variational method, namely

$$\Delta_2 E = \frac{14.9}{R^6} \times 10^{-61} \text{ ergs}.$$

The latter authors suggest that the large difference between their result and the one obtained by applying London's simple approximation, which yields an upper limit $\Delta_2 E_{\text{max}} = 12.4 \times 10^{-61}$ ergs, is occasioned by the neglect of double jumps in London's expression. The calculations presented here make this evident.

AN EXPERIMENTAL STUDY OF THE NATURAL WIDTHS OF THE X-RAY LINES IN THE *L*-SERIES SPECTRUM OF URANIUM

BY JOHN H. WILLIAMS

DEPARTMENT OF PHYSICS, UNIVERSITY OF CALIFORNIA

(Received April 21, 1931)

ABSTRACT

The half widths at half maximum of the rocking curves in parallel positions of the double x-ray spectrometer with calcite crystals reflecting in the first order have been investigated as a function of wave-length and this function is shown to be linear.

The rocking curves of U $L\alpha_1$ in three different antiparallel positions of the instrument give a natural width which is practically independent of the dispersion. The natural widths of U $L\alpha_1$ and U $L\beta_1$ have been observed as a function of voltage and no significant dependence was noted.

The half widths at half maximum of twelve lines in the uranium *L*-series spectrum were studied and the results are:

Line U <i>L</i>	α_1	α_2	β_1	β_2	β_3	β_4	β_5	β_6	γ_1	γ_2	γ_3	γ_4
$\Delta\lambda$ in X.U.	0.439	0.494	0.299	0.369	0.382	0.726	0.252	0.487	0.242	0.57	0.47	0.233
ΔV in volts	6.56	7.20	7.17	8.04	9.40	16.1	5.94	9.71	7.96	19.7	16.2	8.18

Possible correlations with the electron transitions are suggested and the predominance of nuclear effects are evident from the greater widths of lines involving the elliptical orbit L_1 .

The observed widths are compared to the classical and quantum theory widths and the size of the nucleus necessary to explain the discrepancy is given. The possibility of observing the splitting of the energy levels due to nuclear spin as suggested by Breit is rejected. The actual shape of the line U $L\alpha_1$ has been investigated and found to approximate that predicted by the classical theory.

THE natural widths of x-ray lines in the *K*-series of molybdenum have been measured by Ehrenberg and Mark,¹ Ehrenberg and von Susich,² Davis and Purks,³ Allison and Williams,⁴ and Mark and von Susich⁵ with the double x-ray spectrometer. Experiments on the relative widths of some x-ray lines in the *L*-series of lead and thallium have been carried out by Allison.⁶ This paper is a report of experiments performed on the natural widths of the x-ray lines in the *L*-series spectrum of uranium. The accurate measurement of a greater number of lines in the *L*-series offers an opportunity to study any dependence on the transitions involved.

APPARATUS

The double x-ray spectrometer used in these experiments has been previously described.⁷ The following changes have been made. The vertical slits, limiting the divergence of the beam in a plane perpendicular to the axes of rotation of crystals *A* and *B*, were 2 mm in width. The horizontal slits, limiting the divergence of the beam in a vertical plane including the axes of rotation, were of various widths which will be given later.

Fig. 1. Diagram of uranium target x-ray tube.

The x-ray tube used in these experiments is illustrated in Fig. 1. The tube was designed to give a large focal spot which would remain fixed on the target. These two properties of the tube are highly essential in the measurement of line widths as will be discussed later. The focal spot was at a distance of 50 cm from crystal *A*. The filament holder was designed from the type used by Professors Ross and Clark at Stanford University. It enabled the filament to be placed within one cm of the target and allowed the x-rays to be observed at an angle of 135° from the electron beam. The uranium was obtained from the Westinghouse Electric and Manufacturing Company. Many attempts were made to obtain good thermal contact between the uranium or some other metal but without success until finally the method used by S. K. Allison⁸ was adopted. A piece of uranium was hydraulically pressed below the surface of a large copper block and the edges of the copper were peened over while the uranium was under pressure. This served satisfactorily as a target up to a maximum power input of 0.4 kw. The tube was cooled by pumping cold kerosene through the hollow target holder.

The power for operating the tube was developed by a 5 kw. 550 cycle motor generator and the high potential supplied by a transformer was rectified by kenetrons and smoothed by condensers. The calculated voltage fluctuations were 0.6 percent at 48 kv and 6 milliamperes.

The calcite crystals used were those investigated in a previous experiment.⁴ These crystals were preserved in a dessicator over dehydrated calcium chloride and sodium hydroxide, and it has been found that they have deteriorated only very slightly in the course of a year.

⁷ Williams and Allison, J.O.S.A. and R.S.I. 18, 473 (1929). For a further description see reference 4.

OPERATION OF THE INSTRUMENT

The technique of measuring line widths has been previously developed. The degree of accuracy obtained with the double spectrometer can be seen by comparing the values of 0.144 and 0.163 X.U. for the half width at half maximum of $\text{MoK}\alpha_1$ obtained by Mark and von Susich⁵ and the value of 0.147 X.U. obtained by Allison and Williams.⁴ The method of operation used in these experiments was that previously described.⁴ The method of setting the crystal faces vertical was retained. Frequent readings of the temperature were taken while observations were being made and no significant changes were noted.

REDUCTION OF OBSERVED RESULTS

The majority of the results have been obtained in the (1,1) position following a notation given in a previous paper.⁹ The dispersion D of the double spectrometer is given by

$$D \equiv \frac{d\theta_B}{d\lambda} = \frac{n_A}{2d \cos \theta_A} + \frac{n_B}{2d \cos \theta_B} \quad (1)$$

n_A and n_B are the orders in which crystals A and B are reflecting respectively and θ_A and θ_B are the corresponding glancing angles. The sign of n_A is always taken positive. n_B is negative when the first incident and last reflected rays are on opposite sides of the first reflected ray,¹⁰ otherwise it is taken positive. The dispersion D is therefore finite in all anti-parallel positions.

The first correction to be applied to the observed widths in anti-parallel positions is the geometric width due to the vertical spread of the beam. Schwarzschild's¹⁰ equation for the "geometric breadth," $\delta\theta_B$, may be written

$$\delta\theta_B = \frac{1}{2}D\lambda\phi^2. \quad (2)$$

In this equation, $\delta\theta_B$ is the total angular range through which crystal B may be turned while reflecting the wave-length λ . If the widths of the slits limiting the divergence of the beam in a vertical plane are h_1 and h_2 ($h_2 \geq h_1$), and the distance between them is L ,

$$\phi = \frac{h_1 + h_2}{2L}. \quad (3)$$

The correction to be applied to the observed widths has been previously deduced⁴ from Eqs. (2) and (3). Let ξ be the angular deviation of crystal B from the position of reflection for the central ray, (that ray passing through the geometrical centers of the slit apertures). Then the value of ξ at which the geometrical rocking curve drops to half maximum is given by⁴

$$\xi_{1/2} = \frac{1}{2}D\lambda\phi^2 \left\{ \frac{h_2}{h_1 + h_2} \right\}^2. \quad (4)$$

The values of $\xi_{1/2}$, in seconds of arc, calculated from Eq. (4) are arbitrarily subtracted from the observed full widths at half maximum.

⁹ Allison and Williams, Phys. Rev. **35**, 149 (1930).

¹⁰ Schwarzschild, Phys. Rev. **32**, 162 (1928).

The second correction to be applied to the resultant widths in anti-parallel positions is that due to the finite resolving power of calcite crystals. If it is assumed that the line has a Gaussian error curve distribution of intensity we have¹¹

$$W = (W_A^2 + W_B^2 + D^2 W_\lambda^2)^{1/2} \quad (5)$$

In the above equation, W represents the half width at half maximum in angular measure of the observed rocking curve after the geometric correction has been applied, W_A the half width at half maximum in angular measure of the curve representing the intensity of reflection from crystal A as a function of the deviations from the Bragg angle, W_B is the same quantity for crystal B , D is the dispersion given by Eq. (1), and W_λ is the half width at half maximum in linear measure of the line. The quantities W_A and W_B are observed in positions of zero dispersion (i.e. $n_B = -n_A$) and will be discussed under the next heading. These two corrections are the only ones applied to the observed widths if the deviation of the crystal faces from verticality has been reduced to zero.

STUDY OF PARALLEL POSITIONS

In the positions of zero dispersion the observed width W is from Eq. (5)

$$W = (W_A^2 + W_B^2)^{1/2}. \quad (6)$$

Assuming the crystals to be the same, $W_A = W_B = W_C$

$$W = 2^{1/2} W_C. \quad (7)$$

The values of W_C have been studied as a function of λ for the first order of reflection from calcite. There is no geometric correction to be applied to the observed widths in parallel positions if the deviation of the crystal faces from verticality is reduced to zero. The method of imposing this condition has been previously described.⁴ The crystals were first adjusted as accurately as possible by the cathetometer method and a rocking curve was taken. Crystal B was then rotated through a minute of arc about an axis lying in a horizontal plane and a second rocking curve taken. This procedure was repeated until a position of crystal B was found which gave a rocking curve of minimum width. From this observed value of W the interference pattern width of a single crystal, W_C , was obtained by the use of Eq. (7).

The values of W_C have been obtained with the crystals reflecting the wave-lengths 908, 718, and 613 X.U. in the first order. These are plotted in Fig. 2. W_C is seen to be a linear function of the wave-length.

Darwin¹² and Ewald¹³ have considered the problem of reflection of plane monochromatic waves from an ideal crystal. The extent of 100 percent reflection is given by

$$\Delta\theta = 4\delta \operatorname{cosec} 2\theta \quad (8)$$

¹¹ Schwarzschild, reference 10. Obtained by combining Eqs. (43) and (45) of his paper.

¹² Darwin, Phil. Mag. 27, 325 and 675 (1914).

where θ is the glancing angle and δ is the deviation of the index of refraction from unity. Since ¹⁴

$$\delta = 1 - \mu = Ne^2\lambda^2/2\pi mc^2 \quad (9)$$

where N is the number of electrons per cm^3 , e is the electronic charge in e.s.u., m is the mass of the electron, and c is the velocity of light, and from the Bragg law

$$\text{cosec } \theta = 2d/n\lambda$$

we have

$$\text{cosec } 2\theta = d \sec \theta / n\lambda. \quad (10)$$

Fig. 2. The interference pattern width of a single crystal, W_c , as a function of the wave-length.

Substituting from Eqs. (9) and (10) in Eq. (8)

$$\Delta\theta = k\lambda \sec \theta \quad (11)$$

where

$$k = 2Ne^2d/\pi mnc^2.$$

Thus $\Delta\theta$ is an approximately linear function of λ as may be shown from the Bragg law and expansion in powers of λ .

$$\Delta\theta = k\lambda \left[1 + \frac{1}{2}(n\lambda/2d)^2 + 3/8(n\lambda/2d)^4 + 5/16(n\lambda/2d)^6 + \dots \right]. \quad (12)$$

This series is rapidly convergent for first order reflection from calcite in the region examined.

The experimental value of W_c was found to be 1.6 times as large as that calculated for a perfect calcite crystal by a method given in a previous paper.¹⁵ The value of W_c for the calcite crystals reflecting the wave-length 908 X.U. in the second order was 0.90 seconds of arc. This decrease of W_c for calcite with reflection in the second order is in agreement with the results of Davis and Purks¹⁶ and Allison and Williams.¹⁷

STUDY OF $U L\alpha_1$ IN DIFFERENT ORDERS

It has been pointed out that a systematic change in the observed natural widths when measured in positions of different dispersion may be due to the finite size of the focal spot. During the observation of a curve crystal B is rotated through small angles while crystal A is left fixed. Under the previous adjustments when crystal B is reflecting the peak of the line the radiation comes from the most intense part of the focal spot. As crystal B is rotated up to and through this central position, the radiation comes from slightly different parts of the focal spot, and hence will have a different initial intensity. In positions of higher dispersion greater errors would arise from this cause, and the magnitude of the effect can be calculated. In order to overcome this difficulty the broad focus tube was used and the radiation was taken at an angle of 45° from the target. To obtain a measure of the intensity distribution of the focal spot the following experiment was performed. The double spectrometer was adjusted to reflect the peak of a given line and was left fixed in this position. The x-ray tube, which was mounted on a moveable carriage driven by a screw, was advanced by small steps in a horizontal direction perpendicular to the line of the slits. Thus the radiation reflected by the crystals at different steps came from successive parts of the focal spot, and the intensity could be examined directly. It was found that at a distance of 1.5 mm from the center the intensity had fallen to half of the maximum value. It is thus felt that the error arising from this source has been greatly reduced. Any further enlargement of the focal spot would decrease the intensity to a degree causing uncertainty in the observations.

The half widths at half maximum of the line $U L\alpha_1$ were investigated in three different positions of the double spectrometer. The results are given in Table I.

The weighted averages have been secured by a personal estimate of the quality of the data.

For these observations D varies from 36.942 to 105.81 seconds per X.U. and the half width at half maximum, W_λ , varies from 0.442 to 0.437 X.U.

Fig. 3. Observed rocking curves of uranium $L\alpha_1$ at 48 kv. Ordinates are proportional to ionization currents, abscissae to angular settings of crystal B . The vertical scale is different for each curve.

Fig. 4. Observed rocking curves in the (1, 1) position for seven lines in the uranium L spectrum at 48 kv. Ordinates are proportional to ionization currents, abscissae to angular settings of crystal B . The vertical scale is not the same for all the curves.

There is a trend towards narrower widths at positions of higher dispersion but this decrease is well within the experimental error, and the magnitude of this effect is less than formerly noted.⁴ Typical curves of the line $U L\alpha_1$ in three different positions of the instrument are shown in Fig. 3.

THE NATURAL WIDTHS OF THE L -SERIES LINES OF URANIUM

Twelve lines of the L -series spectrum of uranium have been observed in the (1,1) position of the double x-ray spectrometer. Seven of these are shown in Fig. 4.

The half widths at half maximum of these lines have been calculated from the observed rocking curves in the (1,1,) position at 48 kv and are given in Table II. The details given in Table I are partially omitted but all corrections have been applied. The weighted averages of W_λ are obtained from a personal estimate of the quality of the data and the probable errors were calculated from the least squares formula.

The natural widths of $U L\alpha_1$ and $U L\beta_1$ have been examined as a function of voltage. Rocking curves in the (1,1) position were taken at different voltages under identical geometric conditions. The experimental error is greater at lower voltages due to the decrease in intensity as the excitation voltage is approached. The results are given in Table III where again the details of the calculation are omitted though all corrections were applied. An estimate of the experimental error of W_λ is also given.

Voltage in kv.	W_λ of $UL\alpha_1$ in $X.U.$	W_λ of $UL\beta_1$ in $X.U.$
48	$0.440 \pm .005$	0.295 ± 0.005
39	$0.445 \pm .005$	$0.294 \pm .005$
30	$0.439 \pm .010$	$0.287 \pm .010$
24	$0.435 \pm .015$	$0.30 \pm .02$

Table III shows that there is no significant change of width with voltage for $U L\alpha_1$ and $U L\beta_1$ in the voltage region studied. Thus the part of the width of these lines due to satellites arising from multiply ionized states of the atom

is negligible. These lines involve the final orbits L_{III} and L_{II} and it is reasonable to assume that their behaviour is representative of lines arising from transitions to these levels. The lines involving the orbit L_I have such a relatively weak intensity that it is not practicable to measure their widths at voltages less than 48 kv.

DISCUSSION OF THE NATURAL WIDTHS

In order to facilitate the discussion of the natural widths and to make possible any correlations with the electron transitions involved the results are shown in Table IV.

In the third column the energy breadth ΔV in volts is calculated from

$$\Delta V = 12336\Delta\lambda/\lambda^2 \quad (13)$$

where $\Delta\lambda$ and λ are in Angstroms.

The fourth column of Table IV gives the initial and final quantum states of the atom for the transition involved. The fifth column gives the eccentricity of the initial and final orbits on the classical quantum theory measured by k/n .¹⁸

The $\Delta\lambda$ s of the lines vary from 0.233 to 0.726 X.U. and the range of wavelengths from 592.6 to 920.14 X.U. The half width at half maximum predicted by the classical theory¹⁹ is 0.059 X.U. and is independent of the wavelength in question.

A study of Table IV has suggested the following possible correlations. $U L\beta_3$, $U L\beta_4$, $U L\gamma_2$, and $U L\gamma_3$ involving the highly elliptical orbit L_I have the greatest energy widths observed. $U L\alpha_2$ and $U L\beta_1$ involve transitions from the same initial orbit and the eccentricities of the orbits involved are the same; the energy widths agree. $U L\beta_2$ and $U L\gamma_1$ involve transitions from similar initial orbits and the eccentricities of the orbits are the same as well as the changes in quantum numbers; the energy widths agree. For the lines $U L\beta_5$ and $U L\gamma_6$ the changes in the quantum numbers and the eccentricities of the orbits involved are the same but the energy widths are very different. There is however an agreement between their $\Delta\lambda$ s. $U L\gamma_2$ and $U L\gamma_3$ involve orbits of the same eccentricity and there is a rough agreement between their energy widths; however the changes in quantum numbers are different.

These correlations are by no means complete but the wave-length region involved is so relatively great that the validity of a direct comparison between the energy widths or $\Delta\lambda$ s and the transitions involved is doubtful. It is felt that no simple complete empirical correlation can be given. Coster²⁰ has qualitatively considered the question of the width of x-ray lines on the classical quantum theory. He concludes that the width of lines involving transitions between elliptical orbits is greater than those involving circular orbits. If ΔV is considered to be a measure of the width of the line these predictions are born out in general by the results shown in Table IV. The great

width of $U L\gamma_2$, $U L\gamma_3$, and $U L\beta_4$, the last as previously observed by Allison⁶ in lead and thallium, are the best illustrations of the effect of an elliptical final orbit. The lines $U L\alpha_1$, $U L\alpha_2$, $U L\beta_1$ involving both initial and final circular orbits have the smallest ΔV s observed with the exception of $U L\beta_5$.

Professor J. R. Oppenheimer²¹ has calculated the width of $U L\alpha_1$ to be expected on the quantum mechanics from the Einstein probability coefficients of the states involved. He gives

$$\begin{aligned} \frac{\Delta\nu}{\nu} &= \frac{\sum A_n}{\nu} \\ &\sim 3^3 2^{14} \alpha^3 Z^2 / 5^{12} \\ &\sim 6 \times 10^{-6} \end{aligned} \quad (14)$$

where ν is the frequency of the line considered. A_n is the Einstein probability coefficients of spontaneous emission from the levels n to the L level in ques-

²¹ From private conversation with Professor Oppenheimer. I am greatly indebted to him for his interest in these results.

tion, and the summation if taken over all filled levels of the atom lying higher than the L levels, and α is the fine structure constant. On the basis of this reasoning $\Delta\nu/\nu < 10^{-5}$ whereas experimentally $\Delta\nu/\nu \sim 5 \times 10^{-4}$.

Thus the observed width must be due to other phenomena decreasing the life time of the excited state and consequently increasing the line breadth. Some possible causes may be the changes of the energy levels due to Hund coupling with the valence electrons in the atom; interactions with the neighboring atoms in the metal; or the effects of nuclear spin suggested by Breit.²² Since the L levels of uranium are so deeply buried in the atom it seems that the nuclear effects must predominate in broadening the line. Professor Oppenheimer has suggested the following possibilities due to coupling with the nucleus.

- (1) Electron interchange $\Delta\nu/\nu \sim \left(\frac{a_n}{a_0}\right)^2 \frac{1}{Z}$
 - (2) Induced dipole $\Delta\nu/\nu \sim \left(\frac{a_n}{a_0}\right)^3$
 - (3) Quadrapole moment $\Delta\nu/\nu \sim \left(\frac{a_n}{a_0}\right)^2 \frac{1}{Z}$
- (15)

In these equations a_n is the effective radius of the nucleus, a_0 is the mean radius of the orbit, and Z is the atomic number. The first of these arises from energy considerations of electron interchange between the orbital and nuclear electrons.

If a_0 is calculated from the Bohr formula

$$a_0 = \tau^2 h^2 / 4\pi^2 m e^2 Z \quad (16)$$

where τ is the total quantum number and the experimental value of $\Delta\nu/\nu$ is assumed then the following values are obtained for the radius of the nucleus.

- (1) $a_n \sim 4.5 \times 10^{-11}$ cm
- (2) $a_n \sim 1.8 \times 10^{-11}$ cm
- (3) $a_n \sim 4.5 \times 10^{-11}$ cm

From this reasoning alone the probability of finding a nuclear electron at these distances from the center of the nucleus is large whereas from the Rutherford scattering experiments the Coulomb law of force holds down to 10^{-13} cm. The possibility of an unexpected penetration of the orbits is thus suggested.

In Fig. 4 the line $U L\beta_{15}$, first resolved by Allison,⁶ is almost completely resolved but no reliable estimate of its width could be given. It is of the order of magnitude of 0.3 X.U. Its separation from $U L\beta_2$ was found to be 1.89 X.U. as the average of three measurements.

The line $L\beta_5$ on the energy level diagram is a doublet O_V, O_{IV} to L_{III} with a relative intensity of 9 to 1 on the Burger-Dorgelo rules. Although the line is relatively narrow no evidence of the weaker component could be found.

²² Breit, Phys. Rev. 35, 1447 (1930).

U $L\beta_3$ and Mo $K\alpha_1$ have nearly identical wave-lengths, 708.4 and 707.768 X.U., but their widths are greatly different, 0.382 and 0.147 X.U. respectively. The width of an x-ray line is therefore not a function of wave-length alone, but depends on the atom and transition involved. The half widths at half maximum of the L -series lines of uranium are from 1.6 to 5 times as great as that of Mo $K\alpha_1$. This is in agreement with the work of Allison⁶ on thallium and lead but in his work the crystals used were relatively poor and the adjustments of the instrument imperfect thus causing higher values of the widths.

The actual shape of the line U $L\alpha_1$ was investigated by taking many points on a rocking curve when the value of $\xi_{1/2}$ was reduced to negligible proportions. The classical theory gives for the shape of a line²³

$$I_\nu = I_0 / \{ k^2 + [(2\pi\nu)^2 - (2\pi\nu_0)^2] \}. \quad (17)$$

In the derivation of Eq. (5) Schwarzschild¹⁰ has assumed a Gaussian error curve distribution of intensity,

$$I'_\nu = I_0 e^{-k^2(\nu - \nu_0)^2} \quad (18)$$

The values of k and I_0 were selected so as to make the theoretical curves fit the actual curve at the maximum and half maximum ordinates. It was found that Eq. (17) gave a much better fit than Eq. (18). However the tails of the observed curve and the classical curve did not agree, the observed curve falling off more steeply than that given by Eq. (17).

Breit²² has considered the effects of nuclear spin on x-ray terms and has predicted the splitting of the L_{II} level of uranium to be of the order of magnitude of 4.0 volts. This prediction is based upon the assumptions that the uranium nucleus has a spin 9/2 and a magnetic moment 9/2 proton units and that screening effects are neglected. If one attempts to apply this prediction to the line U $L\beta_1$ for example, it is found that the natural breadth of the line is so great that no appreciable evidence of splitting would be expected.

In conclusion, I should like to express my thanks to Professor S. K. Allison for the suggestion of this problem and his helpful correspondence during the course of the investigation. My thanks are also due Professor R.B. Brode for his kindly criticism and interest in this research.

BREADTH OF THE COMPTON MODIFIED LINE WITH THE
DOUBLE CRYSTAL SPECTROMETER

BY ARCHER HOYT AND JESSE DUMOND

CALIFORNIA INSTITUTE OF TECHNOLOGY, PASADENA

(Received April 20, 1931)

ABSTRACT

Three experimenters using the double crystal spectrometer have recently reported very much narrower structure for the Compton modified line than the structure observed photographically by DuMond and Kirkpatrick with the multicrystal spectrograph whose resolution was entirely adequate to reveal such a narrow structure. We have repeated the experiment using a double crystal spectrometer similar to theirs. The results obtained are in satisfactory agreement with the previous observations of Compton line breadth by DuMond and Kirkpatrick with the multicrystal spectrograph and in disagreement with the experimenters who used double crystal spectrometers. The conclusions drawn are: (1) The Compton modified line due to Mo $K\alpha$ radiation scattered by graphite at angles of $165^\circ \pm 10^\circ$ and examined with the double crystal spectrometer has a breadth of from 21 to 22 XU at half-maximum height; (2) Under the above conditions there is no appreciable separation of the $K\alpha$ doublet in the shifted position; (3) No fine structure exists in the scattered spectrum of intensity greater than one-fifth the modified line intensity; (4) The ratio of modified to unmodified line intensity is estimated at (7.3:1); (5) There appears to be no essential difference between the results obtained with the single crystal, multicrystal and double crystal spectrometers in the study of this problem.

PURPOSE OF INVESTIGATION

VERY early in the study of the Compton effect it was suspected that the modified line might be broader than either the primary line or the unmodified line. Ross¹ was apparently the first to attribute this breadth to the momenta of the scattering electrons. An experiment by Sharp² using a single crystal photographic spectrometer at large scattering angle established the fact that the modified line has greater breadth than the primary line or than the unmodified lines.

In the early experiments resolution and homogeneity of scattering angle were sacrificed more or less in order to obtain sufficient intensity for ionization spectrometers or to give photographic spectra in reasonable times. It was therefore difficult to arrive at more than qualitative conclusions as to the breadth and structure of the Compton line. One such qualitative test is to observe whether the $K\alpha$ doublet present in the primary radiation can or cannot be resolved in the modified radiation. In one of the early photographic spectra published by Ross the modified line did appear to be faintly resolved. The resolution of the spectrograph was however barely sufficient to separate the unmodified scattered doublet and the conclusion to be drawn from this

¹ Ross, Proc. Natl. Acad. 9, 246 (1923).

² Sharp, Phys. Rev. 26, 691 (1925).

photograph as to the breadth of the modified line remains consequently quite uncertain. Indeed the apparent resolution of the modified doublet might even be attributed to an accident of the photographic emulsion as Compton suggests in "X-Rays and Electrons," page 293.

More recently one of us in collaboration with H. A. Kirkpatrick has shown³ by means of the multicrystal spectrograph that the breadth of the Compton modified line obeys, as a function of the scattering angle, the law to be expected on the hypothesis that the broadening is a Doppler effect of the moving electrons that scatter the radiation. This law is given roughly by the approximate equation for the breadth

$$\Delta\lambda = \beta\lambda \sin \frac{1}{2}\theta.$$

Thus for small scattering angles and hard primary radiation the modified line should be narrower than for larger scattering angles and soft primary radiation. Less marked differences in the breadths of the modified lines for different scattering materials might also be expected. In comparing experimental results on the breadth of the modified line it is therefore essential to be sure that the conditions of the experiment are essentially the same.

In a previous article one of us⁴ has shown that the breadth and structure of the modified line for scattering of $\text{MoK}\alpha$ radiation at large angles by beryllium was consistent with the assumption of two electrons per atom of beryllium dissociated to form a free electron gas of the type postulated by Fermi and Sommerfeld. The observed shape of the modified line from beryllium could be quite consistently accounted for as a Doppler broadening caused by electrons having the statistical velocity distribution quantitatively predicted by Sommerfeld's theory. (The correctness of the assumption of two free electrons per atom in beryllium has recently received support in the study of BeK lines from the work of Martin Söderman.)⁵ The modified Compton line from beryllium for $\text{MoK}\alpha$ primary radiation scattered at large angles was observed to be about 22 XU broad at half-maximum, a value much too great to permit resolution of the α doublet which has a separation of only 4 XU .

Measurements of the breadth of the modified $\text{MoK}\alpha$ line scattered at large angles by graphite made with the multicrystal spectrograph show also breadths of the same order of magnitude at half-maximum, again about 22 XU . The resolution was entirely adequate to separate the unmodified $K\alpha$ doublet and the inhomogeneity of scattering angle less than one degree. This breadth is in agreement with the electron velocities to be expected in graphite.

In view of the foregoing the authors of this paper were much astonished to read reports of three other investigators⁶ each using a double crystal spectrometer who found much narrower Compton modified lines in quite violent

disagreement with the above results. In one case the $K\alpha$ doublet of molybdenum scattered at large angles by graphite appeared as two extremely sharp peaks in the modified position almost completely resolved.

Some essential and hitherto unsuspected difference might exist between the methods of studying the Compton line with the double spectrometer and with the single spectrometer. The purpose of the present research was therefore to reveal any such effect as well as to check the work of the above mentioned investigators.

METHOD

Spectrometer. The double crystal calcite spectrometer with internal grid ion chamber and Hoffman type electrometer have been extensively described in another article⁷ and need therefore no further space.

Fig. 1. Special x-ray tube for the study of x-rays scattered at large angles provided with scatterer in vacuum in close proximity to target.

Special x-ray tubes. Two types of tube were tried. These are shown in Figs. 1 and 2. The tube shown in Fig. 1 is provided with a cylindrical copper housing carried on the front end of the target. This housing contains on one side the scatterer and on the opposite side an opening filled with thin steel sheets whose planes are parallel to the face of the target.

These sheets are so spaced that the direct radiation from the focal spot cannot issue between them due to its obliquity. They however permit the scattered radiation from the scatterer to issue freely. The scatterer is traversed by three fine slits parallel to the face of the target, one at the center, one at the side nearest the target and one at the side nearest the cathode. The tube was aligned with the spectrometer by sighting at the crystals through these slits and between the steel sheets. Without this precaution the tube might have been so positioned that the parallel rays demanded by the bi-crystalline reflection would be oblique to the steel sheets and considerable loss of scattered intensity would have resulted.

⁷ DuMond and Hoyt, Phys. Rev. **36**, 1702 (1930).

The scatterer was wide enough so that the selective reflection could take place over nearly the entire area of the two calcite crystals.

Considerable difficulty was encountered from gas given off by the graphite scatterer during the operation of the tube. After a gas discharge occurred in the tube it became difficult to reproduce conditions of voltage, current and x-ray intensity accurately. A large number of observations must be made in order to distinguish between accidental fluctuations in the readings and real characteristics of the spectrum and the chance that a gas discharge might occur before a sufficient number of readings could be made was deplorably high. The best of a number of curves taken with this tube is shown in Fig. 3. In the others the accidental fluctuations were even more pronounced. That such fluctuations are accidental is evident from the fact that they are not in the least reproducible.

Fig. 2. Special metal x-ray tube for the study of x-rays scattered at large angles provided with windows in close proximity to target to permit placing the scatterer outside vacuum.

On account of these difficulties the tube illustrated in Fig. 2 was constructed to permit a close approach of the scatterer to the focal spot while having the scatterer outside the tube. The windows in this tube are $\frac{1}{2}$ inch away from the center of the target. At first mica windows were used on this tube but these were several times destroyed by puncture, probably by fast electrons rediffusing from the focal spot. A thin mirror surface of beryllium deposited on the mica window by evaporation and placed on the inward side to conduct away such fast electrons did not suffice to prevent puncture. Finally aluminum windows 0.003 in. thick were resorted to. The direct radiation has to pass once through the window nearest the scatterer and the scattered radiation passed through both windows. These three passages had the effect of reducing the intensity by about 30 percent.

The graphite scatterer is cylindrical in form, 25 mm in diameter and 48 mm in length. It is completely enclosed in a lead housing 3 mm thick fitting closely about it. The front end of the graphite cylinder is turned down to such a diameter (18 mm) as to fit in direct contact with the entire x-ray window. The effect of the graphite alone could be ascertained by taking control readings with the graphite block removed.

The face of the molybdenum target was bevelled at an angle of 13° with the axis of the tube to reduce the absorption of the characteristic radiation excited in the deeper parts of the target and also to prevent the direct radiation from falling on the spectrometer.

The glass parts of the tube were jointed to each other and to the metal parts with de Khotinsky cement. The target was screwed into place and made tight with the same cement as were also the windows. For this reason the rather elaborate system of water cooling ducts shown in the drawing was provided. It was found entirely adequate to maintain all the joints cold enough to operate very satisfactorily.

Vacuum was maintained in this tube by a two stage mercury diffusion pump hanging under the spectrometer table. This pump was supported from the same rotating false table top⁷ to which the x-ray tube was attached so that the pump and x-ray tube moved together as the spectrum was explored, and no flexible vacuum joints were necessary. An internal liquid air trap in a right angle bend in the vacuum line between the pumps and the tube was used instead of the more common type so as to minimize the obstruction offered to the issuance of gas from the tube.

The two curves obtained with this tube are shown in Figs. 4 and 5. It should be noted that much less power was used in this work than was used by two of the above mentioned experimenters. The x-ray tube ran at about 60 K.V. c.p.d.c. and 10.6 and 14.6 ma. in the two cases.

RESULTS

All three curves shown here exhibit deplorably large accidental fluctuations in the readings relative to the faint effects studied. For this reason as large a number of readings as possible were taken. *In every case we have indicated the actual value of every single reading taken by plotting it as one point. No readings taken have been omitted.* In work of this kind there is grave danger of arriving at wrong conclusions by unintentional biased weighting of the observations due to omissions. It was felt to be too misleading to publish only the averages of several readings as this gives no idea of the order of accuracy or reproducibility involved.

Taken alone we do not feel that the curve in Fig. 3 made with the scatterer in the vacuum has enough points to be conclusive.

The other two curves seem to us to definitely indicate a broad diffuse structure for the Compton modified line from $\text{MoK}\alpha$ scattered at large angles by graphite in very satisfactory agreement with the curves obtained at large angles with the multicrystal spectrograph. The smooth curve which we have drawn is intended to guide the eye over the observed points on the steep

sides of the intense unmodified lines. We hope the reader will pardon our continuation of these smooth curves through the modified region where they can only be taken as suggesting the general trend of the observations.

A few points were taken with the graphite scatterer removed, the tube running at the same voltage and current as before removal. The modified scattering disappears as would be expected but the unmodified lines are only partly diminished. The amount of this diminution indicated in Figs. 4 and 5 is to be taken as a measure of the unmodified scattering of the graphite. The line intensity remaining in the unmodified position after removal of the graphite is due principally to (1) unmodified scattering of primary radiation at small angles (where it is strong) at the window nearest the spectrometer and

Fig. 3. Spectrum of x-radiation ($\text{Mo K}\alpha$) scattered at large angles by graphite with scatterer inside vacuum. The tube shown in Fig. 1 was used.

(2) fluorescence of the molybdenum films unavoidably deposited on both windows by vaporization from the target.

The unmodified lines have been plotted in Fig. 6 to a scale one fifth as high and five times as broad as in Fig. 4 to facilitate measuring their areas for the purpose of estimating the ratio of modified to unmodified intensity. The area thus obtained was multiplied by the ratio of the diminution in peak value of α_1 on removal of the graphite to the peak value with graphite in place in order to obtain the contribution of the graphite scattering alone. These curves in Fig. 6 give a clearer idea of the shape of the unmodified lines given by the double spectrometer here used and its resolving power. The vertical divergence or maximum obliquity of the rays with a plane normal to the dihedral angle formed by the two crystal faces did not exceed two degrees.

The maximum false broadening of the shifted radiation due to the inhomogeneity of scattering angle in these experiments is only 2 X.U.

Fig. 4. Spectrum of x-radiation ($\text{MoK}\alpha$) scattered at large angles by graphite with scatterer outside vacuum. The tube shown in Fig. 2 was used.

Fig. 5. Spectrum of x-radiation (MoK α) scattered at large angles by graphite with scatterer outside vacuum. The tube shown in Fig. 2 was used.

Fig. 6. Unmodified lines of Fig. 4 replotted to one-fifth the scale of ordinates and five times the scale of abscissae.

CONCLUSIONS

1. The Compton modified line due to $\text{MoK}\alpha$ radiation scattered by graphite at angles of $165^\circ \pm 10^\circ$ and examined with the double crystal spectrometer has a breadth of from 21 to 22 XU at half-maximum height.

2. Under the above conditions there is no appreciable separation of the $\text{K}\alpha$ doublet in the shifted position.

3. No fine structure exists in the scattered spectrum of intensity greater than one fifth the modified line intensity.

4. The ratio of modified to unmodified intensity is estimated at 7.3:1.

5. There appears to be no essential difference between the results obtained with the single crystal, multicrystal and double crystal spectrometers in the study of this problem.

No explanation has been found for the discrepancy between the results of the three observers above referred to and the results here reported. Of the three the one who obtained the sharpest lines used far greater absolute x-ray intensities incident on his scatterer than were used in the present work. It seems quite out of the question however to suppose that his incident energy was sufficient so profoundly to modify the statistics of electron motion in the scatterer as to give a modified line so much sharper than those reported here.

THE OSCILLATING ARC: ELEMENTS OF GROUP VI

BY E. Z. STOWELL

UNIVERSITY OF MICHIGAN, ANN ARBOR

(Received April 21, 1931)

ABSTRACT

A study of the behavior of sulphur, selenium, tellurium, chromium, molybdenum, tungsten and uranium as cathodes in an arc in hydrogen reveals that all of them permit radio-frequency oscillations to occur in a tuned circuit across the arc. No magnetic field is required for these oscillations. The elements of the sulphur group give unsteady oscillations, disintegrate rapidly and form hydrides with the arc atmosphere. The other elements yield steadier oscillations with no chemical action, and allow the arc to operate at a high temperature. The character of the spectra of these arcs in both the oscillating and the non-oscillating states is described and comparisons made. A mechanism is suggested whereby some elements will permit oscillations to occur and some will not.

I. INTRODUCTION

THE mechanism of the oscillating arc in hydrogen is sufficiently obscure so that much more data are necessary before possible explanations may be intelligently discussed. For this reason, a detailed study of the individual groups of the periodic table seems of value, not only to verify previous work with different equipment and different samples, but to obtain additional information regarding the character of the excitation when oscillating. In order to avoid duplication of work in progress in other laboratories, a study has been made of the behavior of the elements in the sixth group of the periodic table as cathodes in the arc in hydrogen. Group six was chosen because (1) no spectrograms have ever been taken of the elements of the sulphur group in such an arc, and (2) to check former results on the elements Mo, W, and U, which are of exceptional interest.

II. APPARATUS

The arc was that used in previous experiments¹ and consists of a vertical lower electrode, used as the cathode, surrounded at its base by a coil to furnish a steady magnetic field when necessary; a detachable vertical upper electrode, used as anode; both being enclosed in a removable glass cylinder which permits the maintenance of an atmosphere of hydrogen around the arc flame. The upper electrode, or anode, is usually of copper; its composition has little or no effect upon the behavior of the arc. The lower electrode or cathode, is of copper, and cup-shaped, in order to hold various specimens of other elements under investigation. It should be stated that an arc cannot be struck between the anode and the unfilled cathode, in a hydrogen atmosphere. Both electrodes may be water-cooled if desired. Hydrogen is fed in from a standby

¹ Stowell and Huxford, Phys. Rev. 36, 1348 (1930).

tank, and the exhaust disposed of either by combustion or escape to the outer air. The supply voltage is 220 d.c. A 20 ohm resistance and a large choke coil are in series with the arc; a radio-frequency circuit adjusted to about 300 k.c. is connected across the arc, with a current indicator in series. Striking is effected by a thumb screw which raises and lowers the anode.

The spectral region from 5500–3700Å was covered with a double-prism glass spectrograph. This spectrum is about 3.5 inches long, and since usually but one element is worked with at a time, there is little ambiguity in line identification. Exposures intended to be comparable with one another were taken on the same plate with identical exposure times, and as nearly the same arc currents as it was possible to obtain.

III. BEHAVIOR OF THE ELEMENTS OF THE SULPHUR GROUP

In accordance with results expressed in former papers^{1,2} which indicated that elements of even atomic number when used as cathodes permitted the generation of radio-frequency oscillations, sulphur, selenium and tellurium all allow these oscillations to occur. These arcs are characterized by extensive formation of hydrogen sulphide, hydrogen selenide and hydrogen telluride, as the case may be; and also by rapid disintegration of the cathodes. The latter phenomenon doubtless arises from the porous nature of the solid element, and the fact that some of it is continually being removed through the exhaust in the form of hydride. None of these arcs require a magnetic field for the production of oscillations.

From the spectral standpoint this group is interesting because the degree of excitation of the cathode vapor seems to increase with atomic number. This will appear in the discussion of the individual elements.

(1) **Sulphur.** Sulphur is decidedly the worst of the arcs from the standpoint of electrode disintegration; it is difficult to obtain a long enough exposure for spectrographic purposes. An additional difficulty is the settling of the sulphur on the walls of the glass cylinder, thus greatly reducing the light intensity and lengthening the exposure time. It was found necessary to fill the cathode cup with fresh material and to clean the glass in the optical path several times in order to get a single satisfactory exposure.

In the non-oscillating condition (obtained by opening the tuned circuit across the arc) no trace of sulphur was observed in the spectral region covered. Copper lines only were obtained, and the arc was to all intents and purposes a copper arc. Upon closing the oscillating circuit and allowing current to flow therein, the copper spectrum remained, with the addition of one Balmer line, H_{β} , and one band of sulphur with head at $\lambda 4285$, degraded to the red. No sulphur lines appeared. A trace of Al in the original copper electrodes indicated by the pair at $\lambda 3944$ – 3961 , was greatly intensified in this oscillating arc.

(2) **Selenium.** Selenium does not disintegrate as rapidly as sulphur, and one filling of the hollow cathode is generally sufficient for an exposure. The settling of selenium upon the glass walls is not objectionable. The radio-fre-

² Stowell and Redeker, *Phvs. Rev.* 34, 978 (1929).

quency current is maintained at a somewhat steadier value than in the case of sulphur.

The spectral differences between the oscillating and the non-oscillating conditions are not great. Both spectra show copper, H_β and H_γ , and most of the Exner and Haschek lines of Se. Using the identification given by the Blochs,³ these lines belong to Se I. In addition, two bands of Se were obtained, with heads at $\lambda 4285$ and $\lambda 4006$, both degraded to the red. The Al impurity previously referred to as existing in the copper was again intensified in the spectrum of the oscillating arc. An interesting feature is that the Ca II doublet at nearly the same wave-lengths, $\lambda 3933$ – 3968 , was *not* intensified.

(3) **Tellurium.** Tellurium behaves electrically in a similar manner to selenium. The spectrum however shows a higher order of excitation than selenium, just as the latter is excited more strongly than sulphur. In both the oscillating and non-oscillating condition the copper background, with H_β and H_γ , are obtained, together with a multitude of lines due to Te I³ and the following lines due to Te II: $\lambda\lambda 4725$, 4352 and 4120 . These last three are the most intense lines in the spectrum, and are more intense when the arc is permitted to oscillate. No Te bands are found. The same phenomena concerning the doublets of Al I and Ca II that were mentioned in the case of Se are reproduced here.

IV. BEHAVIOR OF CR, MO, W AND U

(1) **Chromium.** Metallic chromium, inserted into the cup-shaped cathode, will not permit an arc to be drawn out in an atmosphere of hydrogen. There are however transients in the radio-frequency circuit at the moment the direct current circuit breaks. Evidently if an arc could be drawn, there would also be oscillations.

(2) **Molybdenum.** Molybdenum, in the form of a spiral of the wire inserted into the cup and projecting a trifle beyond, gives an unsteady arc, intensely white. No magnetic field is necessary for current to flow in the tuned circuit. Electrode disintegration is slow.

A continuous spectrum is obtained with both the oscillating and non-oscillating arcs, with lines of copper, Mo I, Mo II,⁴ H_β and H_γ , as well as lines of Cr and Fe, superimposed. The latter are present as impurities in the Mo. Certain of the Cr lines appear to be reduced in intensity in the oscillating arc. They are:

4698.49
4652.16 (Cr I)
4530.74
4289.72 (sensitive line of Cr I)
4274.81 (sensitive line of Cr I)
4254.34 (sensitive line of Cr I).

The iron lines are about the same intensity in both spectra. Both the Ca II and Al I doublets previously mentioned are intensified in the oscillating state.

³ L. and E. Bloch, *Ann. de Physique* **13**, 233 (1930).

⁴ Meggers and Kiess, *Jour. Opt. Soc.* **12**, 417 (1926).

(3) **Tungsten.** Tungsten furnishes probably the most interesting arc in the sixth group. A spiral of wire (10 mil) placed inside the cup and projecting beyond, gives oscillations of extreme steadiness and reproducibility. No magnetic field or cooling are necessary. The arc is an intense white; since it runs at a high temperature, the electron emission from the cathode is high, the arc length and current are quite constant, and there is little to cause frequency fluctuations. With the arc running properly, its heterodyned note cannot be distinguished from that given by an electron tube oscillator. Electrode disintegration is extremely slow. The arc has the peculiarity that the radio-frequency output is increased, if, after the oscillations have started, the electrodes are made to approach one another slightly.

The non-oscillating arc shows a very simple spectrum: a heavy continuous background, with H_β , the Ca II pair $\lambda 3933-3968$, and $\lambda 5006.17$ of tungsten superimposed. No copper appears.

The oscillating arc likewise produces a heavy continuous background with H_β superimposed; but the Ca II pair is lacking, and instead there appear the following lines of tungsten: $\lambda \lambda 4294.62$, 4074.37 , 4008.76 , and 5006.17 . The last two, at least, are known to arise from W I.

(4) **Uranium.** The uranium arc in hydrogen resembles the tungsten arc, but is not as steady, since the electrode is no longer a homogeneous piece of wire, but crushed metal placed in the copper cup. The arc is much brighter in the oscillating state, and is intensely white.

The spectra obtained are exceedingly rich in lines. The majority of the uranium lines in Vol. 6 of Kayser's Handbuch are found, together with many lines due to the iron impurity. Continuous spectra are obtained with the arc in both the oscillating and the non-oscillating condition; this continuous spectrum is more intense in the former case. There are other marked differences between the two conditions, namely:

(a) the uranium lines in general are intensified in the "oscillating" spectrum.

(b) a small amount of potassium impurity, indicated by the doublet at $\lambda 4044-47$, is slightly intensified in the "oscillating" spectrum.

(c) iron impurity, especially those lines due to Fe I, is much reduced in the "oscillating" spectrum.

(d) Ca impurity, as indicated by lines of Ca I and Ca II, is reduced in intensity by the oscillations.

(e) the trace of Al I impurity in the original copper is reduced in intensity by the oscillations.

Suppression of the iron impurity as in (c) is characteristic of these arcs, and may possibly be of service to spectroscopists, when chemical removal of such impurity in samples to be investigated would be unduly difficult or expensive.

V. DISCUSSION

All of the elements in Group VI. thus permit the generation of radio-frequency oscillations. The elements in the sulphur group have been seen to be-

have somewhat differently from the other elements studied. They are characterized by comparatively rapid electrode disintegration with compound formation, and low excitation. The remaining elements of Group VI. when used as cathodes disintegrate much more slowly, do not form hydrides, and operate the arc at a high temperature, resulting in the emission of a continuous spectrum.

A mechanism whereby some elements will allow current to flow in a tuned circuit across the arc, and others will not, is suggested from fundamental considerations of such arcs. Provided certain secondary conditions as to circuit constants are satisfied, those arcs will permit oscillation which have a negative slope to their dynamic characteristic. For those arcs with no accompanying oscillations, as with the alkali metals when used as cathodes, one may assume that the dynamic characteristic has become excessively flattened, to the extent of losing its negative curvature.

Steinmetz⁵ has shown how this may come about if there is a time lag in the reaction of the arc stream to the amount of current passing through it. Consider the static characteristic of an arc, for direct current, to be represented by

$$e = a + \frac{b}{i^{1/2}},$$

where a is the potential drop at the electrodes, and the second term gives the potential drop across the arc stream. The slope of this characteristic, at any current i_1 , is

$$\left(\frac{de}{di}\right)_{i=i_1} = -\frac{b}{2i_1^{3/2}}.$$

The fluctuation in potential, made available for the tuned circuit, by a small fluctuation in current, Δi_1 , about the mean current i_1 , is

$$\Delta e_1 = -\frac{b}{2i_1^{3/2}} \Delta i_1.$$

If now Δi_1 were periodic and equal to $\Delta I e^{j\omega t}$, Δe_1 would likewise be periodic, and current would flow in the attached circuit.

Suppose however that the volume, and therefore the resistance $(e-a)/i$ of the arc stream, cannot adjust itself immediately to new values of current. Such might occur, for example, if the atoms of the cathode vapor remained in their excited or ionized states for a length of time comparable with the period of the attached tuned circuit. In this case let the potential fluctuation Δe_1 lag behind the current fluctuation by an angle α ; that is,

$$\Delta e_1 = -\frac{b}{2i_1^{3/2}} \Delta I e^{j(\omega t + \alpha)}.$$

⁵ Steinmetz, "Theory and Calculation of Electric Circuits," p. 194.

Elimination of the time gives the shape of the new characteristic; its equation is evidently

$$\Delta e_1 = - \frac{b}{2i_1^{3/2}} \Delta i_1 \cdot \cos \alpha.$$

The potential fluctuation is thus reduced due to the time lag, and less current will flow in the tuned circuit. With α equal to $\pi/2$, the potential fluctuation will be 90° out of phase with the current fluctuation, and no power will be available for oscillations. For large angles of lag, the potential fluctuation, in this picture, would vanish, and no oscillations would appear.

This hypothesis is defective in that it does not introduce the all-important hydrogen atmosphere. The latter may enter the discussion either by determining the excitation and ionization times, or, as arc engineers have supposed, by furnishing a much steeper dynamic characteristic than other gases.

THE HIGH FREQUENCY BEHAVIOR OF A PLASMA

BY LEWI TONKS

RESEARCH LABORATORY, GENERAL ELECTRIC COMPANY

(Received April 20, 1931)

ABSTRACT

An analogue for a uniformly ionized gas on the basis of the known formula $K_p = 1 - \omega_0^2/\omega^2$ for its specific inductive capacity is found in a shunt-tuned circuit. In that formula $\omega_0^2 = 4\pi Ne^2/m$ and ω is the impressed angular frequency. This formula is extended to two simple cases of non-uniform ionization, with the conclusion that non-uniformity may be indistinguishable from large energy dissipation, insofar as reactive effects are concerned. Formulas have been derived for calculating the *conductivity and specific inductive capacity of a cylindrical plasma* (positive column of an arc) between parallel condenser plates from the measured impedance of this condenser by using a modification of Mossotti's Theory. The natural period of such a condenser occurs very nearly when $K_p = -1$. For a fixed frequency the reactance of such a composite condenser was followed for varying arc current by observing the length of Lecher System connected to the condenser plates which was required to cause circuit resonance. Two and sometimes three resonances were found. They occurred in the neighborhood of the calculated plasma-electron resonance as determined from electron density measurements, and varied with impressed frequency according to theory.

The *theoretical variation of K_p* was checked in the range $\omega_0^2 > 2\omega^2$ by the hyperbolic relation between change in condenser reactance and arc current there. Resistance measurements on the Lecher system, used in connection with a more detailed analysis, allowed *calculation of relative electron density* in the range from one-half to five times that giving resonance, checking the actual values. In the same range, the *resistance to electron motion* varied considerably. The maximum value occurred near resonance and checked, roughly, the value calculated from free path considerations. The alternating fields in the plasma varied from 0.17 to 1.2 v · cm⁻¹ and the maximum amplitude of electron motion was 2.1×10^{-3} cm.

A transverse magnetic field was found to double the resonance as H. Gutton has found. The separation of resonances accords with theory.

I. INTRODUCTION

THE reaction of an ionized gas to very high frequency electric waves has been the subject of several investigations. Spontaneous oscillations in the neighborhood of 10^9 herz originally found by Penning¹ have been further investigated by Tonks and Langmuir² using the low pressure mercury arc. They found that the observed high frequency oscillations corresponded to the theoretical value for plasma-electron oscillations³

$$\nu = (Ne^2/\pi m)^{1/2} = 8980 \times N^{1/2} \quad (1)$$

¹ Penning, Nature **118**, 301 (1926) and Physica **6**, 241 (1926).

² L. Tonks and I. Langmuir, Phys. Rev. **33**, 195 and 990 (1929).

³ This frequency appears so often in investigations of the high frequency behavior of ionized gases that it will be given a definite name in this paper, namely, "plasma-electron frequency."

where ν is the oscillation frequency, m is the electronic mass, and N is the ionization density. This frequency, looked upon as the limiting frequency at which radio waves can be propagated in an ionized medium, has been discussed at some length by T. L. Eckersley.⁴ Since an ionized gas exhibits a resonant frequency, it is of interest to know the behavior of such a gas toward forced oscillations. W. H. Eccles⁵ has derived formulae which have been interpreted by Bergmann and Düring⁶ as attributing a dielectric constant

$$K = K_0 - 4\pi Ne^2 m / (m^2 \omega^2 + f^2) \quad (2)$$

and conductivity

$$\rho^{-1} = fNe^2 / (m^2 \omega^2 + f^2) \quad (3)$$

to the medium, where f is a dissipation factor appearing in the equation of motion of the electron.

H. Gutton and J. Clement⁷ have made a rather thorough investigation of the dielectric properties of ionized hydrogen extending through the plasma resonance.^{7,8} It was found that the natural period varied with the intensity of ionization roughly in the way that was theoretically expected, and they were able to obtain a fair numerical check between the ionization density calculated from Eq. (1) and that calculated rather indirectly from their results. More recently, C. Gutton⁸ has confirmed the existence of a natural resonance period in an ionized gas by measuring the change in conductivity of ionized mercury vapor when a 2.76 meter wave was impressed on it. In his theoretical treatment of the gas reaction, however, H. Gutton introduces an elastic restoring force of unknown origin which seems to be not only unnecessary but somewhat in contradiction with the actual experimental results, as has been pointed out by J. Rybner.⁹ Still more recently, Bergmann and Düring⁶ have measured the change in dielectric constant of a small condenser in high vacuum arising from the introduction of electrons between the condenser plates. They have been able to check the theoretical value as given by Eq. (2) roughly, but the electron densities used were so small (in the neighborhood of 10^7 cm^{-3}) that K was but little different from K_0 , that is, unity. Their measurements give an apparent conductivity which is of the order of magnitude given by Salpeter's¹⁰ interpretation of f as arising from the momentum lost in electron collisions with gas molecules.

^{7,8} The term "plasma resonance" denotes the actual resonance of the system comprising the plasma and the condenser of which it forms part of the dielectric. This resonance occurs, in general, at a different ionization density from plasma-electron resonance. See the paragraph following Eq. (27) and the theoretical treatment in Section IX.

⁸ C. Gutton, *Ann. d. Physique* **14**, 5 (1930).

¹⁰ J. Salpeter, *Jahrb. der drahtl. Telegr.* **8**, 252 (1914). But see the criticism of S. Benner, *Annalen der Physik* **3**, 993 (1929) regarding the application of Salpeter's results to this experiment. Salpeter treats the case in which the free time of an electron is variable, whereas in the Bergmann-Düring experiment, the effective free time of every electron is the same.

The present investigation extends the work of H. Gutton with the aim of making direct measurements of electron density so as to be able to check theoretical formulas more directly.

II. THE SPECIFIC INDUCTIVE CAPACITY OF A PLASMA

The use of an ionized gas is necessary if high densities of electrons are to be obtained, but in a plasma the density of ionization is not uniform throughout the whole cross section. It therefore becomes of interest to know how non-uniformity in electron density affects plasma-resonance behavior.

The complex specific inductive capacity of a plasma can be found by direct substitution in the partial differential equation

$$\partial^2 Z / \partial x^2 = \mu K \partial^2 Z / \partial t^2 + [4\pi\mu N e^2 / (f + jm\omega)] \partial Z / \partial t \quad (4)$$

as given by Eccles.¹¹ Substituting

$$Z = \exp \{j\omega[t - (\mu K_p)^{1/2}x]\}$$

where K_p denotes the complex specific inductive capacity and writing

$$4\pi\mu N e^2 / m = \omega_x^2 \quad (5)$$

where ω_x is the local plasma-electron angular frequency and writing also

$$S = f/m \quad (6)$$

we find that

$$K_p = \frac{\omega_x^2 - \omega^2 + j\omega S}{-\omega^2 + j\omega S} \quad (7)$$

This is the specific inductive capacity at each point of the ionized medium looked upon as a function of the electron density, since that enters ω_x and possibly S .

The response of the medium as a whole may be extremely complicated. The simplest case is the one in which the electron density is a function of one coordinate only and the impressed electric field lies in that same direction. In that case we may write

$$dV = (4\pi Q_0 / K_p) dx$$

where V is the impressed voltage and Q_0 is the polarization of the medium. This may be integrated to the form

$$V = 4\pi Q_0 \overline{K_p^{-1}} x_p \quad (8)$$

for a plasma of thickness x_p where

$$\overline{K_p^{-1}} = (1/x_p)(-\omega^2 + j\omega S) \int_{\text{over } x_p} (\omega_x^2 - \omega^2 + j\omega S)^{-1} dx. \quad (9)$$

¹¹ Reference 5, page 87.

It is instructive to apply this formula to a hypothetical case. Neglecting the dissipation factor S , let us assume a simple linear law of variation of N in the plasma, as for instance,

$$N = N_0(1 - x/2a) \quad (10)$$

from $x=0$ to $x=a$. This leads to

$$\overline{K_p^{-1}} = -\frac{\omega^2}{\omega_0^2} \ln \left[\frac{\omega_0^2 - \omega^2}{\omega_0^2/2 - \omega^2} \right]^2 \quad (11)$$

where $\omega_0 = (4\pi N_0 e^2/m)^{1/2}$ is 2π times the plasma-electron frequency where the ionization is densest.

The value of $\overline{K_p^{-1}}$ as a function of N_0 is shown as Curve 1 in Fig. 1.

Fig. 1. Theoretical reactance of non-uniform plasmas.

Throughout the range $1 < \omega_0^2/\omega^2 < 2$ there is always a place in the plasma where local resonance occurs, giving rise to the middle section of the characteristic. The presence of resistance eliminates the infinities and leaves a curve resembling a resonance broadened by high dissipation, with the result that the width of the resonance region may only depend slightly upon the dissipative forces and may rather be a measure of the nonhomogeneity of the plasma. It was thought possible that a parabolic distribution of electron density

$$N = N_0(1 - x^2/2a^2) \quad (12)$$

might more nearly reproduce the asymmetry found in the actual resonance characteristics. Curve 2 was calculated with this in mind and although failing of its purpose, it may be useful in the appropriate case. Its equation is

$$\begin{aligned}\overline{K_p}^{-1} &= 2\eta^{-1}[2(\eta^{-1} - 1)]^{-1/2} \tan^{-1} [2(\eta^{-1} - 1)]^{-1/2} \\ &= \eta^{-1}[8(1 - \eta^{-1})]^{-1/2} \ln \left\{ \frac{[2(1 - \eta^{-1})]^{1/2} + 1}{[2(1 - \eta^{-1})]^{1/2} - 1} \right\}^2\end{aligned}\quad (13)$$

according as $\eta < 1$ or $\eta > 1$.

With the dissipative factor omitted, Eq. (7) takes the form

$$K_p = 1 - \omega_x^2/\omega^2 \quad (14)$$

which shows that each element of the plasma has a simple circuit analogue in a fixed condenser C shunted by a variable inductor L . The shunt admittance of such a circuit is

$$Z^{-1} = j\omega KC = j\omega C + (j\omega L)^{-1}$$

where K is the apparent specific inductive capacity of the condenser. Putting $LC = \omega_0^{-2}$ we obtain

$$K = 1 - \omega_0^2/\omega^2.$$

Each elementary volume ($dx dy dz$, x being parallel to the electric field) in even a non-uniform plasma is thus equivalent to a vacuum parallel-plate condenser of capacity

$$C = dydz/4\pi dx$$

shunted by an inductor of inductance

$$L = mdx/Ne^2 dydz.$$

If, for example, a plasma contains two layers, each of which is uniform in electron density, it can be represented by two shunt circuits in series. Such a system shows double resonance provided that the separation of the two natural periods relative to the damping of the individual circuits is great enough. This double resonance could be observed either by increasing the electron densities proportionally (decreasing inductances in the circuit analogue) while the impressed frequency was maintained constant, or by varying the impressed frequency the keeping ionization densities unchanged. Extension of this reasoning makes it possible to understand how even a continuous variation in electron density, such as found in an actual plasma, may give rise to multiple resonance.

Digressing slightly, it may be remarked that H. Guttonn arrives at a relation essentially different from Eq. (14), namely,

$$K = 1 + (4\pi Ne^2/m)/(\omega_0^2 - \omega^2)$$

In this equation, $\omega_0/2\pi$ is the resonant frequency of the electrons and ω_0 is related to N by the empirical equation

$$\omega_0^2 = AN^{3/4}.$$

These equations make K decrease initially from unity as N is increased from zero, which is qualitatively the same as Eq. (14). When N is infinite, however,

these equations give K a weak positive infinity, whereas the strong negative infinity of Eq. (14) is qualitatively checked by H. Gutton's curves (Fig. 9 of *Annales de Physique* article) and by the measurements to be described below.

Turning now to the case of uniform ionization, it is evident that an analysis of the response of the medium reduces to an analysis of the electrostatic field between condenser plates in the presence of a dielectric of specific inductive capacity K_p . The simplest case is, of course, that of the plane parallel condenser, but that form is not suited to the positive column of an arc. The shape that has been adopted is that of a cylindrical plasma parallel to and midway between two plane condenser plates. This form has the experimental advantage that it is a natural form for a positive column, and that the electric lines of force in a uniform cylindrical plasma are straight and parallel so that there are no strong local fields at any point.

III. THE EFFECTIVE SPECIFIC INDUCTIVE CAPACITY OF A PLANE PARALLEL CONDENSER CONTAINING A CYLINDRICAL PLASMA

Theoretically, a modification of Mossotti's theory of dielectrics makes the arrangement just outlined quantitative.¹² Mossotti's theory in its usual form contemplates a vacuum containing suspended conducting spheres. The response of such a configuration to an electric field can be treated quantitatively.¹³ For present purposes the conducting spheres must be replaced by dielectric cylinders.

We consider then a large volume of dielectric (specific inductive capacity $=K$) made up of matter-free space in which are suspended infinitely long cylinders of specific inductive capacity K_p with their axes perpendicular to the uniform electric field E_e . The electric field tending to polarize any cylinder is

$$E_i = E_e + (4\pi/2)P \quad (15)$$

where P is the polarization of the composite dielectric, and the coefficient $4\pi/2$ applies to cylinders as $4\pi/3$ does to spheres. Within the polarized cylinder the field is

$$E_p = 2E_i/(K_p + 1) \quad (16)$$

analogous to $E_p = 3E_i/(K + 2)$ in the case of spheres. The polarization of the cylinders is then

$$P_p = (K_p - 1)E_p/4\pi = (K_p - 1)E_i/2\pi(K_p + 1). \quad (17)$$

If θ denotes the fraction of the composite dielectric volume occupied by the cylinders,

$$P = \theta P_p = \theta(K_p - 1)E_i/2\pi(K_p + 1). \quad (18)$$

¹² H. Gutton's analysis based on Fig. 12 of his *Ann. de Physique* article cannot be justified theoretically. See J. Rybner, reference 9.

¹³ Livens, *Theory of Electricity*, p. 228; Jeans, *Electricity and Magnetism*, Fifth Edition, p. 131 arrives at a formula which is not valid for sufficiently high values of dielectric constant.

Also

$$P = (K - 1)E_c/4\pi = (K - 1)E_i/2\pi(K + 1) \quad (19)$$

by using Eq. (15). Combining these two equations we find

$$(K - 1)/(K + 1) = \theta(K_p - 1)/(K_p + 1) \quad (20)$$

relating the dielectric constant, K_p , of the cylinders to that of the composite parallel-plate condenser, K . When K is not very different from unity, we can write

$$\delta K = 2\theta(K_p - 1)/(K_p + 1). \quad (21)$$

This formula was checked by the method H. Gutton used to determine the capacity values in the "equivalent" system shown in his Fig. 12. The arc tube, of 3.0 cm internal diameter, projecting well beyond and centered between two 7×7 cm condenser plates 7 cm apart was replaced by an open glass tube of the same size. With this tube empty, the Lecher System and condenser resonated with the thermocouple bridge at 17.9 cm, filled with mercury ($K_{Hg} = \infty$) at 16.3 cm, and filled with benzol ($K_B = 2.26$) at 17.35 cm. From Eq. (21)

$$\delta K_\infty = 2\theta$$

$$\delta K_B = 2\theta(2.26 - 1)/(2.26 + 1) = 0.386 \times 2\theta$$

whence

$$\delta K_B/\delta K_\infty = 0.386.$$

Since the changes in Lecher System length were small, they were proportional to capacity changes, whence

$$\delta K_B/\delta K_\infty = \delta L_B/\delta L_\infty = (17.9 - 17.35)/(17.9 - 16.3) = 0.34.$$

This is a satisfactory check considering that the experimental arrangement was only a rough approximation to that assumed mathematically. Since θ has been eliminated in the course of this calculation, the question naturally arises as to whether its value might not constitute an independent verification. The geometric capacity, C_0 , terminating a resonant length, s , of Lecher system is given by

$$1/\omega C_0 K = Z_0 \tan(2\pi s/\lambda) \quad (22)$$

where Z_0 is the surge impedance of the system. It follows that the change in s required to retune after a slight change in K obeys the relation

$$\delta K/K = -2\pi\delta s/\lambda \sin(2\pi s_0/\lambda) \cos(2\pi s_0/\lambda)$$

and using Eq. (21)

$$\theta = -2\pi\delta s/\lambda \sin(4\pi s_0/\lambda) \quad (23)$$

since $K = 1$.

In the present case $s_0 = 27.2$ cm (for the bridge at 17.9 cm) and $\lambda = 187$ cm whence $\theta = 0.056$. The tube cross-section is $(\pi/4) \times 3.0^2 = 7.07$ cm², while the condenser cross-section is $7 \times 7 = 49$ cm² giving $\theta = 0.14$. This large discrepancy is easily accounted for both by the large edge effect in a condenser of the proportions used and also by the individual capacity of each plate to ground. Under these circumstances it is permissible to treat θ as an empirical constant in Eqs. (20) and (21).

It is fairly obvious that Eq. (21) may not be applicable to plasma resonance since δK becomes very large when $K_p K_c$ nears -1 . In addition, a dissipative term must be included if the analysis is to be complete. From Eq. (7) (treating the plasma as if uniform by using ω_0 instead of ω_e)

$$K_p = \frac{\omega_0^2 - \omega^2 + j\omega S}{-\omega^2 + j\omega S} = \frac{\eta - 1 + jS/\omega}{-1 + jS/\omega} \quad (24)$$

if we put $\omega_0^2/\omega^2 = N/N_\omega = \eta$, N_ω being the electron density for which the plasma-electron angular frequency is ω , that is, $N_\omega = [\omega/(2\pi \times 8980)]^2$. From Eq. (20),

$$K^{-1} = 1 - 2\theta(K_p - 1)/[K_p + 1 + \theta(K_p - 1)] \quad (25)$$

Combining, we have

$$K^{-1} = 1 + \theta\eta/[1 - (1 + \theta)\eta/2 - 2jS/\omega] \quad (26)$$

for calculating the complex dielectric "constant" of the condenser when dissipation is included.

IV. CHARACTERISTICS OF A TUNED CIRCUIT MADE UP OF A CONDENSER CONTAINING A PLASMA AND A VARIABLE INDUCTOR

If we suppose the condenser containing the plasma to be connected in series with an inductance, L , and denote its capacity when $N=0$ by C_0 , the series impedance of the combination is

$$Z = j[\omega L - (\omega C_0 K)^{-1}]$$

Putting

$$L = L_0 + \delta L$$

where L_0 is the inductance which tunes C_0 , that is, $L_0 = (\omega^2 C_0)^{-1}$, this equation becomes

$$Z = j[\omega \delta L - \omega L_0 (K^{-1} - 1)].$$

Substituting from Eq. (26) and separating into real and imaginary parts we find

$$Z = j\omega \left[\delta L - L_0 \frac{(\theta/\phi)\eta'(1 - \eta'/2)}{(1 - \eta'/2)^2 + S^2/\omega^2} \right] + 4 \frac{\omega L_0 \theta \eta S/\omega}{(1 - \eta'/2)^2 + S^2/\omega^2}$$

where $\phi = 1 + \theta$ and $\eta' = \phi\eta$. When L is adjusted so that the circuit is in resonance, the reactance is zero and δL_r , the value of δL at resonance, is given by

$$\delta L_r = L_0 \frac{\theta\eta(1 - \eta'/2)}{(1 - \eta'/2)^2 + S^2/\omega^2} \quad (27)$$

As N is increased from zero, η and η' increase proportionally and δL_r increases from zero, at first proportionally to N but later more rapidly. If S were zero, δL_r would approach $+\infty$ as $\eta' = 2$, to reappear at $-\infty$, but the finite value of S causes δL_r to vary rapidly from a positive maximum to a negative minimum as η' passes through 2. As N becomes still larger, δL_r increases once more approaching $\delta L_\infty = -2\theta L_0/\phi$ as $\eta \rightarrow \infty$. This is just the type of behavior approximated to by the curve in H. Gutton's Fig. 9.

Obviously, the plasma resonance occurs at $\eta' = 2$. The qualitative circuit equivalent of the plasma between its condenser plates, as shown in Fig. 2, makes it evident that the shunt resonance does not occur when the plasma

Fig. 2. Qualitative circuit equivalent of a plasma between condenser plates.

itself is tuned to the impressed frequency. This would be true only when the shunt capacity is zero. For example, the infinite plane parallel plasma is a (rather ideal) case in which plasma resonance would lie at $\eta = 1$. For a spherical plasma between parallel plates, resonance would occur near $\eta = 3$.

In the range where η' is different enough from 2 for S/ω to be neglected, Eq. (27) can be written

$$(1 - \eta'/2)\delta L_r = -(\eta'/2)\delta L_\infty(\theta\phi_\infty/\theta_\infty\phi)$$

the ratio in the right member being introduced to allow for changes in θ with N . It follows that

$$(\theta\phi_\infty/\theta_\infty\phi)\delta L_r^{-1} + \delta L_\infty^{-1}(2/\eta' - 1) = 0$$

and noting that $\eta' = \phi\eta = \phi N/N_\omega$ we have

$$(\theta\phi_\infty/\theta_\infty\phi)\delta L_r^{-1} = (2N_\omega/\delta L_\infty)(\phi N)^{-1} - \delta L_\infty^{-1}. \quad (28)$$

Now, changes in ϕ can be neglected since the actual value of θ is so small. It is thus justifiable to put $\phi/\phi_\infty = 1$, whence Eq. (28) becomes

$$(\theta/\theta_\infty)\delta L_r^{-1} = (2N_\omega/\delta L_\infty)(\phi_\infty N)^{-1} - \delta L_\infty^{-1}. \quad (29)$$

In the range of larger values of N (experimentally when $\eta' > 2$), the variation of θ with N was appreciable, but small, and the values of θ/θ_∞ could be calcu-

lated from the thickness of the wall sheath in the arc tube. For the smaller values of N , however, the variation of θ was not calculable and Eq. (29) could not be quantitatively tested in that range.

V. PRELIMINARY EXPERIMENTS

The plasma used in this investigation was the positive column of a mercury arc because the electrical methods for measuring ionization intensities have been applied most extensively to these arcs.¹⁴ At first a tube containing an oxide-coated cathode was tried, but was found unsuitable on account of a conducting film which forms on the tube walls. This film appeared as a slight blackening, and its conductivity was made evident by the decrease in reson-

Fig. 3. Experimental arc tube.

ance current in the tuned circuit when the unexcited tube was placed between the condenser plates. That this film comes from the oxide cathode was proved by its absence in the next tube which had a hot tungsten filament. This tube, illustrated in Fig. 3, was a long cylinder of uniform internal diameter, 3.0 cm. The lower portion, containing a small quantity of mercury, was immersed in a water vath for pressure control. A short distance above the cathode was a ring electrode intended to be used as an auxiliary anode but soon abandoned. Thirty cm above this were two probes. One was a tungsten wire of 0.127 cm diameter and 1.87 cm long placed in the axis of the tube. The other

¹⁴ I. Langmuir and H. Mott-Smith, Jr., *Gen. Elec. Rev.*, **27**, 449, 538, 616, 762 (1924); H. Mott-Smith, Jr. and I. Langmuir, *Phys. Rev.* **28**, 727 (1926); L. Tonks and I. Langmuir, *Phys. Rev.* **34**, 876 (1930).

was a square molybdenum plate, 1.95 cm on a side, on the tube wall opposite the probe and bent to fit the wall. These probes were intended to measure the intensity of ionization in the arc by well-known methods.¹⁴ The main anode, a hollow cylinder, was 8 cm above these probes. The high frequency field was applied to the uniform column midway between the probes and the auxiliary anode by external electrodes of various shapes and sizes.

Initially a parallel wire system was connected with the external electrodes, later a small single loop inductance with variable condenser in series was employed, but finally a Lecher system consisting of two brass rods each 0.422 cm in diameter, spaced 3.90 cm on centers, and 180 cm long, was used for most of the measurements. The complete arrangement is shown schematically in Fig. 4. The Lecher system was tuned with a moveable bridge which consisted essentially of a low-resistance vacuum thermocouple of 2.6 ohms d.c. resistance. To prevent reflection effects from the free end of the Lecher sys-

Fig. 4. Apparatus for observing ionized-mercury resonance.

tem, a short-circuiting bridge was attached to the thermocouple bridge and some 16 cm back of it, so that the two moved together. This 16 cm of conductor acts as a high impedance shunt to the thermocouple at all wave lengths used and effectively prevents any free-end oscillations without affecting the thermocouple calibration.¹⁵ Stray effects arising from bringing the hand near to the free end of the Lecher system were minimized by by-passing the capacity currents along the thermocouple-to-galvanometer leads direct to the shorting bridge through small condensers.

A split-anode magnetron of Type FH-11 which can generate powerful oscillations up to 4×10^8 herz¹⁶ was used as oscillation source. It was found more convenient to vary the arc current than to vary the frequency of the oscillator, since the e.m.f. in the Lecher system circuit then does not vary.

The earliest experiments showed two resonance frequencies in the plasma. In view of H. Gutton's single resonance, it was thought that this might arise in some way from the distributed excitation of the Lecher system together with its distributed inductance and capacity. With this in mind, a circuit with

¹⁵ Paper to be submitted to I.R.E. Proc.

¹⁶ W. C. White, *Electronics* 1, 34 (1930).

lumped impedances was tried and as the same effect was observed, it was concluded that the double resonance was a property of the plasma itself.

Too high an excitation of the plasma circuit resulted, as pointed out by C. Gutton, in additional ionization in the vicinity of plasma resonance which was often evident visibly by increased light from the region of the arc between the external electrodes. Such effects made measurements erratic and difficult of interpretation so that it was found best to work with very low excitation.

For the higher arc currents the tungsten wire cathode had to be run very hot. When it happened occasionally that it was too cool, the arc changed its appearance and the oscillation readings were erratic and quite different from the other condition. Too cool a cathode gives temperature-limited instead of space-charge-limited emission, the cathode drop increases, and the primary electrons, instead of ionizing the gas and causing glow on the anode side of the cathode only, penetrate down the tube and cause glow there also. With a plentiful supply of primary electrons, the cathode drop exceeds the ionizing potential only slightly so that although the electron at the cathode sheath edge has sufficient energy to ionize, the normal decrease in plasma potential as the electron moves away from the cathode is sufficient to bring its energy below the ionizing value. Of course, toward the anode, the gradient in the arc speeds up the electrons, but in the opposite direction ionization will be prevented. If, however, the electrons have several volts excess energy, as they have with temperature-limited currents, they are able to maintain a plasma even in the absence of an accelerating field in it. The change in oscillation readings undoubtedly arises from the change in arc conditions, and the fluctuations may be caused by line voltage variations which here appear as a variable cathode drop of about the same magnitude as the voltage variation itself, whereas with a hot enough cathode they cause only a small fractional change in arc current.

IV. RESONANCE CHARACTERISTIC MEASUREMENTS

In taking a resonance characteristic, the oscillation frequency of the magnetron oscillator was first fixed by adjusting the position of the bridge on the parallel conductors which, connected to the two anode sections of the magnetron, form the resonant circuit of the oscillator. The oscillation amplitude was fixed at a suitable value by adjusting the anode voltage, anode current (through filament current) and magnetic field of the magnetron. These three quantities were carefully maintained constant. The half wave-length was found from the separation of two successive nodes on a second Lecher system which could be coupled to the oscillator. This value agreed within 2 percent with the value found on the measuring system itself. The difference, which arises from the presence of the wood support in the measuring system, is small enough to be negligible in the present work.

The appendix of the arc tube was then immersed in a Dewar flask containing water at a temperature to give the desired mercury pressure.

With no arc in the tube, the resonance position of the bridge on the meas-

uring system and the thermocouple galvanometer reading were recorded. The arc was then started and the same readings were made at arc currents increasing roughly in a geometric ratio.

Fig. 5. Resonance characteristic of ionized mercury vapor.

The results of such a series of measurements are shown in Fig. 5. The two resonance points at 7.5 and 21.5 m.a., to be denoted as *a*- and *b*-resonances, respectively, are accompanied by the current minima expected at a shunt

Fig. 6. Electrode volt-ampere characteristics for determining the electron density in the arc.

resonance. Excluding the immediate neighborhood of a resonance, the continual increase in s with increasing ionization intensity gives qualitative confirmation of the continual decrease in K_p with increase in N as required by Eq. (14). The variation in resonance current above 80 m.a. is not understood.

In order to compare the experimental results with the theoretical, it was necessary to determine the ionization intensity as a function of arc current. It developed that the wall electrode, Fig. 3, was unsuited to this purpose since the wall sheaths were too thick over the greater range of arc current. Accordingly, the cylindrical electrode w was employed for this purpose. Fig. 6 exhibits two plots of a typical volt-ampere characteristic. Fig. 6a is the semi-log plot which yields electron temperature and space potential. Fig. 6b is the $i^2 - V$ plot, the "slope" of which gives the electron density. Bearing in mind the ideal shape of this curve as shown by f^2 Fig. 7,¹⁷ it is possible to make a

Fig. 7. Theoretical (f^2) volt-ampere characteristic and its approximation $[4(1+\eta)/\pi]$.

very good guess at the straight line whose slope is significant in the following way. This line intercepts the V -axis at the space potential less kT_e/e , the potential corresponding to the electron temperature. The space potential is -3.5 v, $kT_e/e = 2.5$ v, whence the intersection is at -6 v. The upward bend above zero volts is obviously due to ionization in the sheath. Very little latitude is thus left for drawing the asymptote of the ideal characteristic. As drawn, the slope is $4.3 \times 10^{-8} \text{ amps}^2 \cdot \text{v}^{-1}$ which gives¹⁸

$$n_e = 3.32 \times 10^{11} S^{1/2} / A = 3.32 \times 10^{11} \times 2.07 \times 10^{-4} / 0.080$$

$$= 8.6 \times 10^8 \text{ electrons} \cdot \text{cm}^{-3}$$

Like measurements at other arc currents and mercury pressures gave additional points on the curves of Fig. 8. Of course, at the higher pressures, special care was taken that the tube temperature at all points never fell below the appendix temperature.

Fig. 8. Electron density in the arc as a function of arc current for different appendix temperatures.

With these data it became possible to correlate the frequency impressed on an ionized gas with the ionization density. The results of several resonance characteristics have been incorporated in Table I and Fig. 9. The "Theoretical Curve—Plane Plasma" is a plot of the equation $\nu = 8980 N^{1/2}$, ($\omega_0 = \omega$ or

$\eta = 1$ in other forms). It gives the theoretical relation between ionization and plasma-resonance frequency for a plane plasma. The "Theoretical Curve—Cylindrical Plasma" is a plot of $\eta = 2$ and gives the same relation for the cylindrical plasma. The *a*-resonance and *b*-resonance curves show the observed behavior of the *a*- and *b*-resonance conditions in a 2.2-bar arc. It is

to be noted that the actual resonance frequency lies within 30 percent of the theoretical and that the slope of the straight lines is 0.42 and 0.45 compared to a theoretical 0.50. The aa -resonance is one which appeared at lower ionization densities in cases where the applied field was decidedly non-uniform. While it is possible to imagine that the b -resonance may arise primarily from the response of the outer portions of the plasma, and the a -resonance from the axial portion, it is rather difficult to account for a third resonance corresponding either to a still higher electron density or to a configuration approaching more nearly to the plane case.

Fig. 9. Comparison of experimental and theoretical plasma-resonance frequencies.

The plasma resonance was found to be somewhat dependent on the gas pressure in the arc. Fig. 9 shows that a 14-fold pressure change caused a 2.2-fold change in resonant density. The resonance density thus varies roughly as the 0.3 power of the pressure. Compared to its variation with the square of the frequency, this is seen to be a small change which may arise from second order effects. It is probably significant that both a - and b -resonances were affected in the same ratio.

Although exact agreement of theory with experiment is lacking, it seems possible that the method used here may be useful in investigating electron concentration in cases where other methods fail. In recent unpublished work with Ne discharges, for instance, C. G. Found in this laboratory was found that the simple interpretation of probe characteristics fail, probably on account of the specific action of metastable atoms, whereas the present method appears to be directly applicable.

VII. DEMONSTRATION THAT $K_p \propto 1 - \omega_0^2/\omega^2$ IN THE RANGE $\omega_0^2 > 2\omega^2$

It has been remarked that Eq. (29) can give a direct test of the specific inductive capacity formula. The δL 's refer to inductance changes but, in connection with the Lecher system, they may just as well apply to the small changes in tuning length which have been found. Again, since tests have shown that N is very nearly proportional to i_A , we may interpret Eq. (29) as requiring that the reciprocal change in Lecher system tuning length caused by

increasing the arc current from zero to i_A shall be a linear function of the reciprocal of i_A , insofar as θ/θ_∞ is constant. The solid dots of Fig. 10 are plotted in this way from the same data as Fig. 5. At 40 amp⁻¹ the imaginary part of K_p is no longer negligible so that Eq. (29) no longer applies, and at the lower values of i_A^{-1} , the curvature of the plot indicates that a correction for variation of θ is necessary.

This correction has been made in the following manner. If the plasma occupies a radius $a-x$ in the tube of radius a , then $\theta/\theta_\infty = (a-x)^2/a^2$ since x , the sheath thickness, approaches zero as i_A approaches infinity. Thus, to a first approximation,

$$\Delta\theta/\theta_\infty = (\theta - \theta_\infty)/\theta_\infty = -2x/a.$$

Fig. 10. Analysis of the resonance characteristic in Fig. 5.

Now x is related to I_p the positive ion current density to the wall through the space charge equation

$$I_p = 2.34 \times 10^{-6} V^{3/2} / 600 x^2$$

or

$$x = 6.25 \times 10^{-5} V^{3/4} I_p^{-1/2}$$

where V is the potential drop in the wall sheath and 600 is $(m_p/m_e)^{1/2}$. Now I. Langmuir and H. M. Mott-Smith, Jr., have found¹⁹ that $I_p \propto i_A^{1.2 \text{ to } 1.3}$ and in the present tube I have found the relation to approximate

$$I_p = 1.08 \times 10^{-3} i_A^{1.4}$$

With $i_A = 0.060$ amp, it was found that $T_e = 28,600^\circ$ whence²⁰

¹⁹ I. Langmuir and H. M. Mott-Smith, Jr., G. E. Rev. 27, 764 (1924).

²⁰ L. Tonks and I. Langmuir, Phys. Rev. 34, 898 (1929).

$$V = 6kT_e/e = 6 \times 28,600/11,600 = 14.8v$$

Assuming that V changes but little with i_A (T_e changes but slowly) these equations lead to

$$\Delta\theta/\theta_\infty = -0.0191 i_A^{-0.7}.$$

Substituting $1 + \Delta\theta/\theta_\infty$ for θ/θ_∞ in Eq. (29) we have

$$(1 - 0.0191 i_A^{-0.7}) \delta L_r^{-1} = (2N_\omega/\delta L_\omega)(\phi N)^{-1} - \delta L_\omega^{-1}.$$

Thus the δL_r^{-1} coordinate of each point should be decreased by an amount directly calculable from i_A . The fractional corrections were tabulated for a series of values of i_A^{-1} and these were applied in several cases to the smooth curve through the experimental points. As in Fig. 10, the resulting curve is always a straight line, the continuation of which intercepts the δL_r^{-1} axis very near to the actual b -resonance, thus confirming Eq. (14). Later Fig. 11, showing θ/θ_∞ as a function of i_A , was plotted and was found useful in subsequent calculations.

Fig. 11. Fraction of tube cross-section occupied by plasma.

The method here employed, by not requiring that the plasma fill the whole dielectric space, avoids the difficulties of interpretation encountered by Appleton and Childs²¹ because of the formation of positive ion sheaths.

VIII. DETAILED ANALYSIS OF Hg RESONANCE CHARACTERISTICS

The resonant Lecher system length as a function of arc current and the thermocouple current as a function of arc current are the two characteristics so far mentioned. Another characteristic which can be obtained is the equivalent series resistance of the composite condenser.

It can be shown¹⁵ that the resonance curve of a Lecher system readily lends itself to determinations of resistance. Let I_0 be the maximum (resonance) current in the thermocouple on the movable bridge and let I be the current at any nearby position s . The values of $[I^{-2} - I_0^{-2}]^{1/2}$ plotted against s give a straight line whose slope S_i in amp.⁻¹ cm⁻¹ is a measure of the resistance in the circuit. The relation is

$$R \cos^2 (2\pi s_r/\lambda) = 2\pi Z_0/S_i I_0 \lambda - R_t \quad (30)$$

where s_r is the effective length of Lecher system at resonance, R is the equivalent series resistance of the composite condenser, and R_t is the thermocouple resistance, the distributed resistance of the system being neglected.

²¹ Appleton and Childs, Phil. Mag. 10, 969 (1930).

R_t was determined with no current in the arc. The resonance curve at the first resonance, together with $(I^{-2} - I_0^{-2})^{1/2}$ are shown in Fig. 12. Resonance occurred at 11.77 cm. The next resonance occurred at 89.39 cm, giving a wave-length, λ , of 155.2 cm. This compares with 158 cm measured on a sys-

Fig. 12. Lecher system resonance curve and its analysis.

tem almost completely free of excess distributed capacity. The difference is too small to warrant detailed corrections, but in each case where λ appears the value which seems to be the more appropriate will be used.

Fig. 13. Resonance characteristic for $\lambda = 158$ cm.

From the figure $S_t = 143$, $I_0 = 0.020$ amp., using $Z_0 = 353$, and $\lambda = 155.3$ we have $R_t = 4.98 \omega$. At 89.39 cm the resonance curve yields $R_t = 6.81 \omega$. The differences arises from the distributed resistance of the system, but as long as measurements are confined to the neighborhood of the first resonance, it will doubtless be accurate enough to include this resistance in R_t .

Fig. 13 shows the resonance characteristic at this same frequency. For each value of arc current sufficient points (not less than 5) on the resonance curve were taken to permit the slope S_l to be determined. The bridge shortening had been determined by the double-hump resonance method¹⁵ so that s_r could be found from the bridge position. Zero correction and bridge shortening together amounted to +9.2 cm. R was then calculated from Eq. (30), and the values obtained appear in Fig. 14.

Fig. 14. Analysis of resonance and resistance characteristics.

Ranges: ξ_0 from 3.0×10^{-4} to 2.1×10^{-3} cm. $\eta/2$ from 0.51 to 6.2. i_A/i_{AR} is on the same scale. R from 14 to 320 ohms. S/w from 0.02 to 0.33.

It remains to interpret R and s_r in terms of the damping coefficient of the electron oscillations and the density of ionization. The specific inductive capacity K_0 of the composite condenser can be found from s_r readily since

$$\begin{aligned} (\omega K_0 C_0)^{-1} &= Z_0 \tan l \\ (\omega C_0)^{-1} &= Z_0 \tan l_0 \end{aligned} \quad (31)$$

where $l = 2\pi s_r / \lambda$ and l_0 is the value of l for $N=0$ ($K_0=1$). It follows that

$$K_0 = \tan l_0 / \tan l \quad (32)$$

Thus the problem becomes that of a condenser of a complex capacity $C_0 K$ (Eq. (26)) equivalent to the combination, $C_0 K_0$ in series with R ;

$$(j\omega KC_0)^{-1} = R + (j\omega K_0 C_0)^{-1}. \quad (33)$$

Substituting from Eq. (26) and separating into real and imaginary parts we have

$$\begin{aligned} (2S/\omega)(1 - K_0^{-1}) - (\eta/2)\omega C_0 R(1 + \theta) &= -\omega C_0 R \\ (2S/\omega)\omega C_0 R + (\eta/2)[1 - \theta - K_0^{-1}(1 + \theta)] &= 1 - K_0^{-1} \end{aligned}$$

whence

$$S/\omega = \theta\omega C_0 R/D \quad (34)$$

$$\eta/2 = [(1 - K_0^{-1})^2 + \omega^2 C_0^2 R^2/D] \quad (35)$$

where

$$D = (1 - K_0^{-1})[1 - K_0^{-1} - \theta(1 + K_0^{-1})] \quad (36)$$

The necessary data are all available. The calculations of R and K_0 have been discussed, $\theta_\infty = 0.056$, and $\omega C_0 = 0.00250$ by Eq. (31). The values of S/ω and $\eta/2$ calculated in this way are shown in Fig. 14. Since theory requires that

$$\eta/2 = N/N_{\text{resonance}} = i_A/0.031$$

very nearly, $i_A/0.031$ has been plotted for comparison. The higher values of $\eta/2$ for the larger values of i_A may well be due to an error in θ_∞ . This failed to appear in Fig. 10 since there only relative values of θ were involved. A change to $\theta_\infty = 0.053$ would make $\eta/2$ coincide with $i_A/0.031$ at $i_A = 145$ m.a. and would not spoil the present agreement near resonance. It thus appears that the experimental results confirm the oscillation theory, not only to one side of the resonance region, but even through this region. The check is surprisingly good in view of the non-uniformity of the plasma.

It may be that this factor has more influence on the value of S/ω . Salpeter¹⁰ has shown that collisions of electrons with gas atoms introduce a damping factor in the electron equation of motion and S is then the number of collisions per electron per second. In the present experiment with an electron mean free path of about 3 cm^{22} and a speed of $1.22 \times 10^8 \text{ cm/sec}$ ($T_e \sim 30,000^\circ$) $S = 4.1 \times 10^7$. For a 158 cm wave, $\omega = 1.19 \times 10^9$, whence $S/\omega = 3.4 \times 10^{-2}$. On the other hand the electrons are reflected much more frequently from the sheath on the tube wall. Such reflections should, on the average, destroy the directed momentum just as collisions with gas atoms do. In the tube of 3.0 cm diameter, the mean free path for wall collisions may be estimated at 1.5 cm, and the effective speed at $[1.22/(1.5)^{1/2}] \times 10^8 \text{ cm/sec}$, whence, due to this cause, $S/\omega = 0.056$. Adding the two dissipation factors we obtain, finally, $S/\omega = 0.090$, a value of the same order as found experimentally. Since the gas density and the electron temperatures change but little with a change in arc current, S/ω should, theoretically, be constant. Aside from experimental errors, which undoubtedly affect the values when R becomes comparable with R_t , that is, above $i_A = 50$ m.a., the non-homogeneity of the plasma may possibly account for a large part of the variation. The high 15-m.a. value may arise from the proximity to the α -type resonance.

²² T. J. Killian, Phys. Rev. 35, 1238 (1930), Table I.

Expressed as a decrement, δ ,

$$\delta = \pi S/\omega$$

whence, theoretically, $\delta = 0.28$ and the amplitude of a free oscillation would decrease by 24 percent per cycle.

The analysis we have made makes it possible to calculate the electric field in the plasma and the amplitude of the electron motions. From Eqs. (16) and (19)

$$E_p/E_e = (K + 1)/(K_p + 1)$$

from which, using Eq. (20), we find

$$E_p/E_e = \frac{K - 1 - \theta(K + 1)}{-2\theta} = \frac{1 - K^{-1} - \theta(1 + K^{-1})}{-2\theta K^{-1}}$$

for the ratio of the field strength in the plasma to that in the composite condenser. Substituting for K from Eq. (33) we have

$$E_p/E_e = \frac{1 - K_0^{-1} - \theta(1 + K_0^{-1}) - j\omega C_0 R(1 + \theta)}{-2\theta(K_0^{-1} + j\omega C_0 R)} \quad (37)$$

or, in absolute magnitude

$$E_p/E_e = \frac{1}{2\theta} \left\{ \frac{[1 - K_0^{-1} - \theta(1 + K_0^{-1})]^2 + [\omega C_0 R(1 + \theta)]^2}{K_0^{-2} + (\omega C_0 R)^2} \right\}^{1/2} \quad (38)$$

Now

$$E_e = V/d$$

where V is the condenser voltage and $d (= 7 \text{ cm})$ is the plate separation. Also

$$v = i_c Z_0 \tan l \quad (39)$$

where i_c is the condenser current, and

$$i_c = i_t \cos l \quad (40)$$

where i_t is the thermocouple current, whence it follows that,

$$E_e = (i_t Z_0/d) \sin l \quad (41)$$

The equation of motion of an electron on which Eq. (4) was based is

$$\ddot{\xi} + S\dot{\xi} = (eZ/m)e^{j\omega t}$$

whence the amplitude of motion is

$$\xi_0 = 2^{1/2} e E_p / m \omega^2 (1 + S^2/\omega^2)^{1/2}$$

on the understanding that E_p is the r.m.s. value. In practical units

$$\xi_0 = 2.50 \times 10^{15} E_p / \omega^2 (1 + S^2/\omega^2)^{1/2}$$

and for the present case ($\omega = 1.194 \times 10^9$)

$$\xi_0 = 1.75 \times 10^{-3} (1 + S^2/\omega^2)^{-1/2} E_p.$$

Only at $i_A = 15$ m.a. does S/ω make an appreciable contribution to the radical so that throughout most of the range ξ_0 is proportional to E_p . ξ_0 is plotted in Fig. 14 and it is interesting to note that the greatest amplitude was 1/500 cm. For this amplitude the maximum velocity is $\omega/500 = 0.6 \times 10^6$ cm/sec corresponding to a voltage of $10^{-4}v$.

The valley in the ξ_0 curve between 21 and 42 m.a. certainly arises from the effect of the increased resistance near plasma resonance in decreasing the resonant current in the Lecher System.

The values of S/ω given in Fig. 14 are based on simultaneous measurements of tuning length and resistance. But on the assumption of a uniform plasma, the Lecher System characteristic is, by itself, capable of giving a value of S/ω by using either the maximum variation in L_r (Lecher System tuning length) or the change in i_A accompanying this variation. By setting the derivative of Eq. (27) with respect to η (assuming that variations in θ and ϕ are negligible) equal to zero, we obtain the condition for the extreme values of L_r :

$$\eta' = 2 \{ 1 + S^2/\omega^2 \pm [(1 + S^2/\omega^2)^2 - (1 + S^2/\omega^2)]^{1/2} \}. \quad (42)$$

The difference between the values of η' at the extremes of L_r is, therefore,

$$\Delta\eta' = \phi(N_2 - N_1)/N_\omega = 4[(1 + S^2/\omega^2)^2 - (1 + S^2/\omega^2)]^{1/2} \quad (43)$$

Solving for S/ω , noting that $\Delta\eta'/4 \ll 1$,

$$S/\omega = \Delta\eta'/4. \quad (44)$$

At plasma resonance, theory (Eq. (17)) requires that

$$\eta' = 2 = \phi N_r / N_\omega \quad (45)$$

where N_r is the electron density at plasma resonance ^{7.5}. Combining Eqs. (43), (44), and (45) we have

$$S/\omega = (N_2 - N_1)/2N_r \quad (46)$$

or, in terms of arc current

$$S/\omega = (i_{A2} - i_{A1})/2i_{AR} \quad (47)$$

where i_{AR} is the arc current at plasma resonance. The other relation mentioned is

$$S/\omega = [\delta L_\infty / (L_1 - L_2)] \theta \phi_\infty / \theta_\infty \phi \quad (48)$$

and is deduced by eliminating η' between Eqs. (27) and (42).

Applying these to the present case, Fig. 13 gives,

$$S/\omega = (34.5 - 25.)/2 \times 31 = 0.15$$

in the one case and

$$S/\omega = [1.3/(15 - 6.5)] \times 0.79 = 0.12,$$

in the other. These values are roughly twice as large as the maximum values shown in Fig. 14. This fact together with the asymmetry of the resonance characteristic indicates that other factors may be important here. The analysis of Section II shows, for instance, that if frictional factors were absent, the whole spread $\Delta\eta'$ could be due to a 30 percent variation in electron density.

Fig. 15. Effect of transverse magnetic field on plasma-resonance.

IX. THE EFFECT OF A MAGNETIC FIELD

Appleton and Childs²¹ have observed an absorption maximum arising from a constant magnetic field at right angles to the impressed electric field and Benner²³ has observed an accompanying change in dielectric constant. In neither of these cases was the electron density involved as a vital factor. Gutton,⁷ however, observed a doubling of the resonance when he applied such a magnetic field to the ionized gas.

Resonance characteristics have been made of the mercury-vapor plasma at a succession of magnetic fields. The field used was that from a pair of Helmholtz coils so placed that the oscillating portion of the positive column was in the uniform part of the field. The field was calculated from the coil dimensions as $8.1 \text{ gauss} \cdot \text{amp.}^{-1}$. The characteristics obtained for a frequency of 1.605×10^9 herz are shown in Fig. 15. The dashed portions of the curves

²³ S. Benner, *Die Naturwissenschaften*, 17, 120 (1929).

are those which are doubtful, either because experimental points were not obtained or because the points which were obtained were very uncertain on account of the flatness of the resonance curve. The splitting of the *b*-type resonance is clearly seen for magnetic field strengths from 20.2 gauss up, until at 48.6 gauss the curve begins to take on a more complicated form, due perhaps to the approach to the purely magnetic resonance of Appleton and Childs and Benner. For the frequency used this would occur with a magnetic field of $H = 2\pi mc\nu/e = 56.8$ gauss.

The expectation is that the two resonances will lie one to either side of the original. In the figure only the lower current resonance shows displacement for the smaller magnetic fields. This arises from the concentration of the arc by the magnetic field, which results in higher electron densities for the same arc current when the magnetic field is present.

In analyzing these curves we might proceed along the lines already developed, but more insight into the processes involved can be gained by examining the whole phenomena from a less formal point of view.²⁴

Consider a uniform plasma bounded by the sheaths on two plane parallel non-conducting boundary walls. A uniform displacement of the electrons by an amount, ξ , throughout the plasma will develop a surface charge density of

$$\sigma_e = Ne\xi$$

at the sheath edge which exerts the restoring force

$$F_p = -4\pi Ne^2\xi$$

on each electron throughout the plasma. The electrons in the plasma are thus capable of free simple harmonic oscillations in accordance with the equation of motion

$$4\pi Ne^2\xi + m\ddot{\xi} = 0$$

whence the natural frequency is that found for plasma-electron oscillations, Eq. (1).

If the plasma is bounded by a cylinder, and the uniform parallel electron displacements are perpendicular to the axis, the restoring force is only

$$F_c = F_p/2 = -4\pi Ne^2\xi/2$$

and if the boundary is spherical

$$F_s = F_p/3.$$

The natural frequency is lowered in these cases, as has already been seen in the analysis of Section IV.

In proceeding to the case of superposed magnetic field, we may denote this shape factor by ϕ ,

$$F = -4\pi Ne^2\phi.$$

²⁴ J. J. Thomson, *Phil. Mag.*, 11, 697 (1931) develops the same viewpoint along somewhat different lines.

This factor may be different in the ξ -direction from what it is at right angles to both this direction and the magnetic field. For instance, taking ξ perpendicular to infinite parallel plane boundaries, $\phi_\xi = 1$, while, introducing ζ for the electron displacement perpendicular to both ξ and H , $\phi_\zeta = 0$. In general, then, both shape factors must be included in the treatment. We have,

$$F_\xi = -4\pi Ne^2 \phi_\xi \ddot{\xi} - (eH/c) \dot{\zeta} = m \ddot{\xi}$$

$$F_\zeta = -4\pi Ne^2 \phi_\zeta \ddot{\zeta} + (eH/c) \dot{\xi} = m \ddot{\zeta}.$$

Putting $\xi = \xi_0 e^{i\omega t}$, $\zeta = \zeta_0 e^{i\omega t}$, $\omega_H = eH/mc = 1.767 \times 10^7 H$, $\omega_0^2 = 4\pi Ne^2/m = 3.18 \times 10^9 N$ and eliminating ζ_0 and ξ_0 , we have

$$(\omega^2 - \phi_\xi \omega_0^2)(\omega^2 - \phi_\zeta \omega_0^2) = \omega^2 \omega_H^2,$$

as the condition for resonance. For a circular cylinder with axial magnetic field, $\phi_\xi = \phi_\zeta$ from symmetry, so that we may write

$$(\omega^2 - \phi \omega_0^2)^2 = \omega^2 \omega_H^2.$$

Since N was varied in the experiment to obtain resonance, we solve for the two values of ω_0^2 , say ω_1^2 and ω_2^2 , which satisfy this equation. It is readily found that

$$(\omega_2^2 - \omega_1^2)/(\omega_2^2 + \omega_1^2) = \omega_H/\omega$$

so that, in terms of arc currents at resonance, i_{A1} and i_{A2} ,

$$(i_{A2} - i_{A1})/(i_{A1} + i_{A2}) = \omega_H/\omega.$$

Table II based on Fig. 15 shows the agreement between calculated and observed resonance behavior. Columns 4 and 5 should agree. The bad discrepancy

TABLE II. Analysis of magnetic effect.

H , (gauss)	0	10.1	20.2	24.3	26.0	32.4	40.5	44.5	48.6
i_{A1} , (m.a.)	25	22?	13	11	9	7?	4.5?	3.5?	2.
i_{A2} , (m.a.)			27	22	27	32	37		37?

ω_H/ω			0.35	0.43	0.46	0.57	0.71		0.85

ancy at 24.3 gauss is doubtless due to an erroneous determination of the 25-m.a. resonance on that curve, since this curve fails to fall in line with the trend of all the others here. Otherwise the agreement is reasonably good.

THE ULTRAVIOLET ABSORPTION SPECTRUM OF
SULFUR DIOXIDEBY WILLIAM W. WATSON AND ALLAN E. PARKER
SLOANE PHYSICS LABORATORY, YALE UNIVERSITY

(Received April 27, 1931)

ABSTRACT

Measurements of spectrograms of the ultraviolet SO_2 absorption bands taken at different pressures, tube lengths and temperatures together with known infrared and Raman frequencies serve to locate the three fundamental vibrational series. Tables giving the band assignments to these sequences are included. The three lower state frequencies for infinitesimal amplitude are 1369 , 1164 and 610 cm^{-1} , while for the excited state the corresponding frequencies are 341 , 387 and 290 cm^{-1} . The types of addition series are discussed.

The excited state $\Delta\nu_v:v$ curves for $v < 4$ have a positive slope, while for $v > 4$ there is a sudden reversal to the usual negative anharmonic coefficient. The three ground state frequencies indicate a value of 34° for the half-angle at the apex of the SO_2 triangular model. Comparisons of the heats of dissociation estimated from the extended areas under the $\Delta\nu_v:v$ curves with thermal and spectroscopic data suggest the process $\text{SO}_2 \rightarrow \text{S} + \text{O}_2$ for the two symmetrical vibrations and $\text{SO}_2 \rightarrow \text{SO} + \text{O}$ for the asymmetrical vibration. The dissociation products appear to be the same in the two electronic states.

INTRODUCTION

UP TO the present time there has been but very little investigation of the details of the ultra-violet band systems of triatomic molecules. Great advances have been made in the study of diatomic molecular spectra with the aid of the quantum theory, but owing to their quite evident complexity, the spectra of polyatomic molecules have been avoided. Many of the ideas of molecular dynamics developed for diatomic molecules should be applicable to more complex molecules, however, and in addition there is now available much information on the fundamental vibrational frequencies of these molecules from their infrared and Raman spectra. Without this previous knowledge of the three fundamental frequencies of the ground state for molecules such as SO_2 and CS_2 , the vibrational quantum analysis of their complex electronic band systems would be all but impossible.

The infrared vibration-rotation absorption bands of sulfur dioxide have recently been measured by Bailey, Cassie, and Angus.¹ Their work shows that the three fundamental bands are at 1361 cm^{-1} , 1152 cm^{-1} , and 606 cm^{-1} , but since a sufficient number of harmonic bands were not observed, the fundamental frequencies for infinitesimal amplitude of vibration could not be computed. The first and third of these frequencies correspond to a vibrating electric doublet lying along the bisector of the vertical angle of the triangular structure, while the middle frequency corresponds to an effective electric

¹ C. R. Bailey, A. B. D. Cassie, and W. R. Angus, Proc. Roy. Soc. A130, 142 (1930).

doublet in a direction perpendicular to this bisector and in the plane of the triangle. Both the existence of a rather large permanent dipole moment and the indicated structure and intensity of these infrared bands lead to the conclusion that the SO₂ molecule is definitely triangular in shape with an acute angle at the apex. The Raman spectrum of gaseous SO₂ has been investigated by Bhagavantam² who found but one line at 1154 cm⁻¹, whereas for liquid SO₂ Dickinson and West³ find the three lines 1145.9 cm⁻¹ (strong), 1340.1 cm⁻¹ (medium, diffuse) and 524.3 cm⁻¹ (weak, diffuse). The last line is explained by Bailey, Cassie, and Angus as the difference 1152-606.

The ultraviolet absorption bands of sulfur dioxide have been referred to by Henri⁴ and others. The apparent predissociation limit at about λ 2525 (112,000 cal.) has been assumed by Henri⁵ to correspond to SO₂→SO+O, and on this basis he develops an energy equation with other known data to give the heat of dissociation of O₂ as 126,400 cal. (5.5 volts). This calculation has been discussed by Herzberg⁶; and we return to the question in our discussion below.

DESCRIPTION OF SPECTRUM

The ultraviolet absorption band systems of sulfur dioxide have been photographed with a Hilger *E*₁ quartz spectrograph, the gas being contained in a glass absorption tube 111 cm long, closed at the ends with quartz windows. The SO₂ was prepared by dropping HCl on to NaHSO₃, and was dried by passing through a long P₂O₅ tube. The source of continuous radiation for the background was the usual hydrogen discharge tube. The spectrograms with this 111 cm absorption cell were all taken with the gas at room temperature and at pressures varying from 80 cm to less than 1 mm Hg. Spectrograms were also obtained with a 27 cm absorption cell with the SO₂ at 1 cm Hg pressure and at the temperature of a solid CO₂-acetone mixture.

Fig. 1 is a reproduction of a series of spectrograms taken at various gas pressures with the longer absorption tube. To be noted are the evident strong series of band groups in the main absorption region, and the appearance of new bands at the long wave-length end at the higher pressures. These latter bands do not form a separate band system, as has been suggested by Henri⁵; but are associated with the main absorption system and represent transitions from vibrational levels with $v=1, 2$ and 3 of the ground electronic state. At the lower temperature the very weak band at 30961 cm⁻¹ is clearly the band of longest wave-length, suggesting that it is a 0,0 band, and there is considerable simplification in the region of strongest absorption. At the high frequency end of this system, absorption ceases at the lower pressures at about λ 2500, the last bands being rather diffuse but with no continuous absorption in evidence. Another SO₂ band system which we have not investigated extends from about λ 2350 farther into the ultraviolet. At pressures greater than

1 cm these two band systems are fused together, the absorption being continuous from the limit of the discrete bands to be seen in Fig. 1 to some point in the vacuum ultraviolet region.

Some of the stronger and more isolated bands at about $\lambda 3300$ were photographed at high dispersion with a 21-foot concave grating, but these spectrograms fail to resolve any of the rotational structure. Furthermore these SO_2 bands do not have a sharp head, but rather seem to fade out on both sides. In the measurement of the lower dispersion spectrograms, then, we could only set the cross-hair on the estimated center of the band or, in the case of broad bands produced by overlapping, the overall width was measured. This of

Fig. 1. Spectrograms of the ultraviolet SO_2 absorption bands taken with the Hilger E_3 spectrograph. The absorption path was 1 m, and the pressures were as indicated. To be noted are the group of bands at the red end of the high pressure spectrograms and the evident excited state sequences proceeding towards higher frequencies from 30961 at the lower pressures. Higher dispersion plates show that many of these apparently single bands are in reality groups of bands.

course limits the accuracy of the measurements, and entails a possible error in the interval between any two successive bands in the series referred to below, of say, 9 or 10 cm^{-1} .

VIBRATIONAL ANALYSIS

The regular and intense series of bands observable in the region from $\lambda 3200$ to $\lambda 2900$ on the spectrograms for the lowest SO_2 pressures can only be vibrational sequences in the excited electronic state. These and other series terminate on the long wave-length end at about $\lambda 3230$ in a region of bands of very low intensity, suggesting that the origin of the system is at about this frequency. Now in the high-pressure group to the red of this point the first strong band to appear with increasing gas pressure is at 28300 cm^{-1} . Assuming that this represents a transition from a lower vibrational level other than 0 of the symmetrical mode of vibration, another band is found at 29621 , 1321 cm^{-1} to the high frequency side, from which the interval to 30961 , which is the

long wave-length end of the strongest excited state sequence, is 1340 cm^{-1} . From these regularities as a starting point, the double array of bands originating in this (v_1', v_1'') mode of vibration as presented in Table I were found. Measurement towards the violet from the 28,300 band with differences characteristic of the asymmetric mode of vibration (1150 cm^{-1}), however, does not produce any correlation.

It was then to be assumed that the next strongest series of bands proceeding to the high frequency side of the origin is the $v_2''=0$ sequence belonging to the asymmetrical (1150 cm^{-1}) vibrational frequency. There is indeed a band at about this interval on the red side of each of these bands of the $v_2''=0$ sequence, and in this way the fundamental sequences given in Table II were developed. Now it is impossible to have these two double arrays of bands proceed from the same 0,0 band, although they must correspond to the same electronic energy change in the molecule. But if the two sets of frequencies are represented by an equation such as (1) with half-integral vibrational quantum numbers, they both yield the same electronic frequency $\nu_e = 31468$.

This affords experimental proof of the existence of zero-point vibrational energy. It is therefore not possible to represent these SO₂ bands by a double vibrational formula such as found by Henri and Howell⁷ for the ultraviolet absorption bands of phosgene.

Knowing the ν_e frequency and the third fundamental vibration frequency 606 cm⁻¹, for the lowest electronic state, it was possible to predict the 0,0 band frequency for this mode of vibration to within about 100 cm⁻¹ by assuming that the corresponding excited state frequency must lie within the limits 150 to 350 cm⁻¹. Investigation showed that for but one band, 31308, in this predicted interval did another band lie 606 cm⁻¹ to the red with still another spaced 600 cm⁻¹ further to the red. Placing this 31308 in Eq. (1) with $v_3' = v_3'' = 0$ the excited state vibrational interval was computed to be very closely 300 cm⁻¹. This proved to be correct, and the other bands in this third double array as given in Table III were easily arranged. This $v_3'' = 0$ sequence is not obvious from inspection of the spectrograms as for the other two $v'' = 0$ sequences. However, this is in agreement with the fact that the 606 cm⁻¹ fundamental absorption band in the infrared is much weaker than the other two.¹

These three sets of fundamental vibration progressions can be represented by an equation of the type

$$\nu = \nu_e + [a'(v' + \frac{1}{2}) + b'(v' + \frac{1}{2})^2] - [a''(v'' + \frac{1}{2}) + b''(v'' + \frac{1}{2})^2] \quad (1)$$

with $\nu_e = 31468$. For all three sets of progressions, however, the excited state differences first increase to a maximum at about $v' = 4$, after which they decrease in the regular manner (see discussion below). It is therefore necessary to use different a' and b' constants for the low and high values of v' . The mean values of the a and b constants which fit the three sets of band progressions are given in Table IV.

TABLE IV. Fundamental vibrational constants for SO₂ (cm⁻¹ units).

	ν_1	ν_2	ν_3
a''	1369	1164	610
b''	-11	-9	-2.3
a'	+341	+387	+290
b'	+14	+12	+3
a'	+556	+524	+350
b'	-7	-6	-7

All of the sequences in Tables I to III could be extended farther towards higher frequencies, but our accurate measurements do not extend into this region. However, it is obvious that these series account for only some 20 percent of the observed bands of which there are well over six hundred. Now only three fundamental frequencies are possible for a triatomic molecule, but we know from the study of the infrared bands of polyatomic molecules that addition frequencies occur. We have made plausible assignments of most of the

⁷ V. Henri and O. R. Howell, Proc. Roy. Soc. A128, 192 (1930).

remaining bands to various forms of addition series based on the three fundamental series, but these assignments are not unambiguous in many cases because of the density of bands and because of the lack of any guide such as the greater intensity of the $v''=0$ sequences of the main series. Our analysis shows however that there are addition bands present of the type for which addition of one or two quanta of any one of the three modes of vibration happens simultaneously in both electronic states to either of the other two main series. Some of the weaker bands are probably also due to an S isotope effect, but we have not been able to make any assignments on this basis.

DISCUSSION OF RESULTS

Fig. 2 is a plot of the course of the vibrational energy level differences in the three sets of excited state levels as a function of v . The unusual feature of these curves is the initial positive slope. During the accretion of these first

Fig. 2. Diagrams of the spacings of the excited state vibrational levels for the three fundamental modes of vibration. The interesting feature is the initial positive slope for each of the curves.

quanta of vibrational energy, the molecule, as it were, increases in stability, and then some rearrangement occurs after which the usual negative anharmonic term is operative. This phenomenon has been noted in only one instance for diatomic molecules, in the LiH spectrum⁸; but it is possibly of rather common occurrence for polyatomic molecules.⁹

In the ground electronic state of SO_2 the vibrational frequencies decrease in the usual manner with increasing v'' . But since this spectrum originates in absorption by a cold gas, only the levels $v''=0, 1$ and 2 are represented. The anharmonic coefficients b can therefore not be determined with great accuracy, but they do allow an approximate determination of the vibrational

⁸ G. Nakamura, *Zeits. f. Physik* 59, 218 (1930)

⁹ Positive slopes of the $\Delta\nu:v$ curves, but without the maximum and subsequent negative slope, have been reported by H. D. Smyth and T. C. Chow (Abstract, *Phys. Rev.* 37, 1023 (1931)) for CO_2 and by G. B. Kistiakowsky (*Phys. Rev.* 37, 276, 1931) for C_2H_2 .

frequencies for infinitesimal amplitude (the a'' constant in Eq. (1)) which could not be computed from the infrared absorption data.¹ Substitution of these three a'' frequencies in the determinant equation for the vibrational energy of a symmetrical triatomic molecule as given by Dennison¹⁰, yields for α the half-angle at the apex of the isosceles triangle (cf. Fig. 3), the approximate values of 34° and 51° . Owing to the intensity relations in the infrared bands requiring an acute angle,¹ the lower of these two values is to be chosen. The vibrational frequencies a' of the excited state, however, give only imaginary solutions for this angle when placed in this equation.

Some conception of the values of the heats of dissociation for the SO_2 molecule can be obtained from the determination of the areas under the $\Delta\nu_v:v$ curves extrapolated to the convergence limit. The areas under the extrapolations are a rather large part of the whole energy, thereby limiting the accuracy of the calculation. This is particularly true of the lower electronic

Fig. 3. Representation of the three fundamental SO_2 vibrations. *a*, the symmetrical 1369 cm^{-1} frequency; *b*, the asymmetrical 1164 cm^{-1} frequency; *c*, the symmetrical 610 cm^{-1} frequency. These three frequencies indicate α to be approximately 34° .

state values, but nevertheless the results of the computation are of some interest. One obtains the following heats of dissociation (excited state values are the sum of the areas under the curves of Fig. 2 and $\nu_e = 3.9$ volts):

Lower state: $H_{v_1} = 5.3$ volts (121,000 cal.)	
$H_{v_2} = 4.7$	" (107,000 cal.)
$H_{v_3} = 5.1$	" (118,000 cal.)
Excited state: $H_{v_1} = 5.2$ " (120,000 cal.)	
$H_{v_2} = 5.3$	" (121,000 cal.)
$H_{v_3} = 4.3$	" (99,000 cal.)

We picture the vibrations occurring after the manner of Fig. 3. For the two symmetric modes of vibration the dissociation products would be an S atom plus an O_2 molecule. One might expect a measure of agreement between these values and that obtained from thermal data. The heat of formation of SO_2 from sulfur vapor S_2 and O_2 is given as 69,260 calories. The heat of dissociations of S_2 is known from spectroscopic data to be 102,200 calories.⁵ Hence

¹⁰ D. M. Dennison, Phil. Mag. 1, 203 (1926).

The agreement with our lower state H_{v_1} and H_{v_3} values is better than could be expected.

For the asymmetric mode of vibration the dissociation is probably into $\text{SO} + \text{O}$. Now the heat of dissociation of SO has been determined for the normal state of the ultraviolet SO band system by Henri and Wolff¹¹ as 148,000 cal. The value for O_2 should be approximately 5.1 volts.⁶ Therefore one can write the energy equation

This requires H_{v_2} to be about 90,000 cal. as against our value of 107,000 cal. The discrepancy may be in part due to the fact that the SO radical after the dissociation has a considerable amount of vibrational energy. In fact, the distortion in the dissociation process should most certainly produce some vibration of the SO , the energy of which should be subtracted from our extrapolated H_{v_2} value to give the true heat of dissociation.¹²

Judging from the relative values of the computed heats of dissociation for the two electronic states of SO_2 involved, apparently the dissociation products are in both states the same. But because of the possibility of a considerable error in these values due to the large extrapolation, this statement should be made with reservations.

A considerable amount of information may be expected from the study of the ultraviolet band systems of the simpler polyatomic molecules. When the bands have sharp heads, as for example in the CS_2 system on the analysis of which we are now engaged, the accuracy of the measurements can be considerably improved. For absorption bands the rotational fine structure may not be resolvable even at the highest dispersion. But if obtained as emission bands, the theoretical resolving power of a large grating can be more nearly approached, and the rotational line pattern of some of the simpler polyatomic bands may be obtained. In that event the needed test of the theoretical treatment of the rotator with three different moments of inertia as given by Kramers and Ittmann¹³ and others may be made.

FURTHER STUDY OF THE ABSORPTION OF INFRARED
RADIATION BY WATER VAPOR

BY E. K. PLYLER AND W. W. SLEATOR

UNIVERSITY OF MICHIGAN

(Received April 8, 1931)

ABSTRACT¹

Making use of a spectrometer with a salt prism and echelette gratings, and a Moll thermal relay, the authors have reexamined with increased resolution the four absorption bands of water vapor whose centers lie near 1.87μ , 2.66μ , 3.15μ and 6.26μ . The new study has greatly increased the number of measured lines. Near 6.26μ and 3.17μ the number has been more than doubled. The new lines are mostly weak ones, but the work has resulted in a better determination of the wave-lengths of many strong lines, which now appear as sharp single effects freed from the former confusion in which several lines were taken for one. The center of the harmonic of the band at 6.26μ is seen to be better placed at 3.168μ than it was formerly at 3.11μ . It also appears that this band has no absorption at the center, and is of the same type as the fundamental.

INTRODUCTION

THE work to be described in this paper was done at the University of Michigan during the summers of 1928, and 1929, and the fall of 1930. It was found, after working over the atmospheric absorption near 2.66μ , that the apparatus now available, because of the higher resolution of which it is capable, permitted a more precise and complete analysis of the absorption spectrum of water than had been given in the papers by Sleator² and Sleator and Phelps.³ A real advance may be claimed when what was formerly considered to be, and measured as, a single line, proves, as the present work in many cases shows, to consist of three or four. Furthermore many of the lines now given in the charts and tables are very sharp, and many more lines show in these figures quite the same shape, and this indicates that they are single effects, and not likely to break up on more refined analysis. On account of this better identification, and on account of more accurate calibration now employed, there is reason to think that the wave-lengths here given are more precise than the earlier numbers, which they should supplant.

Of the bands here studied, those near 6.26μ and 2.66μ have been classified as fundamentals, with vibration frequencies ν_1 and ν_2 respectively, the latter having a zero branch, the former being double. The frequency at 1.87μ represents the combination $\nu_1 + \nu_2$ and that at 3.16μ is $2\nu_1$, so that this band is the first harmonic of that at 6.26μ . A classification of the known absorption bands of water has been given by Hettner.⁴

EXPERIMENTAL PROCEDURE

The apparatus used was the compound spectrometer with sodium chloride prism and grating in series, of the type commonly used for work in the infra-red, constructed and described by Meyer.⁵ The grating used for the band at 6.26μ had 2,880 lines per inch, that employed for the others had 7,200. They were ruled by Barker. The thermopile was constructed and has been described by Firestone.⁶ By adjusting the lamp which illuminates the thermocouple in the Moll relay the amplification factor could be controlled, and could be brought up to 300 by using a current of 3.5 amperes. At this amplification Brownian motion could be observed, so that four or six, sometimes eight, independent deflections of the galvanometer were taken at each setting of the grating. Small vibrations of the building due to the wind and other things affected the galvanometer. It was necessary to take most of the readings at night.

The spectrometer circle was set at a certain angle, then the deflections were read, then the circle was turned 15 seconds, and deflections taken again. This was continued through the region—that at 6.26μ extended over about 6 degrees. The graph which revealed the absorption lines was plotted with average deflection as ordinate, and angle or wave number as abscissa. The determination of the wave-length of a line depends in most cases upon three independent energy curves—in some cases more.

The step by which the circle was advanced between successive galvanometer readings was less than the angular value of the slit itself. In Table I, the data of which are given separately with the different figures, the degree of resolution used in the different bands is shown by giving the wave-length interval included in the second slit. Values used by Sleator and Phelps are shown for comparison.

TABLE I. *Effective resolving power.*

Region	Slit width (A.U.)	Slit width (cm^{-1})	Slit width (Sleator and Phelps) (A.U.)
1.87μ	4.1	1.16	8
2.66μ	3.1	0.44	
3.15μ	4.5	0.45	32
6.26μ	17.	0.45	80

The observations in this work were made upon the absorption by the water vapor in the air of the room. For the bands at 1.87μ and 3.16μ the absorption did not anywhere exceed forty percent, and it was not necessary to remove any moisture. In the other bands, however, there were very strong lines which could not be separated. In order to reduce the amount of water present a rough box was built around the spectrometer and phosphorus pentoxide was exposed inside. The effect of such drying is shown, for example, by the

⁵ Aaron Levin and Charles F. Meyer, J.O.S.A. and R.S.I. 16, 137 (1928).

⁶ F. A. Firestone, Rev. Sci. Inst. 1, 630 (1930).

inserted sections near line No. 177 in the curve of Fig. 5. Drying the air made it possible to separate and identify the lines. The pressure of water vapor in the undried air was 20 to 30 mm. In the dried air it was 2 to 3 mm. Fig. 3 also represents the energy curve near 2.66μ with dried air. Lines nos. 22, 23 and 24, for example, are better defined in this figure than in Fig. 2, which refers to the normal indoor atmosphere.

RESULTS AND DISCUSSION

The measurements made during this work appear in the curves of the following figures, and in the tables. The tables show an arbitrary number for each line, and its relative intensity, wave-length, and wave-number. The relative intensities represent estimates only, based upon the depth of the lines. In many cases this estimate has been difficult and uncertain, because a certain line may represent only a weak absorption upon the side, so to speak, of a deeper and wider line, or it may represent a stronger effect if its neighbor is in fact a weaker one. Line number 35 in Figure 3, for example, has been assigned a relative intensity of 50 percent. But if it is really only a nick in the curve which shows No. 36 it ought to be marked, perhaps, 15 percent. In all cases where two lines overlap there is doubt about the intensity of each. This composite effect, which partly disappeared when the air was dried, made it impossible to use the criterion of the area of the notch for estimating intensity. Improvement of the present analysis of the water spectrum demands first of all an enclosed spectrometer and absolute control of the amount of the absorbing medium. Second, it demands a resolution even higher than we could command.

When the amount of moisture was reduced by the means described, many lines in all the bands were made more narrow and sharp. On advancing the circle 15 seconds, the galvanometer deflection changed in many cases by 40 mm—say from 100 to 60. An error of 5 seconds in setting might affect the deflection by 15 mm. This unavoidable uncertainty of perhaps 5 seconds in setting may account for the difference in relative intensities of two lines as they appear in different curves, so that in one graph *a* is stronger than *b*, in another not so strong.

Figure 1 and Table II represent our study of the band at 1.87μ . Many new lines have appeared, for example line No. 48 in Fig. 5 of the paper of 1925 seems now to be a composite effect of those numbered 81, 82, and 83. There is no way of deciding what wave length, with the amount of water uncontrolled, such a combination ought to have. Accordingly there is no satisfactory basis for comparison of wave-lengths. In general, however, the new values are larger.

It may be remarked here that the numbers assigned to the lines are arbitrary. Also we have omitted numbers from all the tables at places where there are faint lines of uncertain positions, to which we cannot assign definite wave lengths.

In work done at Johns Hopkins University by Barnes⁷ the energy of a

⁷ R. Bowling Barnes, *Phys. Rev.* **36**, 296 (1930).

source of radiation was mapped in the region between 3 and 4μ . It shows two bands of atmospheric absorption, one of them with center near 3.73μ . With

Fig. 2. Part of the energy curve, region of 2.66μ , two independent series. Echelette grating, 7200 lines per inch. Slits 0.1 mm, 10 sec, 0.44 waves per cm, 3.1A.

Fig. 3. Energy curve, part of the region of 2.67μ , on frequency scale. Air partly dried. Echelette grating, as in Fig. 2.

the prism-grating spectrograph we have carefully gone over part of this region, having the prism so placed that there was no deflection when the grating was set for 1.9μ . No absorption lines were to be found, though the slits were certainly narrow enough to show them. If certain wave-lengths given in Table II, beginning with No. 26, are multiplied by 2, the products agree remarkably well with many of the wave-lengths given by Barnes. Some of his numbers represent a good mean of adjacent wave-lengths, doubled. For example for line No. 26, 2λ is 3.6418μ . Barnes lists 3.642 . Also if one compares the graph under consideration with that for the region near 1.87μ given in Fig. 4 of the paper of 1918 (reference 2) they appear very much alike. The work of Barnes was done with a grating and an infrared filter. It may be that the atmospheric absorption appearing at 3.75μ in Figs. 4 and 5 of that paper is a second order effect due to an overlapping of spectra.

In Figs. 2 and 3 and Table III are given our results for the region of 2.67μ , a fundamental band having a zero branch—showing at any rate strong absorption in the middle portion. Of the two curves in Figure 2 there is less moisture represented in the lower. For Fig. 3 there is less vapor still, and there is less overlapping and general confusion of the lines. For example, line No. 70

is separated in Fig. 3, into two lines some 10A apart. Further comparison shows that the intensity of all the strong lines increases with the amount of water present. This change in intensity indicates that at least the strong lines in this region are due to water vapor, and not to carbon dioxide. The carbon dioxide band in the region of 2.73μ would probably not have strong lines below 2.69μ , corresponding to line No. 59. The effect of carbon dioxide in this region was studied by Sleator² and it was found that the strong lines throughout the region were enhanced by the use of steam (giving much more absorbing material) and reduced by drying the air. Figure 3 has been plotted with deflections on a scale of frequencies and is the reverse of the curves of Figure 2. Lines 22, 23 and 24 may be compared with the unresolved group shown as numbers 8 and 9 in Figure 5 of the paper of 1918, and this comparison fairly indicates the advance represented in the present work.

In Fig. 4 and Table IV are represented the results for the region of 3.16μ . It is perhaps here that previously published results are most inadequate. The table presents lines between 2.85 and 3.33μ , and the lines at the beginning of the table probably belong to the series shown in the previous figures. All the lines are weak in this region, whose center we have placed at 3.168μ , and which is probably the first harmonic of the band at 6.26μ . However, the separation of the two strong lines next the center on either side (Nos. 81 and 82) is 45.3 waves per cm, while the corresponding difference at the fundamental

is 40. The wave-lengths of certain lines listed in Table IV are in good agreement with values given by Barnes in the work cited (reference 7) for this region. In some cases his numbers represent averages of the wave-lengths of adjacent lines.

The results for the fundamental at 6.26μ are shown in part in Figs. 5 and 6, and completely in Table V. Hettner shows this band to extend from 4.5μ to 8.5μ , but we have studied only the central part. In Fig. 6 are represented the most important lines of this region on a scale of wave-numbers, showing by the length of the lines the intensities of absorption. The advancement lately

made is shown definitely in this region. For what appeared in Fig. 2 of the paper of 1925 as uncertain ripples in the level plateau of the center has now become eight very definite lines, numbers 155 to 162, arranged in pairs. The old lines Nos. 69 and 80, the second from the middle region on either side, now appear as two close lines each, Nos. 149 and 150 and Nos. 168 and 169 of Fig. 5. Line 159 which we have marked the center, because it is a geographic mid point, is not a particularly significant line. Some lines separated here, for example, numbers 172 and 173 and 168 and 169, are less than one wave per cm apart.

It may be well to compare some of the wave-lengths with those given in the previous papers from this laboratory. In many cases no basis for comparison exists, for one of the former "lines" now appears as several. However, there are many lines in the region of 2.67μ as it appeared in 1918 which have persisted as single effects, and there are several lines near 1.87μ and 6.26μ

Fig. 6. Region of 6.26μ , middle part. Intensities of the absorption lines shown on a scale of waves per cm.

which may be compared in the paper of 1925 and the present one. The comparison shows that single lines in the band at 2.66μ are now assigned wave lengths from 3 to 7A greater than those of 1918. Perhaps the visual calibration formerly necessary accounts for the systematic difference. Similar differences appear at 1.87μ . At 6.26μ the difference is more irregular and somewhat larger. In many cases, however, no comparison is possible. For example, lines 114 and 115 were formerly given as one, No. 54, and Nos. 120 and 121 as number 58.

Some estimate of the precision attained in the wave lengths listed here is necessary and may be made as follows. The calibration of the 7,200 line grating, used in all the work except for the band at 6.26μ , was based on the mercury line whose wave-length was taken to be 10139.8A in air. This calibration has been done by Meyer, and charts have been made from which wave length and wave number can be read directly in terms of angles. This calibration is believed to involve no error greater than 1 part in 50,000. There exists always some uncertainty in setting the circle. If this amounts to 5 seconds, then the

location of an absorption line which depends at the tip upon perhaps four plotted points is also uncertain. Independently measured values of typical lines in two of the regions are shown in Table VI.

When there are extreme differences of 20'' we have taken more than four independent energy curves. It seems fair to affect the values of wave-length in these regions with a probable error of $\pm 2A$. It is perhaps an even chance that the true value of the wave-length in air, based upon the value used here for the mercury line, is within $2A$ on either side of the values given here. In order to guard against mistakes in reading the calibration charts, values of wave-length and values of wave-number were taken off independently, and afterward checked by looking up all the wave numbers in a table of reciprocals. These considerations and this estimate of precision refer to the regions 1.87μ , 2.66μ and 3.15μ .

The band at 6.26μ was studied with a grating having 2,880 lines per inch. Its calibration was based on the same value of the wave-length of the mercury line at 1μ , and also on work with visual lines. The spectrometer constant was $175,900A$. There was no chart available, and our procedure was to compute independent values of λ , one from each plotted curve, by the equation $\lambda = \kappa \sin \theta$. First the wave numbers were looked up in the reciprocal tables, and then the wave numbers were independently computed by using cologs. Typical values in this region are given in Table VI. It does not seem that the spectrometer constant for this assembly is responsible for an error of $1A$ in our results, and perhaps the wave-lengths in Table V should be written $\pm 3A$. To

reduce this uncertainty requires more observations, and more independent curves. The systematic difference between the wave-lengths given here, and those published in the paper of 1925, for such lines as may properly be compared, must arise from differences in calibration constant. The circle used in all this work, as well as in many other investigations made in this laboratory, has no appreciably eccentricity.

The advance over previous work represented here lies, first, in more reliable determinations of individual wave-lengths. Second, more lines have been measured, and this work should make possible a better classification, if it is demanded by theoretical study of the water molecule. Third, the lines measured represent, in more cases than in previous data, single absorption effects, so that more of the wave numbers are of actual physical significance.

THE DIFFUSION PROBLEM FOR A SOLID IN CONTACT WITH A STIRRED LIQUID

By T. E. W. SCHUMANN
WEST VIRGINIA UNIVERSITY

(Received April 21, 1931)

ABSTRACT

A cylindrical solid of length a in a direction x and of arbitrary cross-section normal to x is in contact on its plane face $x=a$ with a well-stirred liquid. The face $x=0$ of the solid and the lateral surface are impervious to heat. The liquid extends from $x=a$ to $x=a+b$. At $x=a+b$ the liquid is in contact with a source of heat at the constant temperature θ , the transfer of heat from this source being proportional to the difference in temperature between the outside source and the liquid. If the initial temperatures of solid and liquid are given, the problem of the temperature distribution at any subsequent time can be obtained by means of a modification of the well-known Fourier analysis.

IN STUDYING practical problems concerning the one-dimensional flow of heat in a solid, boundary conditions are sometimes met which are not directly amenable to the ordinary Fourier analysis. This is due to the fact that the characteristic solutions of the differential equation subject to the given boundary conditions do not form an orthogonal set of functions. This difficulty can be met in various ways. One method will be given in this paper.

The problem here considered is that of the one-dimensional flow of heat in a solid slab which, at its face $x=a$, is in contact with a well-stirred liquid extending from $x=a$ to $x=a+b$. The liquid receives heat at the face $x=a+b$ from an outside source kept at a constant temperature θ , the transfer of heat to the liquid being proportional to $\theta-v$, where v is the temperature of the liquid. The slab is impervious to heat at the face $x=0$. The lateral surfaces of the slab and the liquid are supposed to be impervious to heat so as to insure the one-dimensional flow of heat.¹ If the initial temperature of the liquid and the initial temperature distribution in the solid are known, then it is possible to determine the temperature distribution throughout the system at any subsequent instant.

Let $u(x, t)$ represent the temperature in the solid at any point x and at time t , and let $v(t)$ represent the temperature of the liquid at any time t . The function $v(t)$ must be continuous for all values of t .

Now, according to the well-known Fourier equation of heat conduction

$$\frac{\partial u}{\partial t} = \alpha^2 \frac{\partial^2 u}{\partial x^2}, \quad t > 0 \quad (1)$$

¹ These conditions are approximately realized when a slab of low thermal conductivity is heated between two similar parallel plates of high conductivity, metal plates for example, the outer plates being heated by a hot gas.

where α^2 , the thermal diffusivity of the solid, is the quotient of its thermal conductivity k by the product of its density ρ and its specific heat c .

Also, since the face at $x=0$ is impervious to heat

$$\partial u / \partial x = 0, \quad x = 0, t > 0. \quad (2)$$

Furthermore, the heat gained by the liquid must be equal to the heat it acquires from the outer source minus the heat which is conducted across the solid-liquid boundary. If K is the heat capacity of a prism of the liquid of unit cross-section and γ is the coefficient of heat transfer from the outer source per unit cross-section, unit difference of temperature and unit time, then

$$K \frac{dv}{dt} = -k(\partial u / \partial x)_{x=a} + \gamma(\theta - v), \quad t > 0. \quad (3)$$

The thermal contact of the solid and the liquid at $x=a$ gives rise to the equation

$$u(a, t) = v(t), \quad t > 0. \quad (4)$$

If v_0 is the initial temperature of the liquid and $u_0(x)$ that of the solid, then we have

$$\lim_{t=0} v(t) = v_0 \quad (5)$$

and

$$\lim_{t=0} u(x, t) = u_0(x), \quad 0 \leq x < a. \quad (6)$$

It will be noticed that we have restricted the validity of the last equation so as to exclude the point $x=a$ for the reason that it would be impossible to satisfy all the conditions imposed by Eqs. (1) to (6) if this point had been included, except for the special case when $u_0(a) = v_0$. The same difficulty, however, is met in any Fourier expansion. Fourier's theorem states that a function $f(x)$ which fulfills Dirichlet's conditions in a given interval can be represented by a series of sines and cosines except at points of discontinuity. If therefore we express u in terms of a Fourier series we shall expect it at time $t=0$, to satisfy the initial temperature distribution except at points of discontinuity including the point $x=a$, $\lim_{t=0} u(a, t)$ having some value different from $u_0(a)$. From physical consideration it is possible to determine the value of $\lim_{t=0} u(a, t)$.

Suppose that at any point $x=x_0$ there is a sudden change in the value of $u_0(x)$ from u_1 to u_2 . This means that the temperature gradient is infinite at x_0 . The heat conducted across unit area is proportional to the temperature gradient, and hence if the temperature gradient is still infinite after a small but finite time ϵ , then the heat transferred across unit area will be infinite, which is clearly impossible. From this it follows that the temperature discontinuity must have disappeared after the time ϵ , however small ϵ may be. These considerations also hold at the point $x=a$, where there is thermal contact between the solid and the liquid. Hence

$$u(a, \epsilon) = v(\epsilon) \quad (7)$$

however small ϵ may be.

Now let us consider the value of $v(\epsilon)$ when ϵ becomes very small. Since the liquid is kept stirred its temperature must be uniform at any instant of time. Therefore the change in temperature $v_0 - v(\epsilon)$ is proportional to the total heat conducted away from the liquid, and by choosing ϵ sufficiently small we may make this heat, and consequently $v_0 - v(\epsilon)$ as small as we please. Hence it follows that

$$\lim_{\epsilon=0} v(\epsilon) = v_0$$

and combining this result with Eq. (7) we have

$$\lim_{\epsilon=0} u(a, \epsilon) = v_0$$

or

$$\lim_{t=0} u(a, t) = v_0. \quad (8)$$

Eqs. (8) and (4) can now be combined into the single equation

$$u(a, t) = v(t) \quad (9)$$

for all time.

Accepting (9), we can rewrite the equations of condition, substituting $u(a, t)$ for $v(t)$

$$\frac{\partial u}{\partial t} = \alpha^2 \frac{\partial^2 u}{\partial x^2}, \quad t > 0 \quad (10)$$

$$\frac{\partial u}{\partial x} = 0, \quad x = 0, \quad t > 0 \quad (11)$$

$$K \frac{\partial u}{\partial t} = -k \frac{\partial u}{\partial x} + \gamma(\theta - u), \quad x = a, \quad t > 0 \quad (12)$$

$$\lim_{t=0} u(x, t) = u_0(x), \quad 0 \leq x < a \quad (13)$$

$$\lim_{t=0} u(a, t) = v_0 \quad (14)$$

and our problem reduces to the determination of u so as to satisfy conditions (10) to (14).

On account of the rather unusual character of the analytical conditions it is perhaps advisable to demonstrate that this set of equations possesses a unique solution, and we proceed to show this briefly. If possible, let there be two independent solutions u_1 and u_2 .

Let

$$V = u_1 - u_2. \quad (a)$$

Then V must satisfy the following set of conditions

$$\frac{\partial V}{\partial t} = \alpha^2 \frac{\partial^2 V}{\partial x^2} \quad (b)$$

$$\frac{\partial V}{\partial x} = 0, \quad x = 0 \quad (c)$$

$$K \frac{\partial V}{\partial t} = -k \frac{\partial V}{\partial x} - \gamma V, \quad x = 0 \quad (d)$$

$$V = 0, \quad t = 0, \quad 0 \leq x \leq a \quad (e)$$

Put

$$J = \frac{K\alpha^2}{2k} V_a^2 + \frac{1}{2} \int_0^a V^2 dx \quad (f)$$

where V_a is the value of V at $x=a$.

Then

$$\begin{aligned} \frac{\partial J}{\partial t} &= \frac{K\alpha^2}{k} V_a \frac{\partial V_a}{\partial t} + \int_0^a V \frac{\partial V}{\partial t} dx \\ &= \frac{K\alpha^2}{k} V_a \frac{\partial V_a}{\partial t} + \alpha^2 \int_0^a V \frac{\partial^2 V}{\partial x^2} dx \end{aligned}$$

by virtue of (b).

$$\begin{aligned} &= \frac{K\alpha^2}{k} V_a \frac{\partial V_a}{\partial t} + \alpha^2 \left[V \frac{\partial V}{\partial x} \right]_0^a - \alpha^2 \int_0^a \left(\frac{\partial V}{\partial x} \right)^2 dx \\ &= -\frac{\gamma}{k} V_a^2 - \alpha^2 \int_0^a \left(\frac{\partial V}{\partial x} \right)^2 dx \end{aligned}$$

by virtue of (c) and (d).

Therefore

$$\frac{\partial J}{\partial t} \leq 0.$$

But since $J=0$ when $t=0$, it follows that

$$J \leq 0.$$

Also, according to the definition as given by Eq. (f), J is essentially positive. Hence $J \equiv 0$, from which it follows that there can be only one solution to the problem.

We now proceed to find this solution.

Let us set

$$u = \theta + \sum_{n=0}^{\infty} E_n \cos \frac{z_n x}{a} e^{-z_n^2 \alpha^2 t / a^2} \quad (15)$$

which is the type of expression to which one is led by the ordinary Fourier analysis. If this series is convergent, then u attains the value θ when $t = \infty$, as

should be the case from physical considerations. Eqs. (10) and (11) are formally satisfied by this expression. Eq. (12) will also be satisfied provided the z 's are the roots of

$$\tan z = -\lambda z + \frac{\gamma a}{kz} \quad (16)$$

where

$$\lambda = \frac{\alpha^2 K}{ak} = \frac{K}{\rho c}. \quad (17)$$

There now remains the problem of determining the values of E so as to satisfy conditions (13) and (14), namely that

$$u(x, 0) = \theta + \sum E_n \cos \frac{z_n x}{a} = u_0(x), \quad 0 \leq x < a \quad (18)$$

and

$$u(a, 0) = \theta + \sum E_n \cos z_n = v_0. \quad (19)$$

A difficulty is met here due to the fact that in (18) the characteristic functions are non-orthogonal.²

To overcome this difficulty we assume for the time being that (18) can be differentiated termwise, the result being

$$\frac{du(x, 0)}{dx} = - \sum \frac{E_n z_n}{a} \sin \frac{z_n x}{a}. \quad (20)$$

² The situation here encountered is entirely similar to that met by March and Weaver in connection with a problem which is a special case of the one here considered (see Phys. Rev. 31, page 1072). A somewhat simpler device than the one here used is, however, sufficient to meet the situation of the former paper. In fact, one sought there to develop a function $u_0(x)$ in a series of non-orthogonal functions $\cos z_n x$ where z_n are the roots of $\tan z + \lambda z = 0$. This can be accomplished indirectly by expanding the integral of $u_0(x)$ in a series of the orthogonal functions $\sin z_n x$. This procedure leads at once to the solution:

$$u = \frac{\bar{u} + v_0 \lambda}{1 + \lambda} + \sum_{n=0}^{\infty} E_n \cos \frac{z_n x}{a} e^{-\alpha^2 z_n^2 t / a^2}$$

where

$$\bar{u} = \frac{1}{a} \int_0^a u_0(x) dx$$

$$E_n = \frac{2}{1 + \lambda + \lambda^2 z_n^2} [(-1)^n (\bar{u} - v_0 \lambda) (1 + \lambda^2 z_n^2)^{1/2} + 2(1 + \lambda^2 z_n^2) Q_n]$$

and

$$Q_n = \frac{z_n}{a} \int_0^a u_0(x) \cos \frac{z_n x}{a} dx$$

the notation being that of the paper referred to.

It will be shown that it is possible to obtain the values of E from (18) and (20) by the usual Fourier method. Multiply (18) by $\cos z_n x/a$ and (20) by $p_n \sin z_n x/a$, add and integrate with respect to x between 0 and a , and determine p_n such that the product terms vanish, i.e., such that

$$\int_0^a \cos \frac{z_n x}{a} \cos \frac{z_m x}{a} dx + \frac{p_n z_m}{a} \int_0^a \sin \frac{z_n x}{a} \sin \frac{z_m x}{a} dx = 0. \quad (21)$$

By making use of Eq. (16) it can readily be demonstrated that (21) is satisfied provided

$$p_n = \frac{\lambda k z_n}{\gamma} \quad (22)$$

The equation from which the value of E_n is to be determined is

$$\begin{aligned} E_n \int_0^a \cos^2 \frac{z_n x}{a} dx - E_n \frac{k \lambda z_n^2}{\gamma a} \int_0^a \sin^2 \frac{z_n x}{a} dx \\ = \int_0^a (u(x, 0) - \theta) \cos \frac{z_n x}{a} dx + \frac{\lambda z_n k}{\gamma} \int_0^a \frac{du(x, 0)}{dx} \sin \frac{z_n x}{a} dx. \end{aligned} \quad (23)$$

All the integrals in the above expression are perfectly straightforward except the last one which can be integrated by parts:

$$\begin{aligned} \int_0^a \frac{du(x, 0)}{dx} \sin \frac{z_n x}{a} dx &= \left[u(x, 0) \sin \frac{z_n x}{a} \right]_0^a - \int_0^a \frac{u_0(x) z_n}{a} \cos \frac{z_n x}{a} dx \\ &= v_0 \sin z_n - \frac{z_n}{a} \int_0^a u_0(x) \cos \frac{z_n x}{a} dx \end{aligned} \quad (24)$$

by virtue of Eqs. (14) and (18). If the other integrations are performed it is found that

$$\begin{aligned} \frac{E_n}{2} \left\{ 1 + \left(\frac{\gamma a}{k z_n^2} + \lambda \right) \cos^2 z_n \right\} \\ = \left(v_0 \lambda - \frac{\theta a \gamma}{k z_n^2} \right) \cos z_n + \frac{1}{a} \int_0^a u_0(x) \cos \frac{z_n x}{a} dx \end{aligned} \quad (25)$$

The problem has now been formally solved, the value of u being given by Eq. (15), where the values of z have to be determined from Eq. (16) and those of E from Eq. (25). The value of v , the temperature of the liquid, is the same as $u(a, t)$ according to Eq. (9). We know that the expression obtained for u will satisfy Eqs. (10) to (12) but it still has to be demonstrated that it also satisfies (13) and (14). If this can be proved, then we know that we have obtained the true and unique solution to the problem. A formal proof that (13) and (14) will also be satisfied would require a considerable amount of space and the inclusion of such a proof in a journal devoted entirely to physics could hardly be justified. It may be stated, however, that a satisfactory

proof has been obtained, the method employed involving the use of Green's functions and being essentially the same as that employed by Carslaw³ in solving a similar type of problem. In brief, the procedure is first to find a solution due to a point source of heat at the point x' , where $0 < x' < a$, subject to the boundary conditions as expressed by Eqs. (11) and (12), with the restriction that θ is assumed to be zero. The result is expressed in the form of a complex integral. By complex integration over a suitably chosen path it is then an easy matter to show that the solution obtained satisfies the equations of condition and also the initial condition of a unit point source at $x = x'$.

Now the sum of any number of such solutions will still be a solution. Hence, by choosing a suitable distribution of point sources we can build up the final solution corresponding to the initial temperature distribution as given by Eqs. (13) and (14). In building up this initial temperature distribution it must be borne in mind that the distribution must be of strength $u_0(x)\rho c$ per unit length of the solid, when we deal with unit cross-section. At the point $x = a$, however, there is concentrated a point source of total strength Kv_0 , corresponding to the heat initially contained in the liquid. This holds for the case when $\theta = 0$. The transition to the case when $\theta \neq 0$ is easy and need not be elaborated here. Since the validity of the solution for a single point source has been proved the solution thus obtained for any distribution of point sources must also be valid. The result, which is in the form of a complex integral can be transformed into an infinite series by integrating over a suitable path and applying Cauchy's theorem to the poles of the integrand. In carrying out this transformation the resulting infinite series was found to be entirely in agreement with that already obtained by the Fourier method. Our problem has therefore been finally and completely solved.

Numerical example.

We give a numerical example which was worked out in connection with the heat conduction into a slab of coal bounded by two plates of steel. The values adopted for the different constants are $K = 2.23$; $k = 0.01425$; $a = 1.27$; $\gamma = 0.0452$; $\rho = 0.8$; $C = 0.2775$; $\theta = 1$; $v_0 = 0.8$; $u_0 = 0$. where the centimeter, gram, minute, and degree Fahrenheit are the fundamental units of length, mass, time and temperature respectively.

It follows that $\lambda = 7.9$ and $\alpha^2 = 0.0645$, and Eq. (16) takes the form

$$\tan z = -7.9z + \frac{4.03}{z}. \quad (17)$$

The values of z as determined graphically from this equation were $z = 0.666, 1.663, 4.74, 7.85$. These values of z were substituted in Eq. (16) and the values of the E 's were found to be

$$E = -0.703, -0.428, 0.213, -0.181.$$

Furthermore the successive values of $\alpha^2 z^2 / a^2$ were

³ Carslaw, *The Conduction of Heat*, p. 180. MacMillan and Co.

$$\frac{\alpha^2 z^2}{a^2} = 0.0178, \quad 0.1105, \quad 0.899, \quad 2.464.$$

Therefore the final form that Eq. (7) takes in this case is

$$u = 1 - 0.703 \cos \frac{0.666x}{a} e^{-0.0178t} - 0.428 \cos \frac{1.663x}{a} e^{-0.1105t} \\ + 0.213 \cos \frac{4.74x}{a} e^{-0.899t} + \text{etc.}$$

The temperature $u(0, t)$ at $x=0$ and the temperature $u(a, t)$ or $v(t)$ were calculated from this equation and the values are given in Table I.

TABLE I.

Time, $t=0$	0.5	0.1	2.0	4.0	10.	20.	30.	80.
$u(0, t)=0$	0	0	0.013	0.104	0.360	0.582	0.753	0.883
$v(t)=0.8$	0.685	0.683	0.683	0.685	0.701	0.739	0.813	0.908

From the table we see that the temperature $v(t)$ of the steel (or stirred liquid) sinks rapidly from its initial value of 0.8, stays practically constant for an appreciable time at about 0.685, and then begins to rise steadily attaining its asymptotic value of 1.0 after infinite time.

From this example it is evident that numerical calculation for any practical problem will in general not require an excessive amount of labor.

My thanks are due to Dr. S. P. Burke, Chairman of the Industrial Science Division of this University for his interest in this problem, and to the Combustion Utilities Corporation for permission to publish the results. I also wish to thank Professor Warren Weaver of the University of Wisconsin for a number of helpful suggestions concerning the form of presentation of the paper.

THE DIELECTRIC CONSTANT OF FORMIC, ACETIC, AND PROPIONIC ACIDS, AND THE ELECTRIC MOMENT OF COMPLEX MOLECULES

(Received April 20, 1931)

ABSTRACT

The temperature and pressure variation of the dielectric constant of formic and propionic acid vapors has been studied experimentally. The behavior is similar to that previously found for acetic acid. For formic acid it is possible to calculate from Coolidge's vapor density measurements the amount of association into double molecules, and to explain the apparent departures from Debye's theory in terms of such association. It is then seen that the apparently linear pressure curves can be explained by the compensation of several factors in the measurements. By assuming that the optical part of the polarization is doubled on association and taking this value from refractivity measurements, values for the electric moment of the single and double molecules of formic acid are obtained, 1.51×10^{-18} and 0.99×10^{-18} c.g.s.e.s.u., respectively. Although no reliable vapor density measurements exist for acetic acid it is assumed that the anomaly in this case also is due to association rather than to the previously suggested effect of vibrational quantization. The previous data are re-interpreted accordingly. By using the optical refractivity as before a value is obtained from the high temperature measurements for the electric moment of the single molecule of acetic acid, 1.73×10^{-18} ; and similarly for propionic acid, 1.74×10^{-18} c.g.s.e.s.u. The electric moment of complex molecules is then discussed with reference to directed valence and to internal free rotation around single bonds. The possibility of the importance of interaction between external rotation and internal free rotation is suggested. The question of the interpretation of measured electric moments is raised for the case where free rotation causes a time variation of electric moment. In this connection the experimental values of electric moment are discussed. The values of the electric moment of these acids indicate that the OH group is tightly bound as supposed by Eucken and Meyer. A structure for the double molecule of formic acid is suggested, with the four oxygen molecules at the corners of a rectangle, the planes of the two constituent single molecules at an angle of about 120° , and the OH groups bound tightly in positions of minimum potential energy. This structure does not seem to be inconsistent with the observed electric moment.

IN A previous communication¹ measurements of the dielectric constant of acetic acid vapor were published. These measurements indicated that there is a change of the electric moment of the acetic acid molecule with temperature, and it was suggested as a possible explanation that the effect is due to a transition in vibrational quantum state of the OH group. The possibility that the apparent change in electric moment could be due to association was considered excluded by the fact that the variation of dielectric constant with pressure was linear within the limits of experimental error. The presence of association could not be further tested since there exist no

¹ C. T. Zahn, Phys. Rev. 35, 1047 (1930).

reliable measurements of the vapor density of acetic acid. It was decided to make a further study of this effect by making measurements of the dielectric constant of formic acid and propionic acid vapors. In the case of formic acid excellent vapor density measurements have been made recently by Coolidge,² who has shown that his measurements can be explained by the existence of double molecules and has given satisfactory equations for the calculation of the degree of association. A study of these data shows that there is a considerable amount of association in the region of temperature and pressure available for convenient dielectric constant measurements. This suggests that the anomaly in the previous acetic acid measurements might be due to association in spite of the apparently linear pressure curves. For example, this might be possible if the shape of the vapor density curve were such as to effect the linearity of the pressure curve only very slightly throughout the measured range of pressure, and particularly if the molecular polarizations of the single and the double molecules were not greatly different.

FORMIC ACID

The present data on formic acid show the same general characteristics as those on acetic acid. The pressure curves are apparently linear and the electric moment apparently decreases with the temperature. This being a partial confirmation of the above suggestion of association, an attempt was made to explain the anomaly in formic acid quantitatively in terms of association and to calculate the electric moment of the single and double molecules. The percentage of associated molecules was calculated from Coolidge's equations for the points of maximum pressure on the curves and at the four different temperatures included by the data. At the highest temperature there was found 9 percent association and at the lowest temperature 58 percent. A

rough calculation from the data of Table I shows that if the effect is due to association the associated molecule cannot have zero electric moment as it would have in case the two associating moments were antiparallel. This also is in confirmation of the above suppositions.

In Table I the data were calculated from the readings at the highest pressures only. An example of a pressure curve is shown in Fig. 1. For economy in space the individual pressure data were not included in the table. In column 3 of Table I the value of the specific volume was calculated from the ideal gas equation and refers therefore to the normal ideal value. Therefore the values in column 3 represent the apparent polarization referred to a normal ideal

² A. S. Coolidge, Jour. Amer. Chem. Soc. 50, 2166 (1928).

number of gas molecules. The values in column 5 represent the molecular polarization, or the polarization referred to a mol of the molecules. The values in column 4 plotted against the absolute temperature would give a Debye line if the molecules were of one kind only. The absolute values of ϵ used here are the values corrected as described later for the extrapolation to zero pressure under the assumption of association.

In order to determine the molecular polarization of the single and double molecules individually, it was assumed that the constant, or so-called optical, part of the polarization is doubled on association. This is probably justified by the well-known principle of the additivity of refractivity, particularly since the energy of association is not great. In any case the optical part is the smaller part of the electric polarization under the available experimental con-

Fig. 1. Pressure Curve.

ditions. The two molecular polarizations are set respectively equal to $A + B_1/T$ and $2A + B_2/T$ according to the Debye theory. Hence the measured molecular polarization is

$$P = n_1(A + B_1/T) + n_2(2A + B_2/T)$$

where n_1 and n_2 are the respective mol fractions. B_1 and B_2 are proportional to the squares of the two electric moments. An approximate idea of the magnitude of the effect of association can be obtained by assuming that the association is negligible at the highest temperature, and then calculating $2A + B_2/T$ from the data at the lowest temperature and maximum pressure. If the pressure curves are then corrected so as to correspond to the single molecule alone, it is found that these curves are still apparently linear. This

can be seen in Fig. 1, where the uncorrected points are shown by crosses and the corrected points by circles.

It can therefore be stated that so far as the linearity of the pressure curves is concerned the assumption of association is justified. It remains only to see whether the constants can be chosen so as to fit all the data satisfactorily. The more accurate calculations are slightly complicated by the fact that it is never possible in a pressure curve to measure accurately the vacuum value of the experimental condenser capacity. This is true because inequalities in the temperature of the condenser plates arise on evacuation.³ It is therefore necessary to extrapolate to zero pressure in order to obtain absolute values of the dielectric constant. Fig. 1 shows that the extrapolated value differs slightly for the corrected and the uncorrected curves. (This shows that the greatest departure from linearity exists at the very low pressures and partially explains why it was not originally detected.) These curves were first corrected roughly as above stated in order to locate the zero, and then new absolute values of the dielectric constant and molecular polarization were determined.

Because of the complicated nature of the calculations and the smallness of the association effect, no attempt was made to determine A , but it was taken from the molecular refractivity of formic acid in the liquid state as given in Landolt Börnstein, 8.53. This value is probably a little too small because of infrared terms in the refractivity, and the resulting calculations are subject therefore to a small error. Appropriate values of B_1 and B_2 were obtained by choosing the value of B_1 which gives on subsequent calculation the most nearly constant value for the ratio B_1/B_2 . The value chosen for B_1 is 14160. Table II shows the corresponding values of B_1/B_2 with a weighted

TABLE II. *Formic acid: calculation of molecular constants.*

mean of 0.43. From these values it can be seen that while the reduction in the electric moment is considerable the doubling of the optical term masks a considerable portion of the effect. Further, in order to show how nearly the data for the four different temperatures and maximum pressures are consistent with these constants A , B_1 , and B_2 , the values of the electric polarization were calculated and compared with the experimental values. This is shown in Fig. 2. The upper straight line is the Debye line for single molecules, and the lower line, for double molecules. The product of the polarization and the absolute temperature is plotted against the absolute temperature. For con-

³ C. T. Zahn, Phys. Rev. **35**, 848 (1930).

venience the values of the polarization here refer not to a mol but to the ideal number of molecules per cc under normal conditions of a gas. The crosses represent the experimental values and the circles the calculated values for the maximum pressures. The deviations are seen to be of the order of one percent. This agreement is almost better than one could expect in view of the nature of the calculations and the possibility of small errors due to absorption on the condenser plates.

Finally it seems that the anomaly for formic acid can be satisfactorily explained by association and the values of the electric moment for the single

Fig. 2. Debye Lines.

and double molecules can be calculated. The above values of B_1 and B_2 correspond to electric moments of 1.51 and 0.99×10^{-18} c.g.s.e.s.u., respectively.

In order to obtain a good specimen of formic acid for these tests Kahlbaum formic acid was distilled at 0°C as described by Coolidge in the paper cited above.

ACETIC AND PROPIONIC ACIDS

In view of the above results of the calculations for *formic* acid it seems more than probable that the previous data on *acetic* acid should also be interpreted in terms of association rather than the previously suggested temperature variation of electric moment. The same can be said for the data here presented on propionic acid, which shows a similar but somewhat smaller effect. The fact that the effect is smaller in propionic acid may be due to a greater masking of the moment reduction by the doubling of the optical term on association; or it may also be due to a smaller amount of association.

For these two acids the calculations cannot be carried out as in the case of formic acid since their vapor densities are unknown at present. Still if it is assumed that the effect is due to association the data can be used to obtain a fairly accurate value of the electric moment of the single molecules.

In Table III are shown the previously published data on acetic acid and also the present data on propionic acid together with calculated values of the apparent electric moment, μ . The values of apparent molecular polarization

are calculated from the uncorrected pressure curves and are subject to small errors due to incorrect extrapolation to zero pressure. At the higher temperatures this error is negligible since the association effect is very small. Values for A are taken as before from refractivity data. The values of μ should approach a constant value as the temperature is increased since the association then becomes negligible. From Table III it is seen that in both cases μ becomes practically constant above 440°K. The asymptotic values may be taken as 1.73 for acetic acid and 1.74×10^{-18} c.g.s.e.s.u. for propionic acid. Because of the danger of decomposition the highest safe temperature for formic acid was about 425°K and there was still 9 percent association. Fig. 2 shows, however, that the association should become negligible at approximately the same temperature as for the other two acids, at 440°K.

In the previous article¹ on acetic acid it was stated that there was evidence at high pressures indicating association in which the polarization is increased. This effect was noticed at pressure beyond the apparently linear portions of the pressure curves near to saturation, and is probably now to be considered as due to surface adsorption on the condenser plates.

The purified propionic acid was obtained by fractional distillation of a specimen from the Eastman Kodak Company.

ELECTRIC MOMENT OF COMPLEX MOLECULES

In recent years a number of authors, chiefly Eucken and Meyer, and Wolf,⁴ have made attempts to calculate the electric moment of molecules,

⁴ H. Sack, *Ergebnisse der Exakten Naturwissenschaften*, Band VIII, 337 (1930).

assuming that the total electric moment can be obtained by adding vectorially electric moments characteristic of each chemical bond and directed approximately along the valence directions given by the tetrahedral theory. These calculations have in some cases been complicated by the fact that whenever there is a single bond between two atoms there is a possibility of free rotation of two atomic groups relative to one another. In such cases the molecules cannot be regarded as rigid in the sense that the average relative positions of the nuclei are practically fixed. In fact, atomic groups having their own characteristic vector electric moments can rotate relatively to one another and cause a time variation of the electric moment. (Hojendahl first used this idea to explain difficulties which had arisen from the fact that certain molecules of the type CR_4 have an electric moment different from zero.) In these complicated molecules the question arises as to how one should regard such molecules in interpreting the apparent measured values of electric moment. Various attempts have been made in this direction. First attempts were made by assuming that the electrostatic interaction between the two rotating groups is negligible and that the rotation is therefore truly free. In this case it was assumed that the measured value of the square of the electric moment was the average square of the moment taken over a random distribution of the angle of free rotation. For example, two electric moments, μ , perpendicular to the axis of free rotation would give rise to an apparent or resultant moment $2^{1/2}\mu$.

Hojendahl has also pointed out that these internal rotations are never truly free but are hindered to some extent by electrostatic interaction; e.g., dipole interaction. In many cases this interaction may be considerable. Meyer⁵ has made an extension of Debye's *classical* theory of the dipole polarization for certain non-rigid molecules, assuming dipole interaction. These calculations indicate an appreciable temperature variation of apparent electric moment when the intermolecular potential exceeds $(1/10)kT$; and that if the rotation is truly free the apparent moment is as if μ^2 were averaged over a random motion of the internal rotation as mentioned above. Certain objections may be raised to these conclusions. If the internal rotational energy were not too great the actual motions of the rotating parts would certainly be affected appreciably by centrifugal action due to the external rotations of the molecules as a whole and these rotating parts might be deformed by electrostatic interaction in varying degrees depending on the kinetic energies of the various parts of the molecule. Then the individual rotating parts of the molecule could not be considered as rigid and Meyer's calculations might be invalid. An idea of the importance of dipole deformation can be gotten from the electric moments of the substitution products of methane.

On the quantum theory it is found that deviations from the classical dipole theory are appreciable only at very low temperatures. Van Vleck has derived the classical formula of Debye to a close approximation from general quantum-mechanical considerations having to do chiefly with the relative values of possible energy transitions in the molecules and spectroscopic

⁵ L. Meyer, *Zeits. f. Phys. Chem. (B)* 8, 27 (1930).

principles. It is assumed that the energy levels of the molecule are such that $h\nu$ is never of the order of kT , but is either much larger or much smaller than kT . Then the dipole term in μ^2/T arises from possible transitions for which $h\nu \ll kT$; and the optical term from transitions for which $h\nu \gg kT$. There arises in the calculations a quantity μ^2 which is interpreted as being associated with the fixed electric moment of the molecule. The theory is developed for the case of rigid molecules and has not been explicitly stated so as to include the possibility of internal free rotation. It seems probable that in this latter case there will arise a quantity which is to be interpreted as an average μ^2 but just how this should be averaged would require further consideration of the theory. Whether this μ^2 appreciably depends on temperature or not will probably depend on the magnitude of the interaction between the rotating parts, and possibly not in the same way as it would on the classical theory.

Strictly speaking Van Vleck's theory applies to the cases where all the transitions in energy can be separated into the above two cases relative to kT . When $h\nu$ is of the order of kT difficulties may arise. Actually this condition may exist for some of the ordinary vibration states, but Van Vleck states that, under his assumptions of invariant fixed moment, these states, which correspond to linear oscillators would cause no temperature variation in the electric polarization. Now in complex molecules there may be certain other types of motion for which $h\nu$ is of the order of kT and a temperature variation does result. In this connection it is interesting to consider the internal rotation of the OH group in organic molecules. Since this group has a large electric moment there exists the possibility of strong electrostatic interaction, for example, with the C=O bond in the COOH group. The quantized motions of the OH group might be similar to those for the physical pendulum as described by Condon.⁶ The lower states correspond to vibration and the higher states to non uniform rotation. The motions of the OH group might be considerable and the corresponding changes in electric moment quite large. Then the assumption of fixed electric moment would be invalid and some kind of average should be taken. This average might depend upon temperature, as was originally suggested to explain the data on acetic acid vapor.⁷

With regard to the interpretation of experimental values of μ three possibilities suggest themselves for the internal rotation here discussed. (1) If the interaction energy were sufficiently small the rotation could be regarded as truly free. Then the corresponding energy levels would be closely spaced and according to Meyer's classical derivation one would expect the apparent μ^2 to be an average over random internal rotational angle. (2) If the interaction energy were large, the lower states might correspond to oscillations of the rotator and have large energy separations. At ordinary temperatures practically all the molecules would be in the lowest state and this

⁶ E. U. Condon, Phys. Rev. **31**, 891 (1928).

⁷ It seems now that such a temperature variation is not necessary to explain the data on acetic acid; still the effect may exist to an appreciable extent but be undetectable as a departure from the linearity of a Debye line, for example if the deviations were approximately linear in temperature in the experimental interval.

oscillation would not contribute to the temperature variation of electric polarization, but would contribute a small amount to the atomic, or infrared, part of the constant polarization. In this ground state the corresponding motions of the oscillator would be fast compared to the external rotations and the apparent fixed electric moment μ should probably be regarded as a *vector* average over the oscillation as for the electronic motions, rather than a root mean square value as for the case of slow internal rotation. (3) The previous two cases are the extreme cases of Van Vleck's theory, for which the Debye equation holds. In the intermediate case where the energy separations are of the order of kT the temperature variation in electric polarization would be very complicated. This variation would now be due not only to the distribution of states of external rotation but also to the distribution in the states of internal rotation. Further because of the combined centrifugal and electrostatic interaction the perturbations of the individual states would no longer be like those of a simple dipole rotator. As regards the interpretation of experimental data, if such an effect exists in any actual molecules, it might be regarded as an apparent variation of electric moment with temperature. Such a variation with temperature will not necessarily be detectable as a deviation from the Debye equation $P=A+B/T$; for it is easily seen that a variation in apparent B which is linear with temperature is equivalent to a different but constant B together with a change in the constant A . If the effect is relatively small it may easily be such that the apparent B is approximately linear in the experimental interval. Then the experimental data would lead to a spurious value of the optical part A . For example, this possibility may be of interest in connection with Sanger's⁸ abnormal value of A for ethylene chloride. Meyer⁹ seems to think that a temperature variation in μ really exists in spite of the linearity of the Debye line.

There exists another serious difficulty in any quantitative treatment of free rotation in that the electrostatic interaction cannot be expressed accurately. Attempts have been made to consider this interaction as due to dipoles concentrated and located in various ways, but such models cannot give anything more than the roughest approximation to the facts, since the atoms are separated by distances comparable to atomic radii. The difficulties seem at present unsurmountable, whether one regards the interaction as a dipole effect, or as due to residual valence and van der Waals' forces as in London's theory.

Tetrahedral symmetry: The assumption of tetrahedral symmetry cannot be accurately true as is seen, for example, from the values of the electric moment of the chlorine substitution products of methane. The discrepancies are usually explained by saying that the valence directions tend toward tetrahedral symmetry in the absence of dipole interaction and that this interaction produces a bending of the valence directions. This seems to be consistent with experimental data. A recent article by Slater¹⁰ is especially interesting in this

⁸ R. Sanger, Phys. Zeits. 32, 21 (1931).

⁹ L. Meyer, Phys. Zeits. 32, 260 (1931).

¹⁰ J. C. Slater, Phys. Rev. 37, 481 (1931).

connection. On the basis of the quantum theory it is suggested that in the carbon atom the valence directions tend toward tetrahedral symmetry, while in the nitrogen and oxygen atoms they tend to be mutually perpendicular. The case of oxygen is of special interest here since it has been assumed by Eucken and Meyer that the undistorted valence angle for oxygen is the tetrahedral angle of about 110° . This is of importance in the original determination of the characteristic electric moments of the various chemical bonds.

STRUCTURE OF THE CARBOXYL GROUP

From the previous calculations it is seen that the electric moments of acetic and propionic acids are of practically the same value, 1.73 and 1.74×10^{-18} , but that of formic acid is smaller, 1.51×10^{-18} . It would be of interest to know whether this difference arises chiefly in the carboxyl group or in the alkyl group. If it arises in the alkyl group one could regard it as due to simple dipole induction which increases with the length of the carbon chain. Such an effect is well known in the series methyl, ethyl, propyl, to butyl chloride, where the moment increases by about 0.2×10^{-18} . This would indicate that the moment of the alkyl group changes from 0.4 to 0.6×10^{-18} by induction. Since the observed change in moment from formic to acetic acid is 0.22×10^{-18} it seems probable that this is also due to induction; particularly in view of the fact that the moment of COOH is not greatly different from that of C-Cl . The only observed difference in the two cases is that the transition is more abrupt in the fatty acid series.

It is, of course, possible that the transition may be at least in part due to a motion of the OH group of the type discussed under the above case (3) of relatively small interaction energy; but the values of the electric moment seem to indicate that the OH group is bound relatively tightly, either oscillating or rotating nonuniformly as in case (2). This is suggested by Meyer's calculated limiting values of the moment of the COOH group for the extreme positions of the OH group allowed by free rotation, 3.5 and 1.1×10^{-18} , corresponding to maximum and minimum potential energy, respectively. Because of the uncertainty in the calculations of electric moment, particularly in the valence directions, one cannot be certain whether these values indicate that the OH group has a considerable oscillation or not. The experimental values may be consistent with a very tightly bound OH group and a simultaneous bending of the valence directions, for example. We can, however, say with some degree of certainty that the motion of the OH group is not free since the expected moment would be much larger than the observed moment, about 3×10^{-18} . This is in agreement with the chemical evidence responsible for the supposition of the existence of a chelate ring in the carboxyl group.

THE DOUBLE MOLECULE OF FORMIC ACID

As regards the structure of the double molecule of formic acid, of moment 0.99×10^{-18} , this value of the electric moment excludes the possibility of the antiparallel type of association. Taking into consideration the relative sizes of the C and O atoms and assuming tetrahedral symmetry for the carbon

atoms, it is almost possible geometrically to fit the molecules together in such a way that the four O atoms lie at the corners of a square and the C atoms on a line perpendicular to the square. The planes of the two associating HCOOH molecules would then be mutually perpendicular. If this is the approximate structure of the double molecule, the OH group of one of the original molecules of HCOOH would tend to be directed toward the doubly bound O atom of the other molecule and would be attracted toward it, distorting the square into the form of a rectangle. The OH group would then be quite near to the C=O group and the interaction would probably bind the OH group relatively tightly in the ground state. It is, of course, impossible to make an accurate calculation of the electric moment of the double molecule, but a rough estimate after the manner of Eucken and Meyer is perhaps of some interest. The sizes of the atoms permit of a distortion of the square by interaction such that the planes of the two HCOOH atoms subtend an angle a little less than 120° . In the position of minimum potential energy the OH groups would lie approximately in the plane of the oxygen rectangle and at an angle of 60° relative to one another. Using the values of Eucken and Meyer for the characteristic moments one obtains a value of about 1.1×10^{-18} for the electric moment of the double molecule. Finally, one can say that the experimental value 0.99×10^{-18} does not seem to be inconsistent with the proposed type of structure so far as this rough estimate is concerned.

At present it is not possible to calculate the electric moment of the double molecule of acetic or propionic acid. These values would be particularly interesting in connection with the interpretation of the transition in electric moment from formic to acetic acid.

ON IMPURITIES IN METALS

BY FRANCIS BITTER

WESTINGHOUSE RESEARCH LABORATORIES, EAST PITTSBURGH

(Received April 27, 1931)

ABSTRACT

In order to arrive at a satisfactory understanding of many of the properties of metals, especially ferromagnetic metals, it is necessary to take into account the distorting effect of impurities and of other irregularities in the crystal lattice. The present paper is an attempt to describe some of the corrections that must be applied to the usual model of a perfect crystal before it can be expected to reproduce the properties of actual substances. Starting with the usual law of force between any two atoms—repulsion for small distances, attraction for large distances—the distortion of the lattice in the immediate neighborhood of an atom of impurity is discussed, with especial reference to the significance of the formation of molecules. Phase distributions in substances capable of allotropy are described, together with the influence of impurities on such distributions. The existence of diffusion makes it possible to apply statistical mechanics to solid solutions. It is shown that, in general, atoms of impurity in solids do not exert long range forces on each other by means of the distortions they produce in the lattice. This makes it possible to give simple formulae for the distribution of concentration of the impurities. These distributions are sometimes far from uniform, and a phenomenon similar to opalescence in gases may occur. Applications of the above concepts to ferromagnetic solutions are pointed out, and it is suggested that the ferromagnetism of austenite containing in the neighborhood of 0.8 percent carbon may be due to the presence of small granules of α -iron resulting from local fluctuations in the distribution of carbon atoms.

IT IS an old story that small amounts of impurities are sometimes of great importance in determining the physical properties of a substance, but in spite of this, the mechanism of such actions is very little understood. The magnetism of iron is a good example of the magnitude and importance of these effects. Yensen¹ has pointed out that in the interval between 1900 and 1928 the maximum permeability of iron has been increased from 2,000 to 61,000, chiefly by controlling small amounts of impurity. The most recent advance in this field is due to Cioffi,² who produced iron having a maximum permeability of 130,000 by annealing at high temperatures in a hydrogen atmosphere. There is little hope of understanding such phenomena until our theories of ferromagnetism and of other structure-sensitive properties are based on models of solids in which allowance is made for the chemical and mechanical effects of impurities. It is the purpose of this paper to describe such a model in some detail.

1. PURE PERFECT CRYSTALS

The substance to be investigated will be supposed made up of atoms between which the usual simple law of force acts—repulsion for small separa-

¹ T. D. Yensen, *Journal of the Franklin Inst.* 206, 503 (1928).

² P. P. Cioffi, *Nature* 126, 200 (1930).

tions, attraction for large separations, and only one position of equilibrium for finite separations. Out of this law of force may be calculated³ the potential energy Φ of any given spacial arrangement of the atoms. Such calculations neglect a possible block structure as postulated by Zwicky,⁴ but they may be thought of as being applicable to a single block and as an approximation to an aggregate of blocks. Since, however, a knowledge of the free energy is necessary for the interpretation of the properties of crystals with temperature agitation, and since this free energy is not calculable from our present knowledge of atomic physics, it is impossible to make any quantitative theory of distorted lattices. A few qualitatively applicable observations can, however, be made, and for these we will confine ourselves in the main to the above simple model, the object being to find which of the properties of actual substances can be found in such a model, and which of the properties require the introduction of further assumptions regarding the atomic interactions.

Beyond the above definition of the substance with which the further discussion deals, there is only one point to be brought out before attacking the problem of the effect of impurities, and that concerns the mechanism of change of phase, and the associated problem of phase distribution throughout the volume of the substance. Let this substance be designated by A , and let it be assumed that A is capable of existing in two phases, α and β . Let the potential energy in each of these phases be designated by $\Phi_\alpha(p)$, $\Phi_\beta(p)$, where p represents those parameters on which the potential energy depends. For the sake of definiteness let us think of p as being the pressure, and as p is varied the lattice expands or contracts uniformly, remaining geometrically similar to itself. If Φ were thought of as the free energy, p might stand for the temperature. Φ_α and Φ_β satisfy the following conditions:

$$\Phi_\alpha < \Phi_\beta \text{ for } p < p_c$$

$$\Phi_\alpha = \Phi_\beta \text{ for } p = p_c$$

$$\Phi_\alpha > \Phi_\beta \text{ for } p > p_c.$$

As p increases from a value just less than p_c to one just greater than p_c , the whole substance *may* suddenly change from the α -phase to the β -phase. The intention is to bring out that this change *need* not take place all at once, because the substance may not be homogeneous, as is usually assumed. These inhomogeneities may be due to several causes. One such would be local spontaneous fluctuations in p (this, of course, only if there is temperature agitation). Another would be the presence of an atom of some foreign substance B , or of an atom of A in an excited state. Such atoms would exert anomalous forces on their neighbors, which would really be equivalent to local pressures. Or the material might, without the interference of any of these factors, have its free energy a minimum for a mixture of the two phases.⁵ For instance, suppose A is at a pressure $p_c - \delta p$, and that due to some unspecified cause a small region R is already in the β -phase. Suppose, further, that nor-

³ Jones and Ingham, Proc. Roy. Soc. A107, 640 (1925) have done this for laws of force of the type $ar^m + br^n$ for various cubic lattices.

⁴ F. Zwicky, Helvetica Physica Acta 3, 269 (1930).

mally an expansion is associated with the $\alpha-\beta$ transition. It follows that the region R will be under compression due to its increase in volume while still surrounded by the unexpanded α -phase. In determining whether this local pressure is sufficient to maintain the region R in the β -phase, and how large R may be expected to be, it is necessary to consider the surface energy of R , the presence of other such regions, etc. A detailed discussion of these considerations cannot be given here, but the following points may be mentioned:

1. That in solid solutions such phase mixtures do occur.
2. That in some pure substances the transition from the crystalline to the liquid state probably involves such phase mixtures.
3. That phase mixtures of purely crystalline phases may exist in pure substances.²³
4. That even under conditions far removed from the critical conditions, under which a phase change $\alpha-\beta$ takes place, small (ultramicroscopic) inclusions of one phase in the other may be present.
5. That such inclusions would have a considerable effect on structure sensitive properties.

2. ONE ATOM OF IMPURITY

An atom of a substance⁶ B in the lattice of a substance A will in general produce very complex changes, especially if B is chemically very different

⁵ A theoretical attack on this problem is possible following a procedure indicated by N. Rashevsky in an article on the size distribution of colloidal particles (*Zeits. f. Physik* **46**, 300, 1927). Instead of considering a substance B in another A , we can think of a phase β in another α , of the same substance. With this change of nomenclature, Rashevsky's results are

$$n(m) = e^{\lambda + \alpha m - K/K}$$

$n(m)$ being the number of regions in the β -phase having a mass m . K is the Boltzmann constant, $\lambda = \phi + k \log n_0$; $\phi = s - (u + pv)/T$, the entropy s being defined by $ds = (du + pdv)/T$. The constant α is chosen to satisfy the equation

$$\int_0^\infty m e^{\lambda + \alpha m - K/K} dm = M$$

where M is the total mass of substance in the β -phase. Further progress can only be made when the function u is known. Rashevsky shows that with reasonable assumptions for u , the function $n(m)$ may have a maximum either for $m=0$ (a true solution), $m=m_0$ (a colloidal solution), or $m=\infty$ (two distinct and separate phases).

If such a phase distribution is wanted at temperatures which are not convenient for observation, the following procedure may be found useful as a basis for extrapolation. Instead of speaking of an inclusion of mass m , it will be convenient to refer to an inclusion of radius R . Then $u(R) = \int_0^T \sigma_\beta dt + l + (3/2)KT + \text{constant}$. The first term represents the energy required per unit mass to heat the β -phase to the transformation temperature. l is the latent heat of transformation of a colloidal particle and may be written (G. Bakker, *Handbuch der (Experimental) Physik* **6**, page 210)

$$l = (v_\beta - v_\alpha)T \frac{d(p_\beta + p_\alpha)}{dT} - \frac{2(v_\beta + v_\alpha)}{R} T \frac{dH}{dT}$$

H is the surface tension. From this equation a reasonable form for $u(R, T)$ can be found, and hence the temperature dependence of the size distribution of the particles in the colloidal phase.

⁶ B may be an excited atom of the substance A .

from A . For the sake of this qualitative discussion, however, it will suffice to assume that ϕ_{AB} , the potential energy between an atom of A and one of B , is the same sort of function as the function ϕ_{AA} which gives rise to the interatomic forces already specified in section 1. Typical curves are to be found in Fig. 1. In the simple case where B is a substitution atom, the effect of the substitution is to add to the undistorted lattice a potential $\phi_{AB} - \phi_{AA}$ resulting from the excess forces exerted by the atom of impurity on its neighbors. This curve may have a maximum for finite values of r , or it may have a minimum, or it may be of a much more complicated nature, the important point being that even with the above simple assumptions a curve of the type shown in Fig. 1 for $\phi_{AB} - \phi_{AA}$ is obtainable.

Fig. 1. The potential energy of two similar atoms $A-A$ and of two dissimilar atoms $A-B$ as a function of their distance apart, and finally the difference between these two functions, which is used in Fig. 3.

The most striking changes are brought about by the atom of impurity in its immediate neighborhood, but these are not of primary importance in this paper, and we shall discuss them only for the sake of their possible bearing on the phenomenon of thermal hysteresis. In Fig. 2 are shown two ways in which an atom of B may interact with its neighbors in accordance with the potential energy curve shown in Fig. 1. In both cases the impurity is in solution, but in order to distinguish between them, one might say that in case a , the atom B is in solution, whereas in case b , the molecule A_4B is in solution. The existence of a solution in two forms as described above is of interest in relation to temperature hysteresis. In Fig. 3 is shown a curve representing the potential energy of the atom A_1 adjoining the impurity as it approaches its neighbors, B and A_2 , the latter being considered fixed. Curve 1 would represent the conditions if no impurity were present. The presence of the impurity necessitates

the addition of $\phi_{AB} - \phi_{AA}$, or curve 2, and the result is curve 3, which has two minima. As Rashevsky has pointed out,⁷ it is just such curves as 3 Fig. 3 that give rise to hysteresis, and it is fairly obvious without further discussion that the relative concentration of atoms in the two minima will depend not

Fig. 2. Two possible distortions of a crystal around an atom of impurity compatible with the potential curves in Fig. 1 and Fig. 3.

only on the temperature and pressure, but also on the previous history of the sample. Since the physical properties of the substance $A+B$ will surely depend to some extent on whether B is in solution in the form A_4B or B , the

Fig. 3. The potential energy of A , as a function of displacement (1) when the atom B is identical with A_1 and A_2 , and (3) when B is an atom of impurity giving rise to the additional energy (2), deduced from Fig. 1.

above described thermal hysteresis will give rise to a thermal hysteresis of other physical properties.

The only influence of the atom of impurity on distant parts of the lattice to be considered here will be the elastic deformation. In the calculation of this effect, it is assumed that the medium is isotropic, and that the distortion produced is spherically symmetrical. Under these conditions the strains in the

⁷ N. Rashevsky, *Zeits. f. Physik* 53, 102 (1929); 59, 562 (1930); 61, 511 (1930); 60, 237 (1930).

lattice will diminish as some function of the distance from the impurity atom, and there will exist a sphere of radius R_0 (see Fig. 4) around this atom such that the strains outside it may be considered small, and proportional to the stresses. R_0 will, as a rule, be of the order of magnitude of a few atomic diameters. Unless the medium is very anisotropic the effect of the impurity at distant points may then be approximated by the strains set up in a homogeneous medium within which a pressure p is exerted normally to the surface of a sphere of radius R_0 . Let E represent Young's modulus; ν Poisson's ratio, ρ the displacement of any given point, which will necessarily be radial; ϵ_r and ϵ_t

Fig. 4. Diagram to illustrate the symbols used in calculating distortions due to impurities in crystals.

the radial and tangential elongations; and σ_r and σ_t the radial and tangential stresses. It then follows that (see appendix A)

$$\epsilon_r = \frac{d\rho}{dr}; \quad \epsilon_t = \frac{\rho}{r}$$

$$E \frac{d\rho}{dr} = \sigma_r - 2\nu\sigma_t \quad (1)$$

$$E \frac{\rho}{r} = -\nu\sigma_r + (1-\nu)\sigma_t.$$

For equilibrium it is necessary that the radial forces acting on any volume element $(rd\theta)^2 dr$ be cancelled by the radial component of the tangential forces, or $F_r = -4[F_t]_r$. But

$$F_r = \sigma_r(rd\theta)^2 - \left[\sigma_r + \frac{d\sigma_r}{dr}dr \right] (r+dr)^2 d\theta^2$$

$$[F_t]_r = \sigma_t r d\theta dr d\theta / 2$$

which gives

$$r \frac{d\sigma_r}{dr} - 2(\sigma_t - \sigma_r) = 0. \quad (2)$$

Solving Eq. (1) for σ_r and σ_t and substituting the result in Eq. (2), we obtain

$$r^2 \frac{d^2\rho}{dr^2} + 2r \frac{d\rho}{dr} - 2\rho = 0. \quad (3)$$

The general solution of this is easily found to be

$$\rho = c_1 r + \frac{c_2}{r^2} \quad (4)$$

and since we are interested in the problem for which one boundary condition is $\rho = 0$ for $r = \infty$, we may put $c_1 = 0$. Using for the other boundary condition that $\sigma_r = p$ for $r = R_0$ we find

$$c_2 = - \frac{(1 - \nu - 2\nu^2)}{2(1 - 2\nu)E} R_0^3 p \quad (5)$$

$$\sigma_r = p \frac{R_0^3}{r^3} \quad \sigma_t = - \frac{p}{2} \frac{R_0^3}{r^3} \quad (6)$$

and for the total energy of the distortion

$$E_n = \frac{1}{2} \frac{4\pi p^2 R_0^3}{E} \frac{1 - \nu - 2\nu^2}{2(1 - 2\nu)} \quad (7)$$

These results⁸ describe the distortion of the lattice at points more than a few atomic diameters removed from the atom causing the distortion and will be used in part 4 in discussing the possible existence of long range forces between atoms of impurity.

3. DIFFUSION

That diffusion and self-diffusion in solids exists has been known for some time, but the mechanism by which it proceeds is considerably in doubt. Frenkel⁹ studied the phenomenon, first with the assumption that the atoms of a solid exchange places, and then¹⁰ somewhat more elaborately with the assumption that some of the atoms occupy positions of "irregular equilibrium" in the interatomic spaces, and that diffusion proceeds by the movement of such atoms down the "aisles" of the lattice. Frenkel, and also Braunbeck¹¹ obtain expressions for the diffusion coefficients, of which the most interesting feature is that $D \sim e^{-b/T}$ where b is essentially a measure of the work required of an atom to break through its potential walls and so change places with a neighbor. The diffusion process is perhaps best described in terms of wave-mechanics. A particle surrounded by a potential wall will eventually appear on the other side no matter what its energy, the probability w of getting through at a single impact being¹² essentially $e^{-(4\pi/\hbar) \int [2\mu(v-w)]^{1/2} dx}$. The diffusion coefficient for particles having an energy W is then proportional¹¹ to w . In the above expression $V(x)$ is the potential energy of the particle at a point x , and the integration extends between values of x that make $(V - W)$ vanish. These two formulae agree in predicting that D will increase rapidly with the temperature. Further, because b and V appear as exponents, it is to be ex-

⁸ I am indebted to Dr. A. Nadai for his advice and help in handling this problem.

⁹ J. Frenkel, *Zeits. f. Physik* 26, 137 (1924).

pected that the diffusion coefficients for different substances will vary greatly—even as to order of magnitude.

4. MORE THAN ONE ATOM OF IMPURITY

The problem of impurities in solids is essentially that of studying the effects of inhomogeneities in a crystal.¹³ But aside from the irregularities produced by the impurity because of its atomic character, there is a large scale effect if its atoms are not disposed at regular intervals. In ferromagnetic substances, for instance, the magnetic quality is determined not by the individual atoms alone, but by their relationship to each other in the lattice. This relationship involves groups of various sizes, such as the crystal grains; the Barkhausen¹⁴ units; the individual blocks, if block structure, as has been suggested,¹⁵ plays a part in ferromagnetic phenomena; and finally, each atom and its immediate¹⁶ neighbors. Therefore, in discussing the effect of an impurity, it is necessary to know how its atoms are distributed among these various groups. Even in the case of a perfect single crystal, fluctuations in the concentration of impurities will in general have the effect of varying its physical properties from point to point, and the macroscopic sample will have to be treated as a heterogeneous medium.

The first case to be considered will be that in which the atoms are incapable of moving through the lattice. Here any distribution whatever will be stable, but the only repeatable distribution will be a random one. In the second case, where diffusion takes place, we shall limit ourselves to stable distributions, namely those which set in after the substance has been kept under constant physical conditions for a sufficiently long time. These distributions will depend on the existence of forces acting between the atoms of the impurity.

Case 1. (see appendix B)

Consider n cells or boxes in which N particles are arranged at random. We require the probability $f(a)$ that a cell chosen at random contain " a " particles. This will be the fraction of the total number of arrangements of the N particles among the n cells in which one particular cell contains " a " particles. The total number of arrangements possible is n^N . If we put " a " particular particles in a given cell, the number of arrangements possible is reduced to $(n-1)^{N-a}$. But the number of ways in which we can choose the " a " particles is $N!/a!(N-a)!$, so that the desired probability becomes

$$f(a) = \frac{N!(n-1)^{N-a}}{a!(N-a)!n^N}. \quad (8)$$

We shall be interested in the case where N and n , but not necessarily a , are large. Applying Stirling's formula for N and n we get

¹³ Impurities along crystal boundaries and other surfaces are here neglected.

¹⁴ J. Frenkel and J. Dorfman, *Nature* **126**, 274 (1930).

¹⁵ F. Bitter, *Phys. Rev.* **37**, 91 (1931).

¹⁶ F. C. Powell, *Proc. Phys. Soc.* **42**, 400 (1930) suggests that this last group may contain as many as 58 atoms in iron.

$$\lim_{N \rightarrow \infty, n \rightarrow \infty} f(a) = \left(\frac{N}{en} \right)^N \left(\frac{e(n-1)}{N-a} \right)^{N-a} \frac{1}{a!}$$

which, neglecting N^{-1} compared to unity, can be written

$$\lim_{N \rightarrow \infty, n \rightarrow \infty} f(a) = \frac{e^{-\xi} \xi^a}{a!} \quad (9)$$

where $\xi = N/n$, and is the average number of particles per cell. This formula is not convenient for computation when ξ is large, and for this case it is possible to derive¹⁷

$$\lim_{N \rightarrow \infty, n \rightarrow \infty, \xi \rightarrow \infty, a \sim \xi} f(a) = \frac{e^{-(\xi-a)^2/2\xi}}{(2\pi\xi)^{1/2}} \quad (10)$$

Curves for various values of ξ are plotted in Figs. 5 and 6. Eq. (10) was used for $\xi = 1000$ only; the other curves represent Eq. (9).

Fig. 5. N particles are randomly distributed among n cells, both N and n being $\gg 1$. $N/n = \xi$. $f(a)$ is the probability of finding " a " particles in a cell chosen at random. This figure shows $f(a)$ for small values of ξ .

Case 2. (See appendix B)

If the particles are capable of motion, they may be considered as a gas exerting a pressure, and the fluctuations will evidently depend on the equation of state. Fowler¹⁸ shows that if v_0 is the volume normally occupied by ξ molecules at a pressure p_0 , then writing $((a/\xi) - 1) = \gamma$, the fluctuations are determined by

$$f(\gamma) d\gamma = \mu d\gamma \exp \left[\frac{1}{KT} \left\{ \frac{v_0^2 \gamma^2}{2!} \frac{\partial p_0}{\partial v_0} + \frac{v_0^3 \gamma^3}{3!} \frac{\partial^2 p_0}{\partial v_0^2} + \frac{v_0^4 \gamma^4}{4!} \frac{\partial^3 p_0}{\partial v_0^3} + \dots \right\} \right] \quad (11)$$

¹⁷ See appendix B.

¹⁸ Fowler, Statistical Mechanics, pp. 515-516.

For a perfect gas $\partial p_0/\partial v_0 = -n_0KT/v_0$, the terms involving $\partial^2 p_0/\partial v_0^2$ etc. are negligible, and (11) reduces to (10).

The problem of finding the fluctuations in concentration of impurities in solids is now reduced to that of determining the forces acting between the impurity atoms, and hence the equation of state of the impurity. Two impurity atoms separated by only one or two atomic diameters may exert forces on each other arising from their electrons. But if they are separated by much greater distances, it seems reasonable to suppose that the only forces to be taken into consideration will be those resulting from the distortion of the lattice as given in Eqs. (4), (5) and (6). Thus it is necessary to determine the energy $E_n(R)$ of the distortion produced by two atoms of impurity a distance R apart, and then derive the forces by taking the gradient of $E_n(R)$.

Fig. 6. For the meaning of the symbols see Fig. 5. In Fig. 6 $f(a)$ is plotted for large values of ξ .

Since the differential equations for small strains in an elastic solid are linear, we may add integrals provided the boundary conditions are still satisfied. Referring to the problem treated in part 2, this means that the small distortion of a continuous elastic medium produced by pressures on the surface of two spheres whose centers are a distance R apart are equal to the sum of the displacements ρ as given in Eqs. (4) and (5). The boundary conditions give rise to the added energy

$$\Delta E_n = \oint p \rho_a ds \quad (12)$$

where the integral is taken over the surface of both spheres, and ρ_a is the normal component of the distortion produced by the one sphere at a point on the surface of the other. As is evident from Fig. 4, $\rho_a = -\rho \cos(\theta + \phi)$, $r^2 = R^2 + R_0^2 - 2RR_0 \cos \theta$, and since $\cos(\theta + \phi) = \cos \theta \cos \phi - \sin \theta \sin \phi$, and $\cos \phi = (R - R_0 \cos \theta)/r$, $\sin \phi = R_0 \sin \theta/R$, ΔE_n may be written

$$\Delta E_n = -2 \int_0^{2\pi} d\phi \int_0^\pi R_0^2 \sin \theta d\theta p \frac{c_2}{r^2} \left[\frac{\cos \theta (R - R_0 \cos \theta) - \sin \theta a \sin \theta}{r} \right] \quad (13)$$

$$= 4\pi p c_2 R_0^2 \int_{-1}^{-1} \frac{R_0 - R_x}{r^3} dx = 0.$$

In the above the substitution $x = \cos \theta$ has been made for simplicity in integration. This means that for dilute solutions to which alone the above considerations are applicable, the heat of solution per atom is independent of the concentration, and that the molecules of the solute or impurity exert no forces on each other over distances greater than a few atomic diameters. Thus the solute may be treated as a perfect gas and the fluctuations in concentration are correctly given by Eqs. (9) and (10) and Figs. 5 and 6.

There may, however, be short range forces between atoms of impurity, such as cause precipitation. Near a temperature at which precipitation occurs,

Fig. 7. A volume containing N gaseous molecules is divided into n regions, both N and n being $\gg 1$. $N/n = \xi$. $f(a)$ is the probability of finding " a " molecules in a cell chosen at random. If the gas is near the critical point and $\xi = 1000$ $f(a)$ is given by the curve above. This should be compared with the curve for $\xi = 1000$ in Fig. 6, which represents the corresponding conditions in a perfect gas.

these short range forces may cause very large density fluctuations, as they are in fact known to do in gases near the critical temperature, giving rise to the phenomenon of opalescence. As an example of the order of magnitude of the fluctuations to be expected under such circumstances, the fluctuations of a gas obeying Dietrici's equation of state

$$p(v - b) = NKT e^{-a/NKTv} \quad (14)$$

at the critical temperature are plotted in Fig. 7 for $\xi = 1000$. The formula for this curve may be derived by substituting Eq. (14) and Eq. (11), and the result¹⁸ is

$$f(a) = \text{constant } e^{-(\xi - a)^4 / 22.2\xi^2}. \quad (15)$$

5. APPLICATIONS

The above ideas may be applied to the effect of impurities on various properties of metals, but we shall in this paper only point out their bearing on a few ferromagnetic phenomena.

As a first example, consider platinum containing 1–10 percent cobalt, as has been studied by Constant.¹⁹ One of the questions of primary importance in attempting to understand the properties of such solutions will be that of determining how many cobalt atoms are adjacent to 1, 2, 3, . . . etc. other cobalt atoms. In this particular case interatomic forces will be of importance, but it seems clear that unless they are strongly repulsive, one can hardly expect such solutions to be homogeneous. That is, the solution will consist of small regions which will behave like pure platinum, and small regions which will approximate pure cobalt, and all intermediate gradations. Since paramagnetism and diamagnetism are as a rule negligibly small compared to ferromagnetism, it may be a good approximation to treat the above solution as a group of ferromagnetic inclusions in non-magnetic material. In a future communication on block structure and ferromagnetism I hope to return to a more detailed discussion of the properties of such solutions.

One of the outstanding facts about ferromagnetism is its susceptibility to strains, and in the preceding sections we have discussed the strains due to individual atoms of impurity. To these may be added strains due to fluctuations in concentration of impurities. Until more is known of the mechanism of magnetization it is useless to say anything about the effects of these strains on the hysteresis loop, magnetization curve, etc. beyond pointing out that strains do have large effects, that impurities do cause strains, and that consequently impurities may be expected to have large effects on magnetic properties by virtue of these strains.²⁰

As has been mentioned, an impure metal may be expected to behave like an aggregate of regions whose physical properties are dissimilar. A phenomenon which would show the effect of these small regions would be the change of phase, if observed under suitable conditions. Suppose that some pure substance *A* undergoes a transformation at the temperature *T*, and that addition of some other substance *B* which dissolves in *A* lowers the transformation temperature. According to what has been said, *B* will distribute itself over *A* in such a way as to produce varying concentrations of *B*. It is to be expected that those regions containing small concentrations of *B* will undergo transformation at higher temperatures than those regions containing larger concentrations. The conclusion is that solutions undergo transformation *gradually* over a finite range of temperatures, a phenomenon which is often observed. So many other factors enter into the rate of transformation, however, that it is not practicable to attempt here a detailed comparison between experimental facts and the above ideas.

¹⁹ F. W. Constant, Phys. Rev. 36, 1654 (1930).

²⁰ In this connection, see, for instance, an article by T. D. Yensen, Metals and Alloys 1, 493 (1930).

Lastly, let us consider a peculiar feature of the iron-carbon diagram as it is usually drawn. This concerns the magnetic transformation A_2 in iron containing between 0.6 percent and 0.9 percent carbon, which, at the A_2 temperature of about 770°C is in the form of austenite, or γ -iron + carbon in solution. The significant point, as Honda and Takagi²¹ have pointed out, is that the A_2 point in γ -iron + carbon is essentially the same as that of α -iron + carbon. This fact, for it has been observed so often as seemingly to leave no room for doubt, is not to be understood in the light of present concepts about the nature of ferromagnetism, and will necessitate fundamental changes, unless it is found that what has heretofore been called γ -iron + carbon actually contains small inclusions of α -iron which are responsible for the observed ferromagnetism of austenite. In the light of the previous discussion one would expect to find small regions having low carbon concentration, and it is these regions that might form inclusions of α -iron. Such regions should be capable of detection by means of x-rays, and an investigation is under way to determine whether or not they are actually present.²²

APPENDIX A

CALCULATION OF SMALL STRAINS DUE TO IMPURITIES, AND THE RESULTING LONG RANGE FORCES BETWEEN ATOMS OF IMPURITY

Consider an infinite isotropic elastic medium in which a spherical hole has been excavated. A pressure p acts normally to the surface of the excavation, whose radius is R_0 . What is the distortion and stress throughout the medium?

E = Young's modulus; ν = Poisson's ratio; ρ = displacement—which is everywhere radial; ϵ_r = radial elongation; ϵ_t = tangential elongation; σ_r = radial stress; and σ_t = tangential stress.

Consider an element of volume bounded by two spherical surfaces $[rd\theta]^2$ and $[(r+dr)d\theta]^2$ and by the four plane surfaces $(r+dr/2)d\theta dr$

$$\begin{aligned} \epsilon_r &= \frac{d\rho}{dr} & \epsilon_t &= \frac{\rho}{r} \\ \left. \begin{aligned} \epsilon_r &= \frac{1}{E}(\sigma_r - 2\nu\sigma_t) \\ \epsilon_t &= \frac{1}{E}(\sigma_t - \nu\sigma_t - \nu\sigma_r) \end{aligned} \right\} & \text{or} & \left\{ \begin{aligned} E \frac{d\rho}{dr} &= \sigma_r - 2\nu\sigma_t \\ E \frac{\rho}{r} &= -\nu\sigma_r + (1-\nu)\sigma_t \end{aligned} \right. \quad \text{I} \end{aligned}$$

²¹ K. Honda and H. Takagi, Sci. Rep. Tohoku Univ. 2, 203 (1914).

²² See item 3 at the conclusion of the first section. Since completing this paper an article by F. M. Jaeger and J. E. Zanstra, Proc. Akad. Amsterdam 34, 15, 1931 has come to my attention. Among other things, the authors investigate the crystal structure of rhodium as a function of temperature, and find (p. 19) that two phases co-exist as a mixture, one phase being present in the other in the form of very small particles containing $(33)^3$ or 36,000 atoms. Not only is the co-existence of the two phases of interest in connection with the previous discussion, but also the estimated size of the small inclusions, as having a possible bearing on the block theory of Zwicky.⁴

F_r and F_t are the forces acting on the various faces of the above volume element. For equilibrium

$$\begin{aligned} F_r &= \sigma_r(r d\theta)^2 - \left[\sigma_r + \frac{d\sigma_r}{dr} dr \right] (r + dr)^2 d\theta^2 \\ -F_r &= \sigma_r 2r dr d\theta^2 + \frac{d\sigma_r}{dr} dr r^2 d\theta^2 \\ [F_t]_r &= \sigma_t r d\theta dr d\theta / 2 \end{aligned}$$

and using the equilibrium conditions

$$r \frac{d\sigma_r}{dr} - 2(\sigma_t - \sigma_r) = 0. \quad \text{II}$$

From I eliminate σ_r

$$E(\rho/r + \nu\rho') = \sigma_t(1 - \nu - 2\nu^2).$$

Eliminate σ_t

$$\sigma_r = E\rho' + \frac{2\nu E}{1 - \nu - 2\nu^2}(\rho/r + \nu\rho')$$

or

$$\begin{aligned} \sigma_t &= \frac{E}{1 - \nu - 2\nu^2}(\rho/r + \nu\rho') \\ \sigma_r &= \frac{E}{1 - \nu - 2\nu^2}[2\nu\rho/r + (1 - \nu)\rho']. \end{aligned} \quad \text{III}$$

Substitute III in II and get

$$r^2\rho'' + 2r\rho' - \nu\rho = 0. \quad \text{IV}$$

Substitute $\rho = r^n$, and it is seen that $n = 1$ or -2 and the solution of IV therefore is

$$\rho = c_1 r + \frac{c_2}{r^2}$$

which in our case becomes $\rho = c_2/r^2$ since $\rho = 0$ for $r = \infty$ and therefore $c_1 = 0$.

If the boundary conditions are put in the form

$$\begin{aligned} \sigma_r &= p \text{ for } r = R_0, \text{ then} \\ c_2 &= -\frac{(1 - \nu - 2\nu^2)}{2(1 - 2\nu)E} R_0^3 p \\ \sigma_r &= p R_0^3 / r^3 \\ \sigma_t &= -p/2a^3/r^3. \end{aligned}$$

If the boundary conditions are given in terms of strains instead of stresses

$$\rho = \delta \text{ for } r = R_0,$$

then

$$\begin{aligned} c_2 &= R_0^2 \delta & \rho &= \delta R_0^2 / 2 \\ \sigma_r &= \frac{-2(1-2\nu)c_2 E}{1-\nu-2\nu^2} \frac{1}{r^3}, & \sigma_t &= -\sigma_r / 2. \end{aligned}$$

The energy of the distortion can be calculated in two ways

$$\begin{aligned} E_n &= \delta \frac{1}{2} \sigma_r \Big|_{r=R_0} \cdot \rho \Big|_{r=R_0} \cdot \text{area} = \frac{1}{2} p \cdot \frac{-(1-\nu-2\nu^2)}{2(1-2\nu)E} \frac{R_0^3 p}{R_0^2} \cdot 4\pi R_0^2 \\ &= \frac{1}{2} \frac{4\pi p^2 R_0^3}{E} \frac{1-\nu-2\nu^2}{2(1-2\nu)} \end{aligned}$$

or

$$\begin{aligned} E_n &= \frac{1}{2} \int_{r=a}^{r=\infty} (\epsilon_r \sigma_r + 2\epsilon_t \sigma_t) dv \\ &= \frac{1}{2} 4\pi \int_a^\infty \left(-2c_2 p R_0^3 - \frac{2c_2 p R_0^3}{2} \right) \frac{dr}{r^4} \\ &= -\frac{4\pi}{2} \int_a^\infty \frac{dr}{r^4} 3c_2 p R_0^3 = 4\pi c_2 p R_0^3 \frac{3}{3R_0^3} \\ &= \frac{1}{2} \frac{4\pi p^2 R_0^3}{E} \frac{1-\nu-2\nu^2}{2(1-2\nu)} \end{aligned}$$

in agreement with the above.

For two spheres whose centers are a distance R apart ($R \gg R_0$) the total energy becomes $2E_n + \Delta E_n$ where

$$\Delta E_n = -2 \int_0^\pi a^2 \sin \theta d\theta p \frac{\delta R_0^2}{r^2} \left[\frac{\cos \theta (R - a \cos \theta)}{r} - \frac{\sin \theta a \sin \theta}{r} \right]$$

see Eq. (13) of the text. Substituting $\cos \theta = x$, we have

$$\begin{aligned} \Delta E_n &= -4\pi p \delta R_0^4 \int_1^{-1} \frac{x(R - R_0 x) - R_0(1 - x^2)}{r^3} dx \\ &= 4\pi p \delta R_0^4 \int_1^{-1} \frac{R_0 - Rx}{r^3} dx = 4\pi p \delta R_0^4 (R_0 A - RB) \end{aligned}$$

where

$$A = \int_1^{-1} \frac{dx}{r^3} \quad B = \int_1^{-1} \frac{x dx}{r^3}.$$

Let

$$r^3 = (\alpha + \beta x)^{3/2} \quad a = R^2 + R_0^2 \quad \beta = -2R_0R$$

$$A = \int_1^{-1} \frac{dx}{(\alpha + \beta x)^{3/2}} = \frac{2}{\beta} \left[\frac{(\alpha - \beta x)^{-1/2}}{-1} \right]_1^{-1} = -\frac{2}{\beta} \left[\frac{1}{(\alpha - \beta)^{1/2}} - \frac{1}{(\alpha - \beta)^{1/2}} \right]$$

$$B = \int_1^{-1} \frac{x dx}{(\alpha + \beta x)^{3/2}} = \frac{2}{\beta^2} \left[\frac{(\alpha + \beta x)^{1/2}}{1} + \frac{\alpha}{(\alpha + \beta x)^{1/2}} \right]_1^{-1}$$

$$= \frac{2}{\beta^2} \left[\frac{2\alpha + \beta x}{(\alpha + \beta x)^{1/2}} \right]_1^{-1}$$

$$B = \frac{2}{\beta^2} \left[\frac{2\alpha - \beta}{(\alpha - \beta)^{1/2}} - \frac{2\alpha + \beta}{(\alpha + \beta)^{1/2}} \right]$$

But

$$(\alpha + \beta)^{1/2} = (R^2 - 2RR_0 + R_0^2)^{1/2} = R - R_0$$

$$(\alpha - \beta)^{1/2} = R + R_0$$

$$A = -\frac{2}{R(R^2 - R_0^2)} \quad B = \frac{2R_0}{R^2(R^2 - R_0^2)}$$

and therefore

$$\Delta E_n = 4\pi p \delta R_0^4 (R_0 A - RB) = 0.$$

APPENDIX B

DETAILS OF CALCULATIONS OF DENSITY FLUCTUATIONS

The derivation of Eq. (8) in the text

$$f(a) = \frac{N!(n-1)^{N-a}}{a!(N-a)!n^N}$$

is perhaps given in sufficient detail to be quite clear. Assuming $N \rightarrow \infty$, $n \rightarrow \infty$, we may write, according to Stirling's theorem

$$\lim_{n \rightarrow \infty} p! = (2\pi p)^{1/2} \left(\frac{p}{e} \right)^p$$

$$\frac{N!}{(N-a)!} = \frac{N^{1/2}}{(N-a)^{1/2}} \frac{\left(\frac{N}{e} \right)^N}{\left(\frac{N-a}{e} \right)^{N-a}} = e^{-a} N^N (N-a)^{-(N-a)}$$

Here $\lim_{N \rightarrow \infty} N^{1/2}/(N-a)^{1/2}$ has been put equal to unity, and we get

$$\lim_{N \rightarrow \infty, n \rightarrow \infty} f(a) = \left(\frac{N}{en} \right)^N \left(\frac{e(n-1)}{N-a} \right)^{N-a} \frac{1}{a!}.$$

It is desired to put this in a form in which N and n appear only as a ratio, $N/n = \xi$. To this end we put

$$\frac{e(n-1)}{N-1} = \frac{e(n-1)}{N} \frac{1}{1-a/N}$$

and hence

$$\begin{aligned} \lim_{N \rightarrow \infty, n \rightarrow \infty} f(a) &= \left(\frac{N}{en}\right)^N \left(\frac{e(n-1)}{N}\right)^N \frac{1}{(1-a/N)^N} \left(\frac{e(n-1)}{N-a}\right)^{-a} \frac{1}{a!} \\ &= \left[\frac{1 - \frac{1}{n}}{1 - \frac{a}{N}} \right]^{N-a} \left(\frac{en}{N}\right)^{-a} \frac{1}{a!} \end{aligned}$$

But, simplifying, we find

$$\begin{aligned} \left[\frac{1 - \frac{1}{n}}{1 - \frac{a}{N}} \right]^{N-a} &= \left[\left(1 - \frac{1}{n}\right) \left(1 + \frac{a}{N} + \dots\right) \right]^{N-a} = \left(1 - \frac{1}{n} + \frac{a}{N}\right)^{N-a} \\ &= \left[1 + \frac{a-\xi}{N}\right]^N \left[1 + \frac{a-\xi}{N}\right]^{-a} = \left[1 + \frac{a-\xi}{N}\right]^N \end{aligned}$$

since

$$\lim_{N \rightarrow \infty} \left[1 + \frac{a-\xi}{N}\right]^N = 1.$$

Expanding $[1 + a - \xi/N]^N$, and neglecting $1/N$ compared to unity, we get

$$1 + a - \xi + \frac{1}{2!}(a - \xi)^2 + \frac{1}{3!}(a - \xi)^3 + \dots = e^{a-\xi}$$

and finally

$$\lim_{N \rightarrow \infty, n \rightarrow \infty} f(a) = e^{a-\xi} \left(\frac{en}{N}\right)^{-a} \frac{1}{a!} = \frac{e^{-\xi\xi a}}{a!} \quad \text{I}$$

and

$$\lim_{N \rightarrow \infty, n \rightarrow \infty, \xi \rightarrow \infty, a \sim \xi} f(a) = \frac{e^{-\xi\xi a}}{(2\pi a)^{1/2}} \left(\frac{e}{a}\right)^a. \quad \text{II}$$

To find for what value of " a ", say a_m $f(a)$ has a maximum, we require the formula

$$\frac{d}{da} \left(\frac{e}{a}\right)^a = \left(\frac{e}{a}\right)^a \log_e \frac{1}{a}$$

We then find

$$\frac{df}{da} = \left\{ \frac{e^{\xi} \left(\frac{e\xi}{a} \right)^a}{(2\pi a)^{1/2}} \left[\log_e \frac{1}{a} + \log_e \xi - \frac{2\pi}{4\pi a} \right] \right\}_{a=a_m} = 0$$

or

$$\log_e a_m = \log_e \xi - \frac{1}{2a_m}$$

and for

$$a_m \gg 1, \quad a_m = \xi.$$

For large values of ξ these formulae are not very satisfactory for numerical computations, and the following procedure leads to a more desirable result.

Given n = number of cells, N = number of particles, $N/n = \xi$ is the average number of particles per cell, a_s = number of particles in cell s .

$$s \sum_1^n a_s = N \quad s \sum_1^n (a_s - N/n) = 0.$$

The fraction of the phase space occupied by this distribution is (see Jeans, Dynamical Theory of Gases, page 47)

$$\theta_a = n^{n/2} (2\pi N)^{-(n-1)/2} e^{-NKa}$$

$$Ka = \frac{1}{N} s \sum_1^n (a_s + \frac{1}{2}) \log_e \frac{na_s}{N}.$$

This assumes the applicability of Stirling's formula. Substituting $\alpha_s = a_s - N/n$ in the expression for Ka , we get

$$Ka = \frac{1}{N} s \sum_1^n \left(\frac{N}{n} + \alpha_s + \frac{1}{2} \right) \log_e \left(1 + \frac{n\alpha_s}{N} \right).$$

Neglecting $1/2$ compared to N/n , we get

$$\begin{aligned} Ka &= \frac{1}{n} s \sum_1^n \left(1 + \frac{\alpha_s}{\xi} \right) \log_e \left(1 + \frac{\alpha_s}{\xi} \right) \\ &= \frac{1}{N} \left\{ \frac{1}{2} \frac{n}{N} s \sum_1^n \alpha_s^2 - \frac{1}{6} \left(\frac{n}{N} \right)^2 s \sum_1^n \alpha_s^3 + \dots \right\} \end{aligned}$$

Whenever we can write

$$s \sum_1^n \left(\frac{n\alpha_s}{N} \right)^2 \gg \frac{1}{3} s \sum_1^n \left(\frac{n\alpha_s}{N} \right)^3 \text{ and higher powers} \quad \text{III}$$

then the expression for Ka is considerably simplified.

$$NK_a = \frac{1}{2} \frac{n}{N} s \sum_1^n \alpha_s^2.$$

Jeans shows (page 48) that the fraction of the phase space which represents distributions for which $K_0 < K < K_0 + dK$ is

$$\frac{N^{(n-1)/2}}{\Gamma\left(\frac{n-1}{2}\right)} e^{-NK_0} K_0^{(n-3)/2} dK.$$

In a similar way it can be shown that the fraction of the phase space for which $K_0 < K < K_0 + dK$ and in addition for which an α_p chosen at random is equal to some given number, say α , is

$$\theta_a n^{-1/2} \frac{dA}{dK} dK$$

where θ_a and K have the values above and

$$A = \frac{\pi^{(n-2)/2}}{\Gamma\left(\frac{n}{2}\right)} \left(\frac{2N^2 K_0}{n} - \alpha^2 \right)^{(n-2)/2}.$$

Substituting $x = NK - n\alpha^2/2N$ we get

$$A = \frac{\pi^{(n-2)/2}}{\Gamma\left(\frac{n}{2}\right)} \left(\frac{2N}{n} x \right)^{(n-2)/2}$$

$$\frac{dA}{dK} dK = \frac{dA}{dx} \frac{dx}{dK} dK$$

or

$$\begin{aligned} \frac{dA}{dK} dK &= \frac{\pi^{(n-2)/2}}{\Gamma\left(\frac{n}{2}\right)} \frac{1}{2} (n-2) \left(\frac{2N}{n} x \right)^{n/2-2} \frac{2N}{n} dx \\ &= \frac{\pi^{n/2-1}}{\Gamma\left(\frac{n}{2} - 1\right)} \left(\frac{2N}{n} \right)^{n/2-1} dx \end{aligned}$$

and

$$\theta_a n^{-1/2} \frac{dA}{dK} dK = \left(\frac{2\pi N}{n} \right)^{-n/2+1/2} \left(\frac{2\pi N}{n} \right)^{n/2-1} \frac{e^{-n\alpha^2/2N}}{\Gamma\left(\frac{n}{2} - 1\right)} e^{-x} x^{n/2-2} dx$$

or

$$\frac{e^{-a^2/2\xi}}{(2\pi\xi)^{1/2}\Gamma\left(\frac{n}{2}-1\right)} e^{-x} x^{n/2-2} dx.$$

In order to find the fraction of the phase space for which $\alpha_p = \alpha$, the above expression must be integrated over all values of K from 0 to ∞ , or of x from $-n\alpha^2/2N$ to ∞ .

$$\begin{aligned} \int_{-n\alpha^2/2N}^{\infty} e^{-x} x^{n/2-2} dx &= \int_0^{\infty} e^{-x} x^{n/2-2} dx + \int_0^{n\alpha^2/2N} e^{-x} x^{n/2-2} dx \\ &= I + II \\ I &= \Gamma\left(\frac{n}{2}-1\right) \end{aligned}$$

and the result is that the fraction of the phase space for which a given cell contains α -particles is

$$f(a) = \frac{1}{(2\pi\xi)^{1/2}} e^{-a^2/2\xi} \left[1 + \frac{II}{\left(\frac{n}{2}-2\right)!} \right]$$

But

$$II = - \left[e^{-x} \left(\frac{n}{2}-1\right)! \left\{ 1 + p \sum_1^{n/2-2} \frac{x^p}{p!} \right\} \right]_0^{a^2/2\xi}$$

and therefore

$$\lim_{n \rightarrow \infty} \frac{II}{\left(\frac{n}{2}-2\right)!} = - [e^{-x} e^x]_0^{a^2/2\xi} = 0$$

and the complete result is

$$\lim_{N \rightarrow \infty, n \rightarrow \infty, \xi \rightarrow \infty, a \sim \xi} f(a) = \frac{1}{(2\pi\xi)^{1/2}} e^{-a^2/2\xi} \quad \text{IV}$$

the condition $\xi \sim a$ being intended to indicate that the assumption in Eq. III must be satisfied.

It remains to be shown that Eq. II and IV are equivalent.

$$\lim_{N \rightarrow \infty, n \rightarrow \infty, \xi \rightarrow \infty, a \sim \xi} \frac{e^{-(\xi-a)^2/2\xi}}{(2\pi\xi)^{1/2}} = \frac{e^{-\xi}}{(2\pi a)^{1/2}} \left(\frac{e\xi}{a} \right)^a$$

Omitting the cumbersome limits, we may write

$$e^{\xi^2-a^2/2\xi} = \left(\frac{\xi}{a} \right)^{a+1/2}.$$

Omitting $1/2$ compared to a and taking the logarithm of both sides this becomes

$$\frac{\xi^2}{a^2} - 1 = \frac{\xi}{a} \log \left(\frac{\xi}{a} \right)^2$$

and expanding the logarithm for values of the argument near unity this becomes

$$\frac{\xi^2}{a^2} - 1 = \frac{\xi}{a} \left(\frac{\xi^2}{a^2} - 1 \right)$$

which is valid for $\xi \sim a$.

LETTERS TO THE EDITOR

Prompt publication of brief reports of important discoveries in physics may be secured by addressing them to this department. Closing dates for this department are, for the first issue of the month, the twenty-eighth of the preceding month; for the second issue, the thirteenth of the month. The Board of Editors does not hold itself responsible for the opinions expressed by the correspondents.

OH Bands and the Ultraviolet Line Spectrum of the Wehnelt Interrupter

With an improved form of Wehnelt interrupter, equipped with a cooling coil and an electrolyte circulator, the spectrum of the discharge at the positive platinum point electrode has been investigated in the region $\lambda 4000$ to $\lambda 2230$. Solutions of hydrochloric, sulphuric, and nitric acid were used.

The OH bands were particularly prominent. A continuous banding from head to head was present. The new lines observed have been analysed and rotational assignments made. Twenty-four new lines have been added to the analysis by Jack (Proc. Roy. Soc. A115, 373 (1927)) of the band $\lambda 2608$, and 120 lines to the analysis by Watson (Astrophys. J. 60, 145 (1924)) of the bands $\lambda \lambda 2811$ and 2875 . A few rearrangements of previous assignments were made in the case of the latter bands—particularly in the R branch of $\lambda 2875$. Seventy three new assignments were made in the

analysis by Fortrat (J. de Physique 5, 20 (1924)) of the bands $\lambda \lambda 3064$ and 3122 . A preliminary comparison of wave-lengths of the new lines observed in these bands with values given in Rowland's table of solar lines showed good agreement with lines of unknown origin.

The band $\lambda 3428$ is present on the plates but seems to present no new features.

A new band in the region $\lambda 3525$ is being investigated in view of its possible relationship to the OH system.

Up to the present only lines arising from the platinum anode have been observed between $\lambda \lambda 2608$ and 2230 .

An Infrared Band System of Iodine Bromide

During an investigation of the absorption of iodine bromide in the visible, the writers recently observed an infrared band system due to this substance which, so far as they are aware, has not previously been reported. When an absorption cell 3 ft. in length was used, containing IBr at about 90 mm pressure at 50° , five band progressions of moderate intensity were observed in the region $\lambda \lambda 6850$ – 8060 . Due to the fact that there is a rather sudden change in the slope of the ω_v v curve for the upper state at $v'=12$ it is not possible to represent the entire system satisfactorily by one simple formula. However, those bands for which v' is less than 12 are well represented by the equation:

$$\nu(\text{cm}^{-1}) = 13,251 + (105.9 v' - 2.42 v'^2) - (266.5 v'' - 0.81 v''^2).$$

The absolute numbering of the vibrational levels of the upper electronic state is still in some doubt as it has not as yet been possible to make use of the isotope effect which is not very readily measurable.

The upper electronic level of the infrared system is a state which yields normal atoms on dissociation. By means of a graphical extrapolation the energy of dissociation of the normal IBr molecule into normal atoms has been estimated to be 1.801 ± 0.007 volts ($41,520 \pm 150$ cal). The good agreement with the value 1.84 volts estimated by Cordes and Spomer¹ from fluorescence data of Loomis

¹ H. Cordes and H. Spomer, Zeits. f. Physik 63, 334 (1930).

is possibly due to a compensation of errors in the latter case.

Recent studies in this laboratory² on the effect of temperature on the equilibrium between iodine, bromine, and iodine bromide have given an accurate value for the heat of formation of iodine bromide (H_{298}°) given in the following equation:

Since the heat of this reaction is practically independent of temperature it may be compared directly with the energy change at the absolute zero, for the reaction, calculated from the spectroscopic determinations of the dissociation energies of iodine,³ bromine, and iodine bromide. This spectroscopic value is 2,440 cal (0.106 volts), which checks with the

thermal value well within the probable experimental error. This agreement is good evidence for the self consistency of the spectroscopic values of the dissociation energies of the three molecules in question.

³ We have used for the dissociation energy of iodine a value 1.535 volts received in a personal communication from Mr. W. G. Brown, at Berkeley, California.

Thermionic Emission in Caesium-Oxide Photo-cells at Room Temperatures

During an investigation of the suitability of some caesium oxide on silver photoelectric cells for astronomical photometric work at low intensities it was noticed that in some cases there was, in total darkness, a large, unidirectional leakage which increased rapidly as the cell was warmed and which could be decreased considerably by the application of a magnetic field. These facts indicated conclusively that the leakage was of thermionic origin. Subsequently more careful temperature measurements were made both above and below room temperatures which showed that the emissions were following the ordinary T^2 equation with thermionic work functions in different cells varying from about 0.40 to 0.80 volt.

The largest thermionic current which we have observed at 20°C and 22.5 volts is 8×10^{-9} amperes in a cell of about 88 cm² cathode area, which is approximately the current given photoelectrically by exposing the cell to an illumination of 3×10^{-4} lumens from tungsten light at 2848°K color temperature. Observations were made on this cell as low as -5°C and could undoubtedly have been continued lower if we had shifted from our high sensitivity galvanometer to the electrometer. The thermionic constants determined from a plot were $A = 5 \times 10^{-3}$; $b_0 = 8550$. At 20°C an increase of one degree increases the thermionic current about 11.2 percent so that when such a cell is used for photoelectric measurements it might well be necessary to control its temperature. The value of b_0 for this particular cell is very close to that

found by Koller (Phys. Rev. 33, 1082 (1929)) for some caesium oxide on silver cells from 100° up to 170°C.

Another cell of somewhat lower photoelectric sensitivity gave the values, $A = 3.7 \times 10^{-10}$; $b_0 = 4290$, the lowest that we have yet obtained. The cathode area of this cell was 19.4 cm², and the total current at 20°C was about 2.7×10^{-10} amperes, with only a 5.8 percent increase in a temperature rise of one degree. The largest thermionic current at room temperature was therefore not obtained with the cell of lowest work function due to the very great decrease in the value of A . The measurements made so far on different cells do not indicate any precise relation between $\log A$ and b_0 which would enable one to predict definitely the emission at room temperature from the thermionic work function. If there is a large decrease in b_0 as shown above, it is of course reasonable to expect a decrease in A otherwise the emission would increase enormously.

Measurements on some of the cells at constant illumination to tungsten light showed a decided drop in the photo current with considerable increase of temperature while on the other hand the effect of cooling did not seem to be nearly as great in producing an increase. This is opposite to what Koller found with cathodes much less sensitive photoelectrically than our own.

We have purposely selected for this work cells with clean walls and stems which gave negligible ohmic leakage. The two kinds of leakage are present in many cells and it is difficult to separate them with certainty. If

the caesium oxide on silver cell is to be used for measuring very small light intensities, the area of the cathode should not be any larger than is necessary to intercept the radiation; that is, the photoelectric emission should be made as large as possible relative

to the thermionic emission.

A Case of Abnormal Molecular Rotation

In the fluorescence of mercury vapor with the addition of nitrogen and a trace of hydrogen, Gaviola and Wood¹ observed the band spectrum of the HgH molecule with an abnormal rotation corresponding to an apparent temperature of 3000°, although the gas was at room temperature. This observation has been interpreted² by the assumption of the following sequence of processes: formation of the HgH molecule, then excitation of this molecule with high oscillation and normal rotation according to the Franck-Condon rule, and finally change of oscillation into rotation during the life time of the excited state through collisions with N₂ molecules. In this interpretation, the high rotation observed in the band spectrum is therefore not directly excited but due to a secondary effect.

An interesting similar observation has recently been described by W. Lochte-Holtgreven.³ He found in the electric discharge in acetylene the C₂ bands with an abnormal rotational energy corresponding to 4700° and the CH bands with 2000°.

By varying the conditions, he found that these "rotational temperatures," being much larger than the real temperatures, are not due to secondary effects such as collisions during the life time of the excited state. Instead he concluded they must arise from the elementary process of excitation itself. Thus the interpretation must differ from that of the rotation of the HgH molecule just described. The present letter deals with this new observation, thus supplementing the interpretation of the HgH bands given in a previous paper.

It seems possible to understand the high rotation of the C₂ and CH bands in the acetylene discharge on the basis of the Franck-Condon rule dealing originally with oscillation. According to Hedfeld and Mecke, the HC≡A molecule in its normal state forms a straight line.⁴ Let us assume that in its excited state it forms a crooked line. Professor Slater has pointed out to me that such a pro-

nounced change in the shape of the molecule is not all an arbitrary assumption, but should be expected, if in the excitation process the carbon atom goes over from the quadrivalent to the divalent state. The same change of valence by excitation has been found e.g. in the CN molecule.⁵ According to Slater's new theory,⁶ the straight line model of the normal state points to quadrivalent C atoms while the two valences of a divalent atom should always be at right angles, thereby forming a crooked molecule.

This pronounced change in the shape of the molecule lends itself to an application of Franck's idea. The change of electron configuration is fast compared with the motion of the nuclear masses. Immediately after the excitation process, the molecule in its new electronic state has still its old shape and therefore a large potential energy leading to intense vibration. Contrary to the vibration of the diatomic molecule, the motion is essentially transverse.⁷ This vibration might produce dissociation, if the potential energy exceeds the dissociation energy. Any dissociation process brought about by absorption of light can be recognized experimentally by the continuous absorption spectrum. In the case of the HCCH molecule, mainly continuous absorption has been observed as reported by

⁷ Cf. R. Mecke, *Zeits. f. Physik* **64**, 173 (1930).

Lochte-Holtgreven and by Kistiakowsky. It might be assumed that this absorption corresponds partly to the described process.

This splitting up of the molecule by *transverse* vibration leads necessarily to strongly *rotating* molecules. (Fig. 1). The transverse vibration which splits up the centre bond of the $\text{HC}\equiv\text{CH}$ molecule leads to two CH molecules strongly rotating in opposite direction,

Fig. 1. Vibration of the excited HCCH molecule.

while the total moment of momentum of the system remains unchanged or changed only by unity. In the other dissociation process mentioned by Lochte-Holtgreven, the H atoms might fly away in the direction of the arrows (Fig. 1) leaving an excited C_2 molecule. This must have high rotation as indicated again by the arrows. Dissociation in steps might take place too.

In general any combination of increasing longitudinal and transverse vibration should lead to a dissociation resulting in a rotating and vibrating molecule, the energy of which is determined by the potential curves and not by the temperature of the gas. Thus we understand the observation reported by Lochte-Holtgreven, that the rotation of the excited molecules C_2 and CH is characteristic for this excitation process starting from $\text{HC}\equiv\text{CH}$ and that its energy shows some deviation from a Boltzmann distribution.⁸

Has this argument a bearing on the diatomic molecule? This might be the case, considering the diatomic molecule in collision with an atom. When by impact of the second kind the HgH molecule takes over excitation energy from the Hg' , it is generally assumed,

that the rotation of the HgH does not change considerably, but that the vibration might change on the basis of the Franck-Condon rule. It must be taken into account, however, that after the excitation process the H atom starts its fast vibration in the close neighbourhood of the colliding slow Hg atom. *In the same collision process*, therefore, this might turn over the motion of the H atom from *vibration* into *rotation*. No appreciable kinetic energy of *translation* is produced due to the heavy weights of the Hg atom and the HgH molecule. In other words, the H atom starts its motion in a modified field of force determined by the new electronic state of the HgH molecule and at the same time the presence of the colliding Hg atom. This motion might be rotation as well as vibration. (If in the case of good resonance the transfer of electronic energy by impact of the second kind takes place over an exceptionally large distance, this argument might fail, because in this case the HgH molecule would become excited without being disturbed in its vibration by the close neighbourhood of a colliding heavy body.)

The statement, therefore, that no appreciable rotation is produced by impact, holds for excitation by electron impact and for every thermal impact. However, it should not be supposed to hold for this type of impact of the second kind between heavy bodies.

This process in addition to the process discussed in the writer's recent paper² would be expected to play a part in Gaviola's and Wood fluorescence experiment.

⁸ R. M. Badger and J. L. Binder (Phys. Rev. 37, 800 (1931)). mention a certain difficulty in calculating dissociation energies of polyatomic molecules from band spectra, due to the fact the fragments might retain a considerable amount of energy in their *electronic* and *vibrational levels*. According to the present result, also the *rotation* is able to keep energy far exceeding the thermal value.

On the Effect of Resonance in the Exchange of Excitation Energy

I should like to add a few words to the letter recently sent to the Editor of the Physical Review, under the above title. The applica-

tion of the Franck-Condon principle to this problem brings out another point which supplements those already considered and which

will be of importance if the two curves shown in Fig. 1 of the above mentioned article reach their asymptotic values at something like the same value of r , which may often be expected to be the case. Then it is seen that, unless the asymptotic values are the same within the order of magnitude of the average relative translational energy of two at the temperature considered, the intersection of the two curves will occur so high up that it will be out of reach of an average pair of colliding atoms even though the initial state be represented by the upper curve; of course if the initial state is represented by the lower curve, the transition cannot occur with an average pair of atoms unless the curves are close enough together so that the difference in energy can be made up by conversion of the limited trans-

lational energy available to electronic energy, but this consideration shows that transitions will often be prevented even when the conversion is in the other direction, from internal to translational energy. It is of interest to note that in the cases considered by Kallmann and London (Zeits. f. physik. Chem. 2B, 226 ff. (1929)) the energy transferred from translational to internal or *vice versa* is, in the case of those transitions which occur with exceptional probability, of the order of magnitude of the translational energy of an atom at room temperature.

Continuous Spectrum of Hydrogen Molecular Ion (H_2^+)

The negative glow is generally accepted as a good source of ionized spectra, due to the probable high concentration of ions at this portion. In hydrogen, therefore, there may be some hope to obtain some spectrum at the negative glow, which had, if any, H_2^+ as an emitter. The hydrogen molecular ion has been dealt with theoretically by a number of investigators. Recently E. Teller¹ has calculated the excited states produced when the ion is separated step by step into a proton and a hydrogen atom in the ground state. According to him almost all the potential energy curves show no minima, except those corresponding to the $1s\sigma$ and the $3d\sigma$.

Following the interpretation of the ordinary hydrogen continuous spectrum, we can expect some continuous spectrum which can be explained by transitions to any one or all of the unstable states of the H_2^+ molecule. With such an expectation a spectroscopic examination of the negative glow in hydrogen, at a pressure of about 0.2 mm Hg was carried out. Although the ordinary continuous spectrum is absent in the negative glow, an indication of the continuous spectrum, even if

not so intense, is observed between H_β and H_γ .

The probable high concentration of the H_2^+ molecule suggests that the above mentioned continuous spectrum may be due to the H_2^+ molecule. The energy involved in this region of spectrum is not inconsistent with such an explanation. As the spectrum was not observed at so extremely low pressures as in the cases of Herzberg² and Brasefield,³ it is not in danger of being confused with that of the fluorescence light on the walls of the tube. So that it will not be inadequate to ascribe this continuous spectrum to the H_2^+ molecule. Details will be published with reproduction in the Science Reports of the Tohoku Imperial University, 20 (1931).

New Covariant Relations Following from the Dirac Equations

1. In an article appearing in this issue of the Physical Review the authors derive by means of the spinor calculus four invariant relations between the four wave functions which are independent of the potentials. (Eq. (6), (11), (12), (13) of Ch. III.) The first of these is

$$\frac{\partial j^\lambda}{\partial x^\lambda} = 0 \quad (1)$$

where j^λ is the four-current. The second relation with which we shall concern ourselves in this letter, may be written, using ordinary tensor notation:

$$\frac{\partial k^\lambda}{\partial x^\lambda} = \frac{mc}{h} J \quad (2)$$

where k^λ is also a four vector quadratic in the wave functions and defined by the equation preceding Eq. (17) of our article. In Eq. (14) two complex quadratic invariants Δ and $\bar{\Delta}$ were introduced; from these we form the two real combinations:

$$\begin{aligned} \frac{1}{2}(\Delta + \bar{\Delta}) &= I \\ \frac{1}{2}i(\Delta - \bar{\Delta}) &= J. \end{aligned} \quad (3)$$

These quantities are identical with the invariants I and J of Darwin. We also prove in our paper that

$$k^\lambda j_\lambda = 0; \quad k^2 = -j^2. \quad (4)$$

Further we proved (Eq. (17)) that:

$$k^\alpha M_{\alpha l} = \frac{h}{mc} j_l J; \quad j^\alpha M_{\alpha l} = \frac{h}{mc} k_l J. \quad (5)$$

Here M_{kl} is the antisymmetric tensor of the polarization (Darwin, Gordon), whose components are again quadratic in the wave functions.

2. For the sake of a possible physical interpretation and to facilitate comparison with recent work of Fock, it seems desirable to express the above relations in term of matrices. It is easily seen, however, that the original α matrices of Dirac are unsuited to express covariance relations. We use instead the form of the Dirac equations

$$(\Gamma^\lambda p_\lambda + mc)\psi = 0 \quad (6)$$

which is used by Weyl and Sommerfeld. (see our paper, Eq. (1), (2), (3), Introduction). The Γ^l matrices satisfy the well known relations:

$$\Gamma^k \Gamma^l + \Gamma^l \Gamma^k = 2g^{kl}. \quad (7)$$

We adopt now the first point of view mentioned in the introduction of our paper, and regard the ψ as invariant and the Γ^l as a matrix four-vector. Using this and the relations (7), we can now form the following covariant quantities.¹

$$\begin{aligned} 1 &\sim I \\ \Gamma^i &\sim j^i \\ \Gamma^i \Gamma^k &\sim M^{ik} \\ \Gamma^i \Gamma^k \Gamma^l &\sim k_m \\ \Gamma^i \Gamma^k \Gamma^l \Gamma^m &\sim J \end{aligned} \quad (8)$$

None of the indices are allowed to be equal. We assert the quantities in the right column are obtained by multiplying the cor-

responding quantities in the left column with ψ' from the left and ψ from the right, (ψ' is the transposed ψ ; see²). The relations (1) and (2) can now be derived independently from the Dirac equation (6); for (1) this is well known, whereas Eq. (2) becomes:

$$\begin{aligned} \frac{\partial}{\partial x_1} \psi' \Gamma^2 \Gamma^3 \Gamma^4 \psi - \frac{\partial}{\partial x_2} \psi' \Gamma^3 \Gamma^4 \Gamma^1 \psi + \dots \\ = \frac{2imc}{h} \psi' \Gamma^1 \Gamma^2 \Gamma^3 \Gamma^4 \psi. \end{aligned} \quad (9)$$

Relations (4) and (5) can now be derived immediately with the help of (7).

3. One can also easily, though not so symmetrically, express the quantities (8) in terms of the Dirac α and the Dirac-Darwin ψ . For j and M we refer to Gordon's² paper. For k , I and J one obtains the following expressions:

$$\begin{aligned} k^1 &= -i\alpha_2\alpha_3 & k^2 &= -i\alpha_3\alpha_1 \\ k^3 &= -i\alpha_1\alpha_2 & k^4 &= -i\alpha_1\alpha_2\alpha_3 \\ I &= \alpha_4 & J &= \alpha_1\alpha_2\alpha_3\alpha_4 \end{aligned}$$

We see therefore that the *spacial* components of k are identical with the three-vector σ as introduced by Dirac³ and further used by Fock⁴ and that the time component of k is equal to ρ_1 (Dirac) or ρ_a (Fock), whereas I is equal to ρ_3 (ρ_c) and J to ρ_2 (ρ_b). It thus appears that from the view point of covariance neither σ nor ρ are true vectors.

4. It follows from the equality of $k_{1,2,3}$ with $\sigma_1, \sigma_2, \sigma_3$ that the spacial components of the four-vector k are equal to the components of the magnetic moment of the electron. On the other hand it is well known that the spacial components of the tensor M^{ik} represent the magnetic moment of the electron also. When neglecting relativity (i.e. considering only the large ψ_3 and ψ_4) the k_1, k_2, k_3 become indeed equal to M_{yz}, M_{zx}, M_{xy} respectively. Thus it is seen that the

¹ For this systematization (without the above identifications) compare J. Schouten, Proc. Amsterdam **32**, 105 (1929); A. Proca, Journ. de Phys. **1**, 235 (1930). F. Sauter, Zeits. f. Physik **63**, 803 (1930) used it very profitably for the solution of special problems.

three-dimensional vector of the magnetic moment can be completed relativistically in two ways, either to a four-vector or to an antisymmetric tensor. In the corpuscular theory already L. H. Thomas⁵ called attention to these two possibilities. What the exact physical meaning of this duplicity in character of the moment and especially of the fourth component of k is remains unclear to us. Perhaps it is connected with the two-fold interpreta-

tion of the spin as angular momentum or as magnetic moment.

On the Gas-Temperature in the Positive Column of an Arc

For the study of thermionization in the positive column of an arc the possibility of measuring exactly the gas temperature is of great importance. We have therefore developed a new method of ascertaining this temperature avoiding any errors of previous methods, which permits measuring the temperature by gas-density.

The density of the arc-gas in the axis of a stabilized (by whirling gas according to Schoenherr) straight d.c.-arc of 2 amp. in air and also nitrogen of atmospheric pressure were measured. This was done by testing the absorption of a soft x-ray (of about 6A) passing along the axis of arc. The intensity of the x-ray was observed by the Geiger-counter. In a comparative test without the arc, the gas density was diminished by evacuating the arc-space until the x-ray intensity became the same as with the arc. The intensity found thereby is also the average density of the arc-gas traversed by the x-ray. The disturbing spaces next to the electrodes were eliminated by measuring arcs of different lengths (5-20 cm).

With the ideal gas-law this density gives a temperature in the positive column of $5270 \pm 300^\circ\text{K}$ in the air-arc, and of $5460 \pm 320^\circ\text{K}$ in the nitrogen-arc. Considering the dissociation at these high temperatures, one gets a gas-temperature of $5000 \pm 400^\circ\text{K}$ in the air-arc and of $5200 \pm 450^\circ\text{K}$ in the nitrogen-arc. By pyrometric measurements a pure carbon (2 mm diameter) inserted in the arc axis had 3100°K in the air-arc and 2300°K in the nitrogen-arc. The temperature of the carbon is not identical with that of surrounding gas; clearly it depends on chemical reactions at its surface (oxidation!).

An extensive report on our investigations will be published in the next number of the "Wissenschaftliche Veröffentlichungen aus dem Siemens-Konzern."

THE PHYSICAL REVIEW

X-RAY WAVE-LENGTH CHANGE BY PARTIAL ABSORPTION

By J. M. CORK

UNIVERSITY OF MICHIGAN

(Received May 11, 1931)

ABSTRACT

The attempt to repeat the experiments of Mr. B. B. Ray in which a change in wave-length occurred in an x-ray beam upon passage through an absorbing substance, has been continued. In the previously reported experiments CuK radiation was passed through absorbers of boron, beryllium, carbon, nitrogen and oxygen. These same absorbers have been retried with tungsten L radiation with a spectrometer of greater dispersion. Although it should have been possible to observe a modified line of $1/3000$ the intensity of the unmodified, in no case has any trace of a modified line been observed.

WHEN x-rays are incident upon matter they react with the electrons of the matter in various possible ways. One type of interaction, the photo-electric effect, in which the x-ray photon communicates all its energy to the electron, ejecting it from the atom, the remainder of the energy of the photon appearing as the kinetic energy of the electron, is now well established. Equally well established is the Compton effect in which the photon interacts with the free electron giving a portion of its energy to the electron, which is ejected as a recoil electron. The emergent photon with lessened energy is consequently of longer wave-length. For electrons bound in definite energy states a fine structure of the scattered modified photon on the long wave-length side would appear as a possibility. Recent experiments¹ indicate that this fine structure does not exist.

Observing the failure of these experiments, Mr. B. B. Ray² examined the wave-length of the emergent photons for zero scattering angle. For this angle the Compton wave-length shift would be zero. A spectral photograph of the transmitted beam showed along with the strong line due to the unmodified incident wave-length, certain fainter companion lines displaced toward longer wave-lengths. The displacements of these lines as reported, were just as would be expected if in the passage through the absorbing substance the photon gave up some of its energy to elevate a bound inner electron to an outer energy level, passing on unchanged in direction but with less energy and hence longer wave-length.

² Ray, *Nature* 125, 746 and 856; 126, 399; *Zeits. f. Physik* 66, 261 (1930).

Thus the energy equations may be shown:

$$\text{Photoelectric effect } h\nu = h\nu_e + (1/2mv^2) \text{ photoelectron} \quad (1)$$

$$\text{Compton effect } h\nu = (1/2mv^2) \text{ recoil electron} + h\nu \text{ mod.} \quad (2)$$

$$\text{Ray effect } h\nu = h\nu_e + h\nu \text{ mod.} \quad (3)$$

The existence of this last effect is thus of such importance that the experiments seemed worthy of repetition.

EXPERIMENTAL

To this end an attempt was made to repeat the work of Ray. The first experiments³ using a copper target x-ray tube equipped with a Lindemann thin glass window with a calcite crystal spectrometer were carried out in the laboratory of Dr. M. deBroglie in Paris. The investigation has been continued in this university using both copper and tungsten target tubes with a calcite crystal spectrometer having slit-crystal and crystal-photographic plate distances of 54 cm. This gives a dispersion on the photographic plate of about 5 x.u. per mm.

The absorbing layer was in every case placed between x-ray target and spectrometer slit. Various thicknesses of material were employed although the thicker the material the more apparent the effect should be. The absorbing layers used by Ray were not well described in his reports, except that he mentions the use of lamp black for carbon⁴ absorption. Besides carbon, absorbing layers of beryllium, boron, nitrogen and oxygen have been used. Screens made of various thicknesses of gold beaters skin have also been tried.

In order to form an estimate of relative intensities a portion of the unmodified line was covered with a shield during most of the exposure. This shield for a twenty hour exposure was generally removed only for 2 minutes. The intensity of radiation was such that generally an exposure of 2 seconds was enough to render the main unmodified line visible.

In these experiments the crystal was kept stationary during two exposures, first with and then without absorber in place.

RESULTS

Using the various absorbers mentioned, no trace whatever of a modified line in the positions to be expected was observed. Typical spectrograms obtained are shown in Fig. 1. For these spectrograms the target was of tungsten, giving the strong line WLa_1 , and also the La_2 line whose intensity is about one-tenth as strong. The copper K lines always appeared unintentionally on the same plate, due presumably to a copper focussing cylinder on the cathode. On certain of these prints even the very faint $CuK\alpha_3, \alpha_4$ line is observable, although its intensity is only about 1/600 that of the $CuK\alpha_1$ line.

The intensity of the modified line as observed by Ray was about 1/400 that of the parent line. In these spectrograms shown in Figure 1 the intensity

³ J. M. Cork, *Comptes Rendus, Acad. Sci. Paris*, 192, 153.

⁴ In a letter to the writer Mr. Ray mentions that 4 or 6 thicknesses of gold beater's skin gave equally good results.

of the $WL\alpha_2$ line on the shielded part of the figure is about $1/6000$ that of the unshielded $WL\alpha_1$. Now a line of the intensity of the $WL\alpha_2$ line located in the region of general blackening on the plate might be somewhat obscured.

Fig. 1. Showing the absence of expected modified lines.

Fig. 2. Showing superposition of $WL\alpha_1$, α_2 2 min. Exposure on general radiation exposure 20 hours.

However, if the general blackening is not too strong it offers but slight hindrance to the observance of relative intensities. This is illustrated in Fig. 2. In this figure after the exposure was completed with shield in place twenty

hours and then removed for two minutes, the whole plate was shifted along and the lines allowed to fall in the region of general radiation for a period of two minutes. One observes little loss in contrast.

If the effect exists therefore, it must be of an intensity much less than that reported by Ray. Other experimenters⁵ have now likewise failed to observe the modified lines, although their existence has been confirmed by others.⁶

This opportunity is taken to express appreciation to M. deBroglie for the generous facilities of his laboratory and to M. Thibaud and M. Duprés la Tour for their kind assistance during the first part of this investigation.

STRUCTURE OF THE HELIUM ARC LINE 3888*

BY R. C. GIBBS AND P. G. KRUGER

PHYSICAL LABORATORY, CORNELL UNIVERSITY

(Received April 24, 1931)

ABSTRACT

The helium arc line ($1s2s\ ^3S_1 - 1s3p\ ^3P_{0,1,2}^\circ$) 3888A, has been examined for structure and has been resolved into the three components which are predicted by theory. The $1s3p\ ^3P_{0,1,2}^\circ$ levels are inverted which is in agreement with previous results for the $1s2p\ ^3P_{0,1,2}^\circ$ levels. The frequency differences in the present case are:

$$\nu_{0,1} = 0.192\text{ cm}^{-1}, \quad \nu_{1,2} = 0.165\text{ cm}^{-1}.$$

INTRODUCTION

IN 1927 Houston¹ reported the structure of the $1s2p\ ^3P_{0,1,2}^\circ$ levels. Later in the same year G. Hansen and P. G. Kruger² finished the analysis of the He arc lines 5876, 4713 and 4472, thus completing the term scheme for $1s2p\ ^3P_{0,1,2}^\circ$ and $1s3d\ ^3D_{1,2,3}$. No attempt was made at that time to determine the structure of higher P° terms.

EXPERIMENTAL

The line 3888A $1s2s\ ^3S_1 - 1s3p\ ^3P_{0,1,2}^\circ$ is one of the strongest lines of the He I spectrum and was easily excited in a metal liquid-air cooled Schüller lamp. A Fabry-Perot interferometer with 5 mm, 8 mm, and 10 mm spaces between the mirror surfaces was used to analyze the line. Mirrors having a reflection coefficient of 92 percent were used so that the resolving power varied from 0.775×10^6 to 1.55×10^6 as the distance between the mirrors was increased from 5 mm to 10 mm.

RESULTS

TABLE I. Components of the helium line 3888.

Int.	λ	$\Delta\lambda$	ν	$\Delta\nu$
10	0.0000A		0.000 cm^{-1}	
7	-0.0247	0.0247A	0.165 cm^{-1}	0.165 cm^{-1}
3	-0.0545	0.0298	0.357 cm^{-1}	0.192 cm^{-1}

Table I gives, in column one, the relative estimated intensities of the components as obtained from several microphotometer curves made from

* The investigations upon which this article is based were supported by grants from the Heckscher Foundation for the Advancement of Research, established at Cornell University by August Heckscher. Acknowledgment is also made of the use of spectroscopic apparatus which was in part purchased by a grant from the National Research Council.

various plates. The wave-lengths (assuming the strongest line zero), wave-length separations, frequency numbers and frequency separations are given in columns 2, 3, 4 and 5 respectively.

Fig. 1 shows a microphotometer curve of one of the plates.

Fig. 1. Microphotometer curve showing the structure of the He arc line 3888.

Fig. 2. Term separations for the first two members of the $1sn p \ ^3P^\circ$ series in helium, He I.

Fig. 2 shows the term scheme for the $1s2p \ ^3P^\circ_{0,1,2}$ and $1s3p \ ^3P^\circ_{0,1,2}$ terms with respect to the $1s2s \ ^3S_1$ term. The relative separations of the two $^3P^\circ$ terms are drawn to the same scale.

DISCUSSION

It is interesting to note that the anomalous separations of the $1s2p\ ^3P^\circ$ terms are no longer so anomalous in the $1s3p\ ^3P^\circ$ terms. In the latter case the separations are more nearly what would be expected if the Landé interval rule were obeyed. Thus if the $^3P^\circ$ term separations continue to become more normal in higher total quantum states the $1s4p\ ^3P^\circ$ terms should have nearly a 2:1 separation.

Resolution of the structure of the line 3187A ($1s2s\ ^3S_1 - 1s4p\ ^3P^\circ_{0,1,2}$) would show whether the separation of the $1s4p\ ^3P^\circ$ terms have a 2:1 ratio. Assuming that the rate of decrease of $\Delta\nu_{0,2}$ between the first and second members of this series of terms is continued to the third member, a value of about 0.120 cm^{-1} is computed for $\Delta\nu_{0,2}$ for the $1s4p\ ^3P^\circ_{0,1,2}$ terms. Thus if the 2:1 ratio exists in the third member, the components of the 3187 line would be 0.0082 and 0.0040Å apart. The complete resolution of components lying as close together as this necessitates cooling the discharge in liquid hydrogen or preferably in liquid helium. It is hoped that some other laboratory in which these low temperatures are available will undertake to study the structure of this line.

In 1926 Heisenberg³ calculated the separation of the $1s2p\ ^3P^\circ_{0,1,2}$ term and obtained results which were later found to be in agreement with experimental results.^{1,2} It would be desirable now to have the $1s3p\ ^3P^\circ_{0,1,2}$ term separations calculated by quantum theory or wave mechanics to see if the agreement here is as good as in the previous case.

A possible reason why the P° term separations in higher quantum states should approach the normal 2:1 ratio, is that in the higher quantum states the p electron is less tightly bound to the nucleus and thus the energy conditions in these higher states are more nearly like those in heavier elements. Furthermore the coupling of the np electron to the $1s$ electron becomes weaker in the higher quantum states,—so that possibly with increasing n the interaction arising from the action of the orbital motion or the spin of one electron on the spin of the other becomes less effective in determining the internal ratio.

³ W. Heisenberg, Zeits. f. Physik 39, 499 (1926).

RAMAN SPECTRA OF SULPHURIC ACID

BY RAYMOND M. BELL AND W. R. FREDRICKSON
PENNSYLVANIA STATE COLLEGE AND SYRACUSE UNIVERSITY

(Received May 11, 1931)

ABSTRACT

Concentrated H_2SO_4 gives a series of Raman lines which, with the exception of the 4566A line, decrease in number and intensity with a decrease in concentration and finally disappear. At the point at which the above lines vanish, a broad line (4817A) appears and persists in dilute solutions. At low concentrations the water bands are present. The 4566A line is present at all concentrations of acid and increases in intensity with a decrease in concentration, but is missing in pure water. A line with the same wave-length (within experimental error) and intensity variation is found in HNO_3 , and it is suggested that the two lines have the same origin.

RAMAN spectra have made possible a new approach to the study of conditions in acids at various dilutions. Rao¹ found that the Raman lines obtained from HNO_3 could be classified into the three following groups according to their behavior as the acid was diluted: (1) those due to the HNO_3 molecule, (2) those due to the NO_3^- ion, and (3) those due to the water molecule. The lines of the first group decrease in intensity as the concentration is decreased and finally disappear. The lines in the second group increase in intensity as the concentration is decreased, reaching a maximum at the concentration when the lines of the first group vanish, and then these lines also decrease in intensity. The lines of the third group appear as bands which first appear faintly as the acid is somewhat diluted and gradually increase in intensity and broaden as the concentration is decreased. The purpose of this paper is to present similar data obtained from sulphuric acid at various dilutions. A preliminary account of data has previously been reported in a letter to Nature.²

The method used to obtain spectrum was similar to the general method described by R. W. Wood,³—using a mercury arc. Most of the photographs were taken with a prism spectrometer, but plates were also obtained with a plane grating on the spectrometer table in place of the prism. The latter arrangement gave greater dispersion, but the intensity was, indeed, greatly reduced.⁴ Definite traces of lines and bands were found at all concentrations. With the prism, most of the lines could be obtained with an exposure of three minutes and the strongest could be detected on plates of a minute exposure. The lines in Table I are all taken from plates with 30 minute exposure,—

² Bell and Fredrickson, Nature 125, 895 (1930).

³ R. W. Wood, Phil. Mag. 6, 729 (1928).

⁴ Attempts were made to obtain Raman spectra with a small concave grating of 120 cm focus, but without success.

with experimental conditions exactly the same throughout. A fifteen hour exposure with the grating gave the same intensity as the thirty minute prism exposure and those lines are listed in Table II. The concentrations are measured in mol percent. That is, 50 percent concentration is one H_2SO_4 molecule to one H_2O molecule; 100 percent is the purest acid available, commercial 96 percent; and 0 percent is pure distilled water. The wave-lengths are accurate to 3Å. The numbers in parentheses are eye estimates of the intensity of the lines.

Notes. 4817 was a broad line or band at all times.

4566 became broad at low concentrations.

4750 to 4700 and 4225 to 4175, water bands, became sharper and less intense as concentration increased.

TABLE II. Raman spectrum of H_2SO_4 (Grating).

Concentration (percent)	Wave-length in Angstroms							
100	4585 (1)	4566 (1)	4540 (4)	4470 (3)	4440 (2)	4279 (0)	4225 (1)	4203 (2)
80		4566 (2)	4540 (3)	4470 (3)	4440 (2)		4225 (1)	4203 (1)
60		4566 (3)	4540 (3)	4470 (3)	4440 (2)		4225 (0)	4203 (1)
40		4566 (4)	4540 (2)	4470 (3)	4440 (2)		4225 (0)	4203 (0)
30		4566 (3)	4540 (1)	4470 (1)	4440 (1)		4225 (0)	4203 (0)

From Table I we see that the lines found in concentrated H_2SO_4 persist as far down as 40 percent. The lines given for 100 percent agree with the re-

sults obtained by Ganesan and Venkateswaran⁵ with concentrated H_2SO_4 . The intensity of all lines except the 4566 line decreases in intensity with a decrease in the concentration. The 4566 line, however, increases in intensity to a maximum and then broadens and decreases in intensity. The two water bands are in approximate agreement with the measurements given by others. It is interesting, however, to note the decrease in breadth and the sharpness of these bands at their first appearance at high concentrations. The origin of the 4817 line or band is uncertain. It makes its appearance when the other lines disappear and is always broad. The 4470 line is the only one which seems to indicate a shift in wave-length as the concentration is decreased. On some of our plates there is a slight indication that this line has shifted slightly to the red.

The lines obtained with the grating, as listed in Table II, are similar to those in the preceding one. Here even the 30 percent concentration shows some of the H_2SO_4 molecule lines. The most striking thing about the grating plates is the change in intensity with concentration. The 4540 line decreases considerably in going from 100 to 40 percent, while the 4566 line increases correspondingly.

Comparing the above results with those reported by others we find two interesting facts. (1) Several experimenters⁶ working with sulphates find in all cases lines at 4552A and 4214A which they attribute to the $\text{SO}_4^{=}$ ion. Our plates fail to reveal these lines, not even the plates of very long exposure time. (2) Rao⁷ reports a line at 4567A which he finds at all concentrations of HNO_3 . We also find a line at 4566A which appeared at all concentrations. Ganesan and Venkateswaran⁸ give 21895 cm^{-1} as the measurement for the same H_2SO_4 line and 21893 cm^{-1} for the HNO_3 line. Both of these lines increase in intensity with a decrease in concentration. Neither line appears in pure distilled water. We are inclined to believe that this close agreement in wave-length and variation in intensity with concentration is not fortuitous, but rather an indication that the two lines may have the same origin—perhaps a hydrated hydrogen ion.

The experimental work described above was done in the Department of Physics at Syracuse University.

INVESTIGATIONS IN THE SPECTRAL REGION
BETWEEN 20 AND 40 μ

BY JOHN STRONG*

CALIFORNIA INSTITUTE OF TECHNOLOGY, PASADENA

(Received May 5, 1931)

ABSTRACT

An apparatus is described which is convenient for studying the optical properties of substances with reststrahlen having wave-lengths from 6 to 150 μ . A vibrationless support is described, the essential features of which are copied from the design of R. Müller but the construction is simplified. The transmission of several gases was studied with reststrahlen having wave-lengths 20 to 33 μ . SO₂ shows strong absorption at 20.75 μ . The reflectivity of SO₂ was tested and found to be zero at both 20.75 μ and 8.7 μ where it has strong absorption bands. Gas absorptions from 20 to 33 μ are compared with the Raman indications. Transmissivities and reflectivities of various materials are given for the spectral region 20 to 33 μ . β -MgO was found to have a reststrahlen near 23 μ . Potassium iodide was found to be transparent to wave-lengths greater than 33 μ .

THE region of the spectrum between 20 and 40 μ has not been as extensively investigated as the regions on either side, due to the lack of materials having suitable optical properties for windows, dispersing prisms and filters. The use of various reststrahlen and gratings with open thermocouples (or microradiometers) has given us most of the knowledge we have of the optical properties of substances in this region. Recently, L. Kellner¹ has studied the transmission of paraffin (Kahlbaum M.P. 68°–72°C) and found that layers of 1.2 mm thickness are sufficiently transparent beyond 20 μ for use as thermocouple windows. This discovery materially decreases the difficulty of investigation in this region.

Potassium chloride is transparent to 23 μ , potassium bromide to 30 μ , and potassium iodide to wave-lengths greater than 33 μ . The technique for growing large crystals of these materials was developed by the author² at the University of Michigan. With these materials available the region now open for prism spectroscopy extends beyond 15 μ by more than an octave of frequencies. The purpose of this present paper is the extension of our knowledge of the optical properties of substances in this new region.

Schaefer and Matossi³ have prepared a table of the reststrahlen bands which have well established wave-lengths. Several of these bands fall in the spectral region 20–40 μ and the present investigation was made with these bands.

The reststrahlen bands are not as monochromatic as might be desired but this is compensated for by the abundance of available energy and the

³ Schaefer and Matossi, Das Ultrarote Spektrum, p. 60 (1930).

wide range of wave-lengths which are obtainable with the one technique. Wave-lengths from 6 to 150μ are thus obtainable, corresponding to a frequency range of more than five octaves.

THE APPARATUS

A reststrahlen apparatus was devised for these experiments which was superior to older reststrahlen arrangements in the following ways. First, the crystal reflectors needed were of small size and, consequently, easier to obtain than the large crystals required for the old arrangements. Second, the transfer of crystals in going from one wave-length to another was a simple operation requiring only a few seconds of time and this operation did not disturb the air through which the radiations passed and thus it was possible to keep the air dry at all times.

Fig. 1. Diagram of reststrahlen apparatus.

Fig. 1 is a diagram of the reststrahlen apparatus used for this research. Light from the Welschback mantle is reflected by the mirror, M_1 , into the reststrahlen apparatus through the circular hole, A_1 , where it subsequently passes, after reflection from the concave spherical mirror, M_2 , to a second circular hole, A_2 . A crystal mirror, R_1 , covers this hole and reflects the light to the concave mirror, M_3 , where it is returned for the second reststrahlen mirror, R_2 . After three (or four) successive reflections from reststrahlen mirrors and possibly one reflection from a metal mirror, the light is focused onto the receivers of the vacuum thermocouple, T . The thermocouple is a compensated two junction type, with one of the junctions covered by a rocksalt plate. This thermocouple was made for me by Dr. C. H. Cartwright. The window for the thermocouple was a 1 mm plate of potassium iodide.

For studying the absorption of gases, an absorption cell may be introduced into the radiation path between the mirror, M_1 , and the circular hole, A_1 .

The housing for the reststrahlen apparatus is made from brass sheet laid over a framework of half inch square iron rod. This is mounted on a wooden support. The corners were sealed with beeswax to make the apparatus gas tight so the air might be dried with P_2O_5 . The base of the housing was penetrated by three adjusting screws (not shown) for each of the spherical mirrors, M_2 to M_6 . The outside of the housing was covered with a layer of felt and to protect further the apparatus from temperature fluctuation, it was encased within galvanized iron walls. The insert, *A*, in Fig. 1 shows a cross section of one of the small brass cylinders which fit over the holes A_1 to A_5 . This is drawn to a scale twice as large as that for the rest of the figure. The cylinders each have a lacquer window, *L*, stretched over their base.

These lacquer windows are very transparent (96 to 100 percent) for waves longer than 20 μ and permit the air within the apparatus to be kept dry, when the reststrahlen mirrors are being interchanged. A paper ring on the top of each cylinder protects the mirrors from being scratched.

Because the silver mirrors are not used on their optical axes, there is considerable astigmatism. This results in a large final image with smaller intensity than if there were no astigmatism. The illumination in the center of the final image will increase, however, as the size of the reststrahlen mirrors is increased. It is believed that since the reststrahlen surfaces used were each $\frac{3}{4}$ inches in diameter, the illumination of the thermocouple receivers was not greatly attenuated due to astigmatism.

In order to have the galvanometer free from microseismic vibrations, it was mounted on a vibrationless support. This support was a simplification of the one designed by R. Müller,⁴ and was constructed in the following manner. Three triangular plywood boards, each $\frac{1}{2}$ " thick and 11" on an edge were clamped and bored with six $\frac{3}{8}$ " holes, two holes in each corner. (See Fig. 2). The two upper triangles were separated 20" and bolted together at this distance with three $\frac{3}{8}$ " brass rods, one at each corner, to form the swinging framework for the galvanometer. The top and bottom plywood triangles were fastened together by three 24" brass rods $\frac{3}{32}$ " diameter. These rods passed freely through the remaining $\frac{3}{8}$ " holes in the middle triangle. The bottom triangle served for the base of the support while the $\frac{3}{32}$ " rods afforded the necessary looseness of mechanical connection between the swinging framework and the earth. Three levelling nuts screw on the termini of the $\frac{3}{32}$ " rods below the bottom triangle. Four 10" pie pans are filled with transformer oil and stacked on top of the swinging framework to dampen oscillations. These pans were filled to the depth found by experiment to give maximum damping. The galvanometer was mounted on the middle triangle and above it on a tripod ballast was placed to make the period of oscillation of the support about two seconds. When this period is attained, the mechanical coupling is sufficiently loose to isolate effectively, the galvanometer from the horizontal components of microseismic vibrations. No protection against vertical components is necessary as these do not cause a spurious deflection

⁴ R. Müller, *Ann. d. Physik* 1, 613 (1929).

of the galvanometer. In order to clamp rigidly the support for making adjustments, tapered pins are dropped along the side of the $3/32''$ rods in two of the holes in the middle plate. The swinging framework suffers a slight parallel displacement when these pins are removed but this does not affect the galvanometer adjustment. This support is conveniently housed on a corner shelf to shield it from air currents.

Fig. 2. Vibrationless support for galvanometer.

In order to shield the Welschback mantle, *W*, from air currents, a lacquer film, *L*, was stretched across the opening of the water-cooled chamber, *C*, which surrounds it. The radiations were taken off at nearly grazing incidence because the mantle was porous. Although the mantle material is quite opaque to waves $20-40\mu$, the mantle at normal incidence, showed an absorption of only 70 percent for these radiations due to its porosity.

The thermocouple receivers were blackened with a paint made from pulverized mantle material and colorless lacquer. Tests showed that these re-

ceivers absorbed as much as when coated with a mixture of soot and water glass but the paint did not cause the receivers to curl as water glass did.

THE RESTSTRAHLEN

The table of Schaefer and Matossi is reproduced in part. This gives the method used for obtaining reststrahlen having wave-lengths of 20 to 33 μ .

TABLE I.

Substance	Number of reflections	Filter	λ	E	Literature
Quartz	4	2.5 mm AgCl	20.75 μ 8.7 μ	18.0 12.0	H. Rubens and E. F. Nichols, Wied. Ann. 60, 418 (1897).
Fluorite	3	5 mm KCl	22.9 μ	6.0	H. Rubens Berl. Ber., 1915, p. 4.
Calcite Fluorite	2 2	3 mm KBr	27.3 μ	8.0	H. Liebisch and H. Rubens, Berl. Ber., 1919, p. 876.
Marble	4		29.4 μ 6.7 μ	14.0 4.0	E. Aschkinass, Ann. d. Physik 1, 42, (1900).
Fluorite	3	0.4 mm SiO ₂ 1.2 mm KBr	32.8 μ	0.75	H. Rubens, Wied. Ann. 69, 576 (1899).

The numbers given in column E represent the observed galvanometer deflection in centimeters for the various reststrahlen. A Leeds and Northrup high sensitivity galvanometer was used with the scale at 3 meters. In order to eliminate shorter waves as much as possible a soot filter was used and these values are for the energy transmitted by this filter.

In the present experiments a 1 cm KCl filter was substituted for the 2.5 mm AgCl filter recommended by Rubens and Nichols. This is justified by the transmission curves given by Rubens and Trowbridge⁵ for AgCl and KCl.

In the present experiments, the 27.3 μ rays were not polarized as specified by Liebisch and Rubens and it was not possible to test the wave-length of the rays to find the effect of this omission.

The 32.8 μ rays were apparently homogeneous for the transmission of a KBr plate. 1.2 mm thickness was found to be 68 percent while Rubens states that it transmits more than $\frac{2}{3}$ of the 32.8 μ reststrahlen.

Except for the 20.75 μ and 29.4 μ reststrahlen a rocksalt shutter of 3 mm thickness was used. For these reststrahlen both rocksalt and metal shutters were used. If E_T was the energy of both reststrahlen and A_T was the absorption of the sample for this energy, then if E_s was the energy passed by a rocksalt filter, i.e., the energy of the short reststrahlen, and A_s the part of this energy absorbed by the sample, then, allowing 9/10 as the transmission of the rock-salt shutter for the short waves, the long wave (i.e. the 20.75 and 29.4 μ reststrahlen) energy is $(E_T - E_s/0.9)$ and the long wave energy absorbed by the sample is $(A_T - A_s/0.9)$.

⁵ H. Rubens and A. Trowbridge, Wied. Ann. 60, 724 (1897).

MEASUREMENTS

Gases. The gases used for the present measurements were not especially purified. They were drawn from stock cylinders or were the vapors of chemically pure liquids. The chief difficulty in obtaining consistent results was due to the variable concentration of vapor within the absorption cell. Benzene and CCl_4 were observed to wet the lacquer windows at times and this gives an indication that these liquids would, in all probability, be transparent. The values given in Table II are averages of four to eight independent runs taken on different days and are thought to be correct to about 2 percent. They are slightly different from some preliminary results published in a Letter to the Editor. These differences in some cases are due to additional data but for the wave-lengths 20.75 and 29.4μ the differences are due chiefly to corrections for the transmissivity of the rocksalt filter used.

TABLE II. *Percent transmission. (Length of cell, 4 inches).*

Material	Pressure	6.7μ	8.7μ	20.75μ	22.9μ	27.3μ	29.4μ	32.8μ
	Millimeters							
NH_3	760	24	26	79	93	83	82	62
N_2O	760	102	77	90	100	101	101	102
C_2H_2	760	95	92	99	101	101	100	98
H_2S	760	97	98	98	97	92	90	83
SO_2	760	98	5	7	58	100	100	96
C_6H_6	96	65	97	102	99	100	98	95
CCl_4	114	95	99	97	99	99	99	91
CS_2	361	30	98	100	86	98	99	96
CHCl_3	200	93	90	99	98	98	97	97
$(\text{C}_2\text{H}_5)_2\text{O}$	526	17	6	61	45	69	71	61

The gradual decrease of transparency for H_2S and N_3H at longer wave-lengths may be due to the short wave-length end of the pure rotation spectrum.

The only strong absorption band discovered in the new spectral region was for SO_2 at 20.75μ . This band agrees with Raman indications⁶ and is possibly the third fundamental band for SO_2 . The strong absorption of SO_2 for both the reststrahlen of quartz is quite striking. The absorption cell filled with SO_2 cuts off these radiations almost the same as a metal shutter.

R. W. Wood⁷ has shown that the mercury line 2536 is reflected by hot mercury vapor at a high pressure. He states "It appeared highly probable that if the molecular resonators were packed closely enough together, the secondary wavelets which they emit, having a definite phase relation would unite into a single wave, and the scattered light would disappear, regular reflection taking its place." Because of the strong absorption of SO_2 for the reststrahlen of quartz it was decided to test this hypothesis. High pressures should not be necessary on account of the long wave-lengths involved. Accordingly, a cell was fitted with a window of KBr and one of the quartz reststrahlen plates was replaced by it in such a way that there was reflection from the outer and inner surfaces of the window. The cell was connected to a vacuum pump and

⁶ R. G. Dickinson and S. Stewart West, *Phys. Rev.* **35**, 1126 (1930).

⁷ R. W. Wood, *Physical Optics*, p. 429 (1929).

a tank of SO₂ by a three way stopcock so that it might be alternately evacuated and filled with SO₂ at a pressure of two atmospheres. No change, whatever, in the galvanometer was observed when the cell was emptied and filled with SO₂. This seems to show that this gas does not reflect at either 8.7 μ or 20.75 μ .

The results of Table II are in agreement with results of Rubens and von Wartenberg⁸ for the 22.9 μ reststrahlen with the exception of CS₂. For this gas, using a cell about 8" long, these authors get a value of 97.8 percent as compared with my value of 86 percent for a 4" cell.

Coblentz⁹ observes absorption bands at or near 6.7 μ for liquid CHCl₃ (0.16 mm layer) and CCl₄ (0.1 mm layer) which are not observed for the vapor with the 6.7 μ reststrahlen.

For CCl₄ there is a Raman line corresponding to an active infrared vibration at a wave-length of 31.6 μ and for CHCl₃ there is a line corresponding to 27.93 μ . Also for (C₂H₅)₂O there is a line corresponding to a wave-length at 23 μ . There is no corresponding absorption for the CHCl₃ line but the low transmission of ether at 22.9 μ and CCl₄ at 32.8 μ may be associated with the Raman indications.

Optical properties of various substances. Lacquer films may be prepared by dropping a single drop of colorless brushing lacquer on a large water surface. The lacquer spreads out immediately and the amyl acetate evaporates leaving a tenacious film. These films are useful as windows for absorption cells and so their optical properties are of interest. Since the films are of the order of 1 μ thickness, there is no total reflection on account of the destructive interference between the energy reflected from the front and back surfaces. The absorption of a typical film is given in the first row of Table III. These films are so transparent that the reststrahlen are not seriously weakened in passing twice through four films, besides the sooted film over the first hole in the reststrahlen apparatus and the film over the Welschback mantle chimney. Values for a film covered with soot are also given in Table III.

TABLE III. *Percent transmission.*

Material	Description	6.7 μ	8.7 μ	20.75 μ	22.9 μ	27.3 μ	29.4 μ	32.8 μ

⁹ W. W. Coblentz, *Investigations of infrared spectra*, part I pp. 180 and 182.

Other possibilities for windows in this region are mica, quartz, glass and cellophane. Their transmissions are given in Table III.

In a MgO deposit, we have an interesting absorption at 22.9μ . It seemed from the results given in Table III that one might expect a reststrahlen for MgO near 23μ . The Vitrofrax Corporation of Los Angeles supplied the author with some beautiful synthetic crystals of β -MgO with which experiments were made. There is no doubt but that this material showed a strong reststrahlen near 23μ as will be observed from its reflectivity given in Table IV.

TABLE IV. Percent reflection

Description of reflector	22.9μ	32.8μ
Deposit of MgO from burning Mg ribbon	0	0
Reflection β -MgO	80	33
Galena	28	24
Stibnite	>16	—
Mica	32	—
Paraffin	04	—
Pencil mark on paper	09	—
Soot coating	43	48
Silver covered with MgO coating	08	91
ZnO coating	01	52
Optical black	31	—
Gold foil blackened with bismuth	>19	—
KBr	04.3	—
KI	05.5	—
KBr+ 1.5μ CaF ₂ deposited by evaporation	10	—
KI+ 1.5μ CaF ₂ deposited by evaporation	13	—

It was not convenient to measure the reflectivity of β -MgO for the other wave-lengths but it was possible to substitute the magnesia for one of the reststrahlen plates and determine the relative galvanometer deflections. This gives the ratio of the reflectivity of MgO to that of the reststrahlen plate. Assuming 0.7 for the reflectivity of the reststrahlen plates we get the approximate values for the reflectivity which are given in Table V.

TABLE V. Percent reflection of β -MgO.

6.7μ	8.7μ	20.75μ	22.9μ	27.3μ	29.4μ	32.8μ
5	10	49	80	42	35	33

S. Tolksdorf¹⁰ reported the fundamental for MgO at 14.2μ but since MgO has a cubic lattice and therefore only one reststrahlen, it does not seem possible that the 14.2μ absorption that he reports can be the fundamental. This point requires further investigation.

S. Tolksdorf predicts, from the absorption spectrum of ZnO, that this material has fundamental absorption bands at 22 and 28μ . The data in Table III give an absorption for one and not the other of these bands. An investigation of the reflectivity of zincite is being made to clear up these points.

Measurements on a KI crystal would indicate that a layer of this material 2 cm in thickness would transmit 50 percent of the 32.8μ reststrahlen.

ON THE AXIAL ROTATION AND SPECTRA OF STARS

BY ROSS GUNN

NAVAL RESEARCH LABORATORY, WASHINGTON, D. C.

(Received April 30, 1931)

ABSTRACT

Struve's remarkable relation between high observed axial rotations of stars and their bright line spectra is considered theoretically. It is shown that the two phenomena are closely related to the same electromagnetic effects that account for the anomalous solar rotation. High electromagnetic winds, resulting from crossed electric and magnetic fields, account for the high apparent rotational velocity and transfer sufficient momentum to the star in the course of stellar time to account for the high true rotations necessary to produce fission. The large electromagnetic wind velocities require the presence of comparatively large radial electric fields and it is shown that these can add sufficient additional excitation energy to the atmospheric ions to produce bright line spectra. Thus, high apparent axial rotations, high true rotations and bright line spectra in stars are intimately related and the existence of one, usually demands the presence of the others. An approximate expression is derived for the time rate of increase of angular momentum in a star.

IN TWO recent papers,¹ Otto Struve has drawn attention to a remarkable correlation between the spectra of stars and their apparent rotation as derived from measurements of Doppler displacements. Dr. Struve points out that emission lines are found principally in the O and B type stars and that in these "Excessive rotations, estimated at . . . (. . . 250 km/sec or more), are frequent. Apparently bright lines occur preferentially in stars having rapid axial rotation." The very high peripheral velocities indicated by his observational data suggest that certain stars are rotating so fast that they are on the verge of division to form binary systems. This conclusion is in accord with statistical data on binary systems which show that most close binary systems are B type stars or later. In the following discussion we will assume that the internal constitution and atmosphere of a given star is not greatly different from that of our sun and show that Dr. Struve's strange observed relations follow directly from a consideration of electromagnetic effects which we have shown to account for certain observed solar peculiarities.

SUPERPOSED ELECTROMAGNETIC WINDS

In a series of papers dealing with the electricity and magnetism of the sun² it has been shown that the observed variations of the apparent solar rotation with latitude, altitude, and time are readily explained in terms of atmospheric motions superposed upon the body rotation of the sun proper. These systematic motions of the atmosphere result from the interaction of

¹ O. Struve, *Astrophys. J.* **72**, 1 (1930); **73**, 94 (1931).

² R. Gunn, *Phys. Rev.* **35**, 635 (1930); **36**, 1251 (1930); **37**, 283 (1931); **37**, 983 (1931); **37**, 1129 (1931).

crossed electric and magnetic fields with the atmospheric ions and we may express its magnitude u by²

$$u = \frac{E \times B}{B^2(1 + (R/\lambda)^2)} \quad (1)$$

where E is the radial electric field of the star at the observed level and B is the magnetic field (both quantities being expressed in e.m.u.), R the radius of the spiral generated by the moving ion, and λ the mean free path. We will hereafter refer to this systematic superposed atmospheric motion of the ions as an "electromagnetic wind."

The electrical energy dissipated in the solar atmosphere is an appreciable fraction of the total radiated energy.² This seems probably to be true in all stars having magnetic fields and indicates that stars with high surface temperatures (high radiation per unit area) are surrounded by a comparatively large radial electric field. Thus in O and B type stars with surface temperatures ranging from 35,000° to 12,000° electrical effects would be expected to be very important. We have no knowledge of the magnetic field of a star and can only suggest that its magnitude and distribution is not unlike that of the sun. If this is the true situation then we would expect the ratio of the magnitudes of the electric and magnetic fields in early type stars to be large and high velocity electromagnetic winds to result. Dr. Struve's observation that excessive rotations are common in O and B type stars is consistent with the above conclusions.

EXCITATION OF RADIATION BY ELECTRIC FIELDS

Eddington³ has concluded that bright line spectra in a non-nebulous star is evidence for the existence of "thunderstorms" in the atmosphere of the star, but he was unable to make his suggestion quantitative. We proceed to calculate the electrical energy added to an ion during its free path as a result of the presence of an electric field. An ion in the atmosphere of a star having electric and magnetic fields does not move in the direction of the electric field, on the average, but describes a cycloidal path and progresses in a direction at right angles to both the impressed electric and magnetic fields.² Due to the presence of the magnetic field, an ion cannot acquire more than a definite amount of energy from the electric field, even if the ion describes an infinitely long free path. The mean energy W added to an ion by the electric field is given by²

$$W = mvu[1 + u^2/v^2]^{1/2} \quad (2)$$

while the maximum energy W_m is considerably more than twice as much or

$$W_m = 2mvu(1 + u/v) \quad (3)$$

where m is the mass of the ion, v the component of its initial velocity in a plane perpendicular to B the magnetic field and u the magnitude of the elec-

² Internal Constitution of the Stars, (1926).

tromagnetic wind given by Eq. (1). If we neglect the relatively less frequent case of successive collisions where an ion of initially large energy collides with another and starts it off with abnormally high velocity, we can express Eq. (2) in terms of the electromagnetic wind velocity u and the surface temperature of the star. Thus if we express W in terms of equivalent electron volts V , Eq. (3) becomes

$$V = \frac{u(2mkT)^{1/2}}{10^8 e} \left[1 + \frac{u^2 m}{2kT} \right]^{1/2} \quad (4)$$

where e is the electronic charge expressed in e.m.u., k the Boltzmann constant, and T the atmospheric or effective surface temperature. Table I gives the average increase in energy of an ion due to electrical fields in terms of equivalent electron volts, assuming that the initial energy of the ion when it starts its path is purely thermal. Many of the ions and electrons will have more than these energies and can produce additional excitation.

It will not be necessary to discuss in detail the exact mechanism whereby bright emission lines are produced, for it should be clear from Table I that ions in the atmosphere of a star can absorb sufficient energy from the star's electric field to excite bright line radiation. The table and Eq. (2) bring out

TABLE I. *Average increase in energy due to electric field.*

u km/sec	Hydrogen ion Surface Temperature		Electron Surface Temperature	
	10,000°	20,000°	10,000°	20,000°
10	1.74 volts	2.19 volts	0.031 volts	0.044 volts
25	7.80 "	8.46 "	0.079 "	0.111 "
50	28.8 "	29.4 "	0.16 "	0.22 "
100	112. "	113. "	0.32 "	0.45 "

clearly that the electrical excitation energy and hence the prevalence of bright lines increases rapidly with increase in the magnitude of the electromagnetic wind which is proportional to the apparent rotational velocity. Thus the theory that has been developed to account for the observed anomalies of the sun's rotation leads directly to a quantitative explanation of Struve's observed relation between high rotational velocities and bright line spectra in stars.

ADDED ANGULAR MOMENTUM AND BODY ROTATION

With the possible exception of close binary stars in which the axial and orbital periods are identical, it seems impossible to determine the true rotational period of a star, either by observing the motion of its magnetic pole or by a determination of its departure from a true spherical form. We must have knowledge of the true body rotation in order to separate the various components of the motion and we are forced to assume that the initial rotation of a star is small and estimate the body rotation from the observed apparent motions, the physical properties of its atmosphere and its age. The directions of the electric and magnetic fields of stars are undoubtedly related to the

direction of their rotation in the same manner as those of the sun and earth. The electromagnetic winds therefore blow in the direction of the body rotation, but much faster, and add momentum to the star proper. Thus, we definitely abandon the principle of the conservation of momentum in an evolving star. In connection with the sun this effect was considered² and it was shown that since the sun was formed, sufficient angular momentum has been transferred to the sun proper by its own electromagnetic winds to account for its present axial rotation.

The superposed systematic momentum of an ion in a star's atmosphere is derived entirely from the radial electric field, and the magnetic field serves only to change the direction of the moving ion. The mechanism is therefore one for converting radial momentum into angular momentum. There can be no reacting momentum transferred to the star's magnetic field by the mechanism described, for the magnetic force on an ion is always at right angles to its motion and the magnetic field cannot transfer energy to the ion or the ion energy to the magnetic field. Momentum, therefore, cannot be transferred by this means and we are left to consider only the momentum transferred to a star by viscous forces between the star proper and its fast moving atmosphere. This transfer of momentum is always in such a direction as to accelerate the axial rotation and calculations indicate that in the course of stellar time the added momentum is adequate to increase the angular velocity until a star becomes rotationally unstable.

The data available for a typical star are not sufficiently complete to warrant a detailed calculation and in the following we shall make a rough calculation which will serve to indicate only the approximate magnitude of the effects. The electromagnetic winds of the star's atmosphere transfer momentum to the star proper which we assume to be a semi-rigid gaseous body held together by gravitational, radiative, and electromagnetic forces. The torque T applied to the star as a result of the systematic motion of its atmosphere is

$$T = \eta A R_0 \frac{du}{dr} = \frac{d\Omega}{dt} \quad (5)$$

where η is the mean coefficient of viscosity of the transition layer between the atmosphere moving with a velocity u and the surface proper, A the effective areas in contact, R_0 the radius of the star, du/dr the radial velocity gradient and $d\Omega/dt$ the time rate of increase of angular momentum. It is clear from Eq. (1) that the superposed electromagnetic wind velocity u drops rather abruptly when the ion pressure increases sufficiently to make the mean free path λ as small as R , the radius of the spiral generated by the ion moving in the magnetic field. If the low lying regions of the star's atmosphere are in gravitational equilibrium, then the difference in altitude Δr , corresponding to a fractional change in the ion pressure of unity, is given by

$$\Delta r = \frac{kT}{zhg} \quad (6)$$

where k is the Boltzmann constant, T the temperature of the atmosphere, z its mean atomic weight, h the mass of a hydrogen atom, and g the surface acceleration due to gravity. The fractional change in the superposed velocity u in the interval given by Δr is also approximately unity so that we may write

$$\frac{\Delta u}{\Delta r} = \frac{zh\gamma M u_0}{kTR_0^2} \quad (7)$$

where u_0 is the superposed electromagnetic wind velocity in the observed regions of the star's atmosphere, γ the gravitational constant and M the mass of the star.

The coefficient of viscosity η of the transition layer is

$$\eta = \frac{(3zhkT)^{1/2}}{2^{3/2}\pi\sigma^2} \quad (8)$$

where σ is the diameter of the gaseous ions or molecules according to kinetic theory. We assume that the effective area in contact is a ring around the equator of the star of width R_0 . Combining the foregoing relations and making obvious substitutions we have that the rate of increase in the angular momentum of the star proper is

$$\frac{d\Omega}{dt} = \left(\frac{3zh}{2kT}\right)^{1/2} \frac{zh\gamma u_0 R_0 M}{\sigma^2} \quad (9)$$

or if ω_t is the present value of the angular velocity

$$\omega_t = \omega_0 + \left(\frac{3zh}{2kT}\right)^{1/2} \frac{zh\gamma R_0 u_0 \tau}{\sigma^2 d^2} \quad (10)$$

where ω_0 is the initial angular velocity of the star and will be set equal to zero, d is the radius of gyration of the star about its axis of spin and τ is the age of the star. We have assumed a steady state and have made no attempt to allow for greater values of u_0 during the youth of the star or for its variation with latitude.

Now if V_0 is the apparent or observed peripheral velocity of the star and $\omega_t R_0$ the peripheral velocity of the surface proper then $V_0 = u_0 + \omega_t R_0$ and

$$\frac{V_0}{u_0} = \left[1 + \left(\frac{3zh}{2kT}\right)^{1/2} \frac{zh\gamma R_0^2 \tau}{\sigma^2 d^2} \right]. \quad (11)$$

Numerical data for calculating V_0/u_0 from Eq. (11) are lacking and we must assume that the star is of uniform density, its atmosphere is not unlike that of the sun and its age approximates 2×10^{20} sec. or the mean indicated age of all stars. Substituting therefore $z=3.3$; $h=1.67 \times 10^{-24}$ gm; $k=1.37 \times 10^{-16}$; $\sigma=10^{-8}$ cm; $\gamma=6.67 \times 10^{-8}$; $\tau=2 \times 10^{20}$ sec; $d^2=0.4R_0^2$ and for a typical B type star $T=15,000^\circ$ we find $V_0/u_0=4.1$ and therefore the true rotational velocity is roughly 3/4 the apparent observed value. A similar calculation for the sun yields 6.2 while the observed ratio is 4.0. It is clear from the results of

our calculation that, unless B type stars are much younger in actual years of existence than their state of evolution indicates the true rotations are large fractions of the apparent rotations and therefore many of these types of stars are on the verge of division to form binary systems. It seems clear that high electromagnetic winds necessarily produce high speed axial rotations in a star of moderate age and the calculations of the present paper are not in disagreement with Dr. Struve's conclusion that many B type stars are almost rotationally unstable.

The observed high apparent axial rotations in O and B type stars, together with the well established fact that close binary systems with few exceptions are B type stars or later, seem significant, and strongly suggest that stars in this period of their evolution divide as a result of a tremendous increase in their angular momentum. The increase in angular velocity appears to be accounted for by electromagnetic effects rather than by an increase due to contraction of the star. The contraction of the star may play an important part; but there is great difficulty in accounting for the original angular momentum, and a mechanism to add momentum to the system must be provided somewhere in the plan of stellar evolution. It seems quite possible that the above mechanism for adding angular momentum to a star represents physical reality but further supporting evidence is desirable.

CONCLUSION

Dr. Struve's values for the apparent peripheral velocity of type B stars (approximating 250 km/sec) together with the present calculations suggest that the electromagnetic winds may have velocities of 50 km/sec or more and therefore in these stars the ratio of the magnitude of the electric and magnetic fields must be very large. The large electric fields are capable of adding considerable energy to the ions constituting the star's atmosphere and emission lines should be observed. The very high superposed atmospheric motion of the star will, as well, transfer momentum to the star proper and we should expect this stage of development of a star to be characterized by a large increase in angular momentum resulting ultimately in the formation of binary systems. Statistical evidence supports this conclusion. We see therefore that high apparent axial rotations, high true rotations and bright line spectra in stars are intimately related and the existence of one usually demands the presence of the others.

THE NEUTRON

BY R. M. LANGER AND N. ROSEN
MASSACHUSETTS INSTITUTE OF TECHNOLOGY

(Received May 12, 1931)

ABSTRACT

The writers point out that the postulation of the existence of the "neutron," a combination of an electron and a proton, of small size and low energy would be very useful in explaining a number of atomic and cosmic phenomena. They find that a mathematical treatment based on existing theory leads to indications of such a state but no definite proof.

I. INTRODUCTION

IT IS an attractive speculation to try to describe a process by which the various elements could be formed. In the present state of atomic theory it is really an anomaly that there are elements other than hydrogen; for no one has hitherto attempted to show that quantum systems could exist with the dimensions and energies appropriate to nuclei or constituents of nuclei. Our purpose here is to indicate how such systems may exist on the basis of wave-mechanics, and thus offer a way of describing the process of building up of the heavier elements.

The present article is devoted to a discussion of a combination of an electron and a proton of low energy and very small size which we shall speak of as the "neutron." Such a particle, if it exists, must have a mass but slightly smaller than that of a hydrogen, a diameter of 10^{-12} to 10^{-15} cm, and energy of the order of magnitude of m_0c^2 ($15m_0c^2$ is an upper limit; m_0 = electron mass) less than that of hydrogen in order to account for observed phenomena. It seems proper to begin by pointing out reasons for the assumption of the existence of a neutron and to show how it might help to explain certain phenomena.

II. APPLICATIONS

In most ordinary phenomena the effect of a particle like the neutron would be unobservable. It is small enough, for example, to penetrate material walls and therefore would not contribute to a gas pressure. Its only large scale property is its gravitational field. In atomic and cosmic processes however, it can play an important role.

1. The process of the increase of atomic number.

In a universe whose initial state was a mass of free protons and electrons it is natural to imagine that the most readily formed combination would be that of ordinary hydrogen. This process has a large cross-section because the final state is comparatively large and because there is attraction at large distances with the possibility of radiation always present to provide for the con-

servation of energy in the change of state involved. On the other hand, a stable combination of two protons or two electrons would surely have to be of extremely small size because we know that down to very small separations the forces are repulsive. The latter fact decreases the probability of close collisions; and any radiation that might occur could only make the collision less intimate. The alternative process of simultaneous collision of at least six particles to form a complex nucleus is obviously unimportant even at high densities, as long as a suitable building process can be described which involves the collision of only two bodies at a time.

Once hydrogen atoms are formed the way is now open for the building up process. The neutron as we describe it, is actually a low state of hydrogen so that in any hydrogen atom there is always a probability of transition into a neutron with emission of a high energy quantum. Due to its small size the neutron has a very small external electric field so that its long range influence is the gravitational attraction. At small distances there are of course further polarization attractions and possibly magnetic effects. Such systems will collide readily in spite of their small size because they are electrically neutral. Resonance, polarization or magnetic forces may then hold them together until a complex system is formed which by expulsion of some of its electrons might rearrange itself into a stable atomic nucleus. A neutron being small and field-free could penetrate outer shells of electrons and enter nuclei. The tremendous initial velocity which must be assumed in the usual picture in which protons or α -particles are added to one element to form a heavier one, is no longer required. The resulting configuration could well be a stable one but need not be the most stable. The measured values of packing fractions indicate a remarkable degree of stability in the ordinary nuclei. It may therefore be that a close cluster of neutrons could lose energy by the expulsion of electrons to form nuclei.

2. Cosmic radiation.

There are two ways of distributing the energy which is released in the formation of helium. Either most of the energy is given out in the formation of neutrons from hydrogen and a smaller amount accompanies the rearrangement of the four neutrons into helium or else the formation of neutrons liberates a comparatively small amount, the remainder of the packing energy being radiated in a single quantum as the rearrangement occurs. In either case the radiation might be of the type of cosmic radiation as observed by Millikan and others. The second alternative however is entirely in agreement with the conclusion of Millikan as to the significance of his measurements. However, the gradual gathering of neutrons with a subsequent sudden transition to a stable nucleus is much more agreeable than the assumption of a multiple collision by means of which this process is ordinarily supposed to happen.

3. High density matter in stars.

The usual explanation of the white dwarfs involving a high degree of ionization of the atoms is not the only one. There are in fact great advantages

from this point of view in favor of our neutron. Being small it has a great mean free path and is comparatively insensitive to light pressure. It therefore goes easily to the center of a gravitating mass. Being neutral and having an extremely small external field, it permits high densities to build up before it deviates appreciably from perfect gas behavior. Further, the possibility of high densities is not dependent on having a high temperature or pressure nor is there much danger of violating the Pauli exclusion principle by exceeding the maximum electron density for a given pressure.

III. THEORETICAL TREATMENT

If one naively examines the solutions of the ordinary Schrödinger equation for hydrogen, one is inclined to wonder why, in addition to the ordinary states for quantum numbers, $n = 1, 2, 3, \dots$, there is no state for $n = 0$. Since in general the solutions (for $l = 0$) are of the form:

$$\psi \sim e^{-r/n} P_n(r)$$

the wave function for this state, if normalized, would be a δ -function, zero everywhere except at the origin, so that this state would correspond to an electron which had fallen into the nucleus. Such a condition in view of the attraction between the two is by no means inconceivable.

That this is unsatisfactory is at once evident. In the first place the energy, which is given by:

$$W = Rh/n^2$$

would be infinite. In the second place, a simple calculation shows that the transition probability from a higher state to this one is zero in every case. From a physical point of view the state can therefore be considered as non-existent.

However, the above considerations are too rough. The assumption of a $1/r$ potential must certainly be incorrect for small distances (for the infinity at the origin surely does not exist in nature). If then the potential deviates from $1/r$ at small distances, it may well be that an atomic state exists corresponding to the one under discussion with low *but finite* energy, of small *but not zero* dimensions, and therefore with small *but non-vanishing* transition probabilities.

As a better approximation one can consider the electron in a Coulomb field modified by a small correction term, for example, of the form b/r^2 (the singularity still remains however). One can think of this as an actual potential, or one can consider the relativistic Schrödinger equation for a Coulomb field, thus bringing in a b/r^2 term.

If that is done, it is found without difficulty that for s -states ($l = 0$), in addition to the usual solutions, there exist solutions corresponding to the second root of the indicial equation with energies given by

$$E_2 = m_0 c^2 [1 + \alpha^2 / (n_r + \frac{1}{2} - (\frac{1}{4} - \alpha^2)^{1/2})^2]^{-1/2},$$

where α is the Sommerfeld fine-structure constant. These energies differ very little from the ordinary energies given by:

$$E_1 = m_0 c^2 [1 + \alpha^2 / (n_r + \frac{1}{2} + (\frac{1}{4} - \alpha^2)^{1/2})^2]^{-1/2}$$

for the next smaller value of n_r except in the case $n_r = 0$. For this case E_2 is very low:

$$E_2 \sim 0.073 m_0 c^2.$$

That is E_2 is nearly $m_0 c^2$ below the energy of a normal hydrogen atom.

The wave functions corresponding to E_2 have singularities for $r = 0$. They are quadratically integrable and hence would be acceptable according to the views of many physicists. However, the variational integrals turn out to be infinite and for this reason we reject them.¹ Incidentally these wave functions are not necessarily orthogonal to the usual ones of energy E_1 .

Another way of attacking the problem is to construct potential energy curves which differ inappreciably from e^2/r for distances greater than 10^{-12} cm, but which have much steeper slopes in the range 10^{-12} to 10^{-16} cm and then flatten out and remain finite at the origin. With such potential functions one can obtain a low "neutron" state without appreciably changing the energies of the higher hydrogen levels. However, setting up such a potential function involves several arbitrary factors; and there are as yet no experimental data to determine them without ambiguity. Further development along this line is very intriguing but in their present state of uncertainty the authors feel themselves not bold enough to offer the results for publication.

GROUP THEORY AND THE ELECTRIC CIRCUIT*

BY NATHAN HOWITT

NAVAL RESEARCH LABORATORY, BELLEVUE, ANACOSTIA, D. C.

(Received March 20, 1931)

ABSTRACT

Electrical networks consisting of inductances, resistances, and capacitances form a group with the impedance function as an absolute invariant. That is, to a given impedance function there corresponds an infinite number of networks, any one of which can be obtained from any other by a special linear transformation of the instantaneous mesh currents and charges of the network. In this manner one may arrive at the complete infinite set of networks equivalent to a given network of any number of meshes. This is done by writing down the three fundamental quadratic forms of the network. Then a linear affine transformation of the instantaneous mesh currents and charges of the network results in the formation of new quadratic forms, the matrices of the coefficients of which represent a member of the group, i.e., an equivalent network. Instead of performing the substitutions, the three matrix multiplications $C'AC$ are used, one for each quadratic form, where A represents the original matrix, C the transformation matrix, and C' its conjugate. It may be possible to extend this theory to include continuous systems where the quadratic forms become integrals or infinite series and one deals with infinite matrices and infinite transformations.

IN 1904, in an address before the Mathematics section of the International Congress of Arts and Science, Professor James Pierpont said, "The group concept, hardly noticeable at the beginning of the century, has at its close become one of the fundamental and most fruitful notions in the whole range of our science."¹ And now this abstract notion of groups finds application in an important branch of physics—electric circuit theory.

Considerable has been written on electrical networks and the impedance function,² but it has hardly been suspected that electrical networks formed a group with the impedance function as an absolute invariant and that it was possible to proceed in a continuous manner from one network to its equivalent network by a linear transformation of the instantaneous mesh currents and charges of the network.

Before proceeding with the general n -mesh network it will be instructive to construct the quadratic forms and the impedance function for the two-mesh network with all three network elements present, shown in Fig. 1.

The elements λ_{12} , ρ_{12} and σ_{12} are the elements common or mutual to meshes 1 and 2. λ_{11} , ρ_{11} and σ_{11} are the *total* parameters of mesh 1, that is, they are, respectively, the total inductance, resistance and elastance of mesh

* This is part of a dissertation presented to the Massachusetts Institute of Technology for the degree of Doctor of Science in 1930.

¹ J. Pierpont, Bulletin of the American Mathematical Society 2, 144 (1904).

² O. Heaviside, Electromagnetic Theory, 1912, and Electrical Papers, 1925; J. R. Carson Electric Circuit Theory and the Operational Calculus, 1926; V. Bush, Operational Circuit Analysis, 1929.

1. Similarly, λ_{22} , ρ_{22} and σ_{22} are the total parameters of mesh 2. The quantities i_1 and i_2 are the *instantaneous mesh* currents, the arrows indicating their directions. Let q_1 and q_2 be the corresponding mesh charges, so that

$$i_1 = dq_1/dt \quad (1)$$

$$i_2 = dq_2/dt. \quad (2)$$

The total *instantaneous* magnetic energy in the complete network is given by

$$\begin{aligned} T &= \frac{1}{2}(\lambda_{11} - \lambda_{12})i_1^2 + \frac{1}{2}\lambda_{12}(i_1 + i_2)^2 + \frac{1}{2}(\lambda_{22} - \lambda_{12})i_2^2 \\ &= \frac{1}{2}(\lambda_{11}i_1^2 + 2\lambda_{12}i_1i_2 + \lambda_{22}i_2^2). \end{aligned} \quad (3)$$

Similarly, the total *instantaneous* electrostatic energy in the complete network is given by

$$\begin{aligned} V &= \frac{1}{2}(\sigma_{11} - \sigma_{12})q_1^2 + \frac{1}{2}\sigma_{12}(q_1 + q_2)^2 + \frac{1}{2}(\sigma_{22} - \sigma_{12})q_2^2 \\ &= \frac{1}{2}(\sigma_{11}q_1^2 + 2\sigma_{12}q_1q_2 + \sigma_{22}q_2^2). \end{aligned} \quad (4)$$

Fig. 1. General two-mesh network.

Finally, the total *instantaneous* power lost in the resistances of the complete network is given by

$$\begin{aligned} R &= (\rho_{11} - \rho_{12})i_1^2 + \rho_{12}(i_1 + i_2)^2 + (\rho_{22} - \rho_{12})i_2^2 \\ &= \rho_{11}i_1^2 + 2\rho_{12}i_1i_2 + \rho_{22}i_2^2. \end{aligned} \quad (5)$$

In more compact notation, T , V and R may, respectively, be written

$$T = \frac{1}{2} \sum_{j,k=1}^2 \lambda_{jk} i_j i_k \quad (6)$$

$$V = \frac{1}{2} \sum_{j,k=1}^2 \sigma_{jk} q_j q_k \quad (7)$$

$$R = \sum_{j,k=1}^2 \rho_{jk} i_j i_k \quad (8)$$

Since $\lambda_{jk} = \lambda_{kj}$, $\sigma_{jk} = \sigma_{kj}$, $\rho_{jk} = \rho_{kj}$ it is readily seen that by giving j and k all possible values from 1 to 2 in any manner, Eqs. (6), (7) and (8) reduce to Eqs. (3), (4), and (5).

It might be well at this point to generalize Eqs. (6), (7) and (8) for n meshes. This is done simply by changing the upper limit of the summation from 2 to n . For n meshes, then, these equations become

$$T = \frac{1}{2} \sum_{j,k=1}^n \lambda_{jk} i_j i_k \quad (9)$$

$$V = \frac{1}{2} \sum_{j,k=1}^n \sigma_{jk} q_j q_k \quad (10)$$

$$R = \sum_{j,k=1}^n \rho_{jk} i_j i_k \quad (11)$$

where j and k take on all possible values from 1 to n , in any manner.

The quantities T , V and F are the so-called quadratic forms³ which are positive and definite. That is, they are positive for all values of the variable i or q , and they are zero when and only when all the variables are zero or when the corresponding parameters are all zero. The positiveness of these forms follows at once from physical considerations since the magnetic energy, the electrostatic energy and the power lost in the resistances of the network are positive quantities, and are zero when and only when all the currents or charges are respectively zero, or when the corresponding parameters are zero. These quadratic forms play an important role in dynamics, and significant results are obtained from their positive and definite character.

It is instructive to point out here that the coefficients of the quadratic forms (6), (7) and (8) may be obtained directly from certain matrices. Thus, the coefficients of the quadratic form (6) are contained in the matrix

$$\begin{vmatrix} \lambda_{11} & \lambda_{12} \\ \lambda_{12} & \lambda_{22} \end{vmatrix} \quad (12)$$

and the form is obtained at once by writing

$$\lambda_{11}i_1^2 + 2\lambda_{12}i_1i_2 + \lambda_{22}i_2^2$$

which is, of course, $2T$. Similarly, the coefficients of the forms (7) and (8), respectively, are contained in the matrices

$$\begin{vmatrix} \sigma_{11} & \sigma_{12} \\ \sigma_{12} & \sigma_{22} \end{vmatrix} \quad \begin{vmatrix} \rho_{11} & \rho_{12} \\ \rho_{12} & \rho_{22} \end{vmatrix} \quad (13)$$

Also, in the n -mesh case, the coefficients of the quadratic forms T , V and F are contained, respectively, in the matrices

$$\begin{vmatrix} \lambda_{11} & \lambda_{12} & \cdots & \lambda_{1n} \\ \lambda_{12} & & & \\ \vdots & & & \\ \lambda_{1n} & \cdots & \lambda_{nn} \end{vmatrix}, \quad \begin{vmatrix} \sigma_{11} & \sigma_{12} & \cdots & \sigma_{1n} \\ \sigma_{12} & & & \\ \vdots & & & \\ \sigma_{1n} & \cdots & \sigma_{nn} \end{vmatrix}, \quad \begin{vmatrix} \rho_{11} & \rho_{12} & \cdots & \rho_{1n} \\ \vdots & & & \\ \vdots & & & \\ \rho_{1n} & \cdots & \rho_{nn} \end{vmatrix} \quad (14)$$

From these matrices, the respective quadratic forms of the n -mesh network as well as the respective networks are readily constructed.

The impedance function is obtained from the determinant of the network.⁴ Thus the determinant of the network of Fig. 1 is

$$D_1 = \begin{vmatrix} \lambda_{11}p + \rho_{11} + \sigma_{11}/p & \lambda_{12}p + \rho_{12} + \sigma_{12}/p \\ \lambda_{12}p + \rho_{12} + \sigma_{12}/p & \lambda_{22}p + \rho_{22} + \sigma_{22}/p \end{vmatrix} \quad (15)$$

and the impedance function is obtained by dividing this determinant by the minor of the element in the first row and first column. Thus

$$Z(p) = \frac{D_1}{\lambda_{22}p + \rho_{22} + \sigma_{22}/p} \quad (16)$$

³ See M. Böcher, Introduction to Higher Algebra, 1927, p. 150.

⁴ V. Bush, reference 2, Chapter III.

It will be helpful first to consider the simple two-mesh network containing only two kinds of network elements shown in *a*, Fig. 2.

The parameters of the network are $\lambda_{11}=2$, $\lambda_{22}=1$, $\lambda_{12}=1$; $\rho_{11}=2$, $\rho_{22}=2$, $\rho_{12}=1$, and thus the quadratic forms are

$$T = \frac{1}{2}(2i_1^2 + 2i_1i_2 + i_2^2) \quad (17a)$$

$$F = \frac{1}{2}(2i_1^2 + 2i_1i_2 + 2i_2^2) \quad (17b)$$

and the matrices of the coefficients of these forms are

$$\begin{vmatrix} 2 & 1 \\ 1 & 1 \end{vmatrix}, \quad \begin{vmatrix} 2 & 1 \\ 1 & 2 \end{vmatrix}. \quad (18)$$

Some members of the group of networks having

$$Z(p) = \frac{p^2 + 4p + 3}{p + 2}$$

Fig. 2.

The minimal networks of the impedance function

$$Z(p) = \frac{p^2 + 4p + 3}{p + 2}$$

Now perform the following linear transformations of the instantaneous mesh currents in the network

$$i_1 = i_1' \quad (19a)$$

$$i_2 = a_{21}i_1' + a_{22}i_2' \quad (19b)$$

where the *a*'s are any real numbers, positive or negative. Substituting these values for *i*₁ and *i*₂ in the quadratic forms (17a) and (17b), we have

$$T = \frac{1}{2}[(2 + 2a_{21} + a_{21}^2)i_1'^2 + (2a_{22} + 2a_{21}a_{22})i_1'i_2' + (a_{22}^2)i_2'^2] \quad (20a)$$

$$F = \frac{1}{2}[(2 + 2a_{21} + 2a_{21}^2)i_1'^2 + (2a_{22} + 4a_{21}a_{22})i_1'i_2' + (2a_{22}^2)i_2'^2] \quad (20b)$$

Thus, the transformations (19) give the new quadratic forms (20). The two matrices containing the coefficients of these new forms are then

$$\begin{vmatrix} 2 + 2a_{21} + a_{21}^2 & a_{22} + a_{21}a_{22} \\ a_{22} + a_{21}a_{22} & a_{22}^2 \end{vmatrix}, \quad \begin{vmatrix} 2 + 2a_{21} + 2a_{21}^2 & a_{22} + 2a_{21}a_{22} \\ a_{22} + 2a_{21}a_{22} & 2a_{22}^2 \end{vmatrix} \quad (21)$$

These two matrices determine an infinite group of networks equivalent to the network shown in *a*, Fig. 2. The different networks are obtained by assigning different real values to a_{21} and a_{22} . Thus, for example, by giving the values of $+1$ and -1 respectively to a_{21} and a_{22} , the matrices (21) become under these substitutions

$$\left\| \begin{array}{cc} \frac{5}{4} & \frac{1}{2} \\ \frac{1}{2} & 1 \end{array} \right\|, \left\| \begin{array}{cc} \frac{3}{2} & 0 \\ 0 & 2 \end{array} \right\|. \quad (22)$$

From these matrices the parameters of the network are readily obtained. They are

$$\lambda_{11} = \frac{5}{4}, \quad \lambda_{22} = 1, \quad \lambda_{12} = \frac{1}{2}; \quad \rho_{11} = \frac{3}{2}, \quad \rho_{22} = 2, \quad \rho_{12} = 0$$

and the corresponding network is shown in *b*, Fig. 2. It is a simple matter to verify the fact that the networks *a* and *b* of Fig. 2 have the same impedance function, namely,

$$Z(p) = \frac{p^2 + 4p + 3}{p + 2}. \quad (23)$$

In the same way, by assigning different real values to a_{21} and a_{22} , one can obtain the complete infinite group of networks having (23) for an impedance function. Thus, for example, all the networks shown in Fig. 2 have the same impedance function, namely, (23). These networks are some of the members of the infinite group of networks contained in the tensors (21). It is not difficult to ascertain what values of a_{21} and a_{22} in the transformation matrix will give these networks.

Note that the networks $a'-g'$ are, respectively, identical with the networks $a-g$, except that the branches in mesh 2 are interchanged. The former networks may thus be considered images of the latter. Mathematically, two networks with their branches in mesh 2 interchanged, are considered different networks, and to exhaust the complete infinite group of networks, both networks and their images must be included.

Note also that the networks $d-g$ and their respective images $d'-g'$ are minimal networks. That is, they are the networks of the group containing the least number of network elements. These can be easily obtained from the tensors (20). Finally, note that it is unnecessary to go through the work of substituting (19) in (17) to obtain the matrices (21) of the quadratic forms (20). We merely make use of an important theorem on matrices, namely, that if we subject the x 's in a quadratic form with matrix A to a linear transformation with matrix C , we obtain a new quadratic form with the matrix $C'AC$, where C' is the conjugate of C .⁵ In open form, the matrix of the new quadratic form is obtained by multiplying the three matrices

⁵ M. Böcher, reference 3, Theorem 1, p. 129.

$$\begin{vmatrix} c_{11} & c_{21} & \cdots & c_{n1} \\ c_{12} & & & \vdots \\ \vdots & & & \vdots \\ c_{1n} & \cdots & \cdots & c_{nn} \end{vmatrix} \times \begin{vmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & & & \vdots \\ \vdots & & & \vdots \\ a_{n1} & \cdots & \cdots & a_{nn} \end{vmatrix} \times \begin{vmatrix} c_{11} & c_{12} & \cdots & c_{1n} \\ c_{21} & & & \vdots \\ \vdots & & & \vdots \\ c_{n1} & \cdots & \cdots & c_{nn} \end{vmatrix}. \quad (24)$$

In our problem, the linear transformation is (19), the matrix of which is

$$\begin{vmatrix} 1 & 0 \\ a_{21} & a_{22} \end{vmatrix} \quad (25)$$

which corresponds to the C matrix. Hence, using this matrix and the matrices (18), we obtain for the matrices of the transformed quadratic forms

$$\begin{vmatrix} 1 & a_{21} \\ 0 & a_{22} \end{vmatrix} \times \begin{vmatrix} 2 & 1 \\ 1 & 1 \end{vmatrix} \times \begin{vmatrix} 1 & 0 \\ a_{21} & a_{22} \end{vmatrix} \quad (26a)$$

$$\begin{vmatrix} 1 & a_{21} \\ 0 & a_{22} \end{vmatrix} \times \begin{vmatrix} 2 & 1 \\ 1 & 2 \end{vmatrix} \times \begin{vmatrix} 1 & 0 \\ a_{21} & a_{22} \end{vmatrix}. \quad (26b)$$

Performing the multiplication of the matrices in (26a), we have

$$\begin{vmatrix} 2 + 2a_{21} + a_{21}^2 & a_{22} + a_{21}a_{22} \\ a_{22} + a_{21}a_{22} & a_{22}^2 \end{vmatrix}. \quad (27a)$$

Note that this is the left-hand matrix of (21), which was obtained from the transformed quadratic forms (20). In the same way, performing the matrix multiplication in (26b), we have

$$\begin{vmatrix} 2 + 2a_{21} + 2a_{21}^2 & a_{22} + 2a_{21}a_{22} \\ a_{22} + 2a_{21}a_{22} & 2a_{22}^2 \end{vmatrix} \quad (27b)$$

which is the right-hand matrix of (21).

Thus, however complicated a network may be, and however numerous its meshes, a transformation (24) will give the complete set of equivalent networks. Some of the networks of this infinite set may contain negative as well as positive elements. To obtain networks with only positive elements, it is necessary that the transformation matrix be such that the elements in the main diagonal of the transformed matrix are positive and greater than the corresponding non-diagonal elements.

The infinite group of networks with all three kinds of network elements, namely, inductance, resistance and capacity elements, which have the same impedance function, are obtained exactly in the same manner. Now, however, the transformations are

$$i_1 = i_1' \quad (28a)$$

$$i_2 = a_{21}i_1' + a_{22}i_2'$$

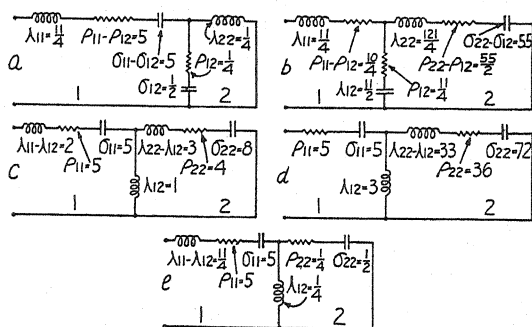

$$q_1 = q_1'$$

$$q_2 = a_{21}q_1' + a_{22}q_2' \quad (28b)$$

and we will have three matrices representing a network instead of two. Fig. 3 shows some of the members of the group of networks having the impedance function

$$Z(p) = \frac{11p^4 + 32p^3 + 64p^2 + 60p + 40}{p(4p^2 + 4p + 8)}. \quad (29)$$

As before, the number of arbitrary constants, namely a_{21} and a_{22} , tells us the number of network elements which may be eliminated from the network without disturbing the invariance of the impedance function. Thus, for the two-mesh network containing three kinds of elements, the minimal forms will have, in general, seven elements.

Some members of the group of networks having

$$Z(p) = \frac{11p^4 + 32p^3 + 64p^2 + 60p + 40}{p(4p^2 + 4p + 8)}.$$

Fig. 3.

For the general case, then, of networks of any number of meshes containing all three kinds of network elements, namely, inductance, resistance and elastance elements, we have the following three matrices which represent or definitely fix the network.

$$\begin{bmatrix} \lambda_{11} & \lambda_{12} & \cdots & \lambda_{1n} \\ \lambda_{12} & & & \vdots \\ \vdots & & & \vdots \\ \lambda_{1n} & \cdots & \cdots & \lambda_{nn} \end{bmatrix}, \begin{bmatrix} \rho_{11} & \rho_{12} & \cdots & \rho_{1n} \\ \rho_{12} & & & \vdots \\ \vdots & & & \vdots \\ \rho_{1n} & \cdots & \cdots & \rho_{nn} \end{bmatrix}, \begin{bmatrix} \sigma_{1n} & \sigma_{12} & \cdots & \sigma_{1n} \\ \sigma_{12} & & & \vdots \\ \vdots & & & \vdots \\ \sigma_{1n} & \cdots & \cdots & \sigma_{nn} \end{bmatrix} \quad (30)$$

Making the following linear transformations of the instantaneous mesh currents or charges in the network, we have

$$\left. \begin{aligned} i_1 &= i_1' \\ i_2 &= a_{21}i_1' + a_{22}i_2' + \cdots + a_{2n}i_n' \\ &\vdots \\ i_n &= a_{n1}i_1' + a_{n2}i_2' + \cdots + a_{nn}i_n' \end{aligned} \right\} \quad (31a)$$

for the currents, and

$$\begin{aligned}
 q_1 &= q_1' \\
 q_2 &= a_{21}q_1' + a_{22}q_2' + \cdots + a_{2n}q_n' \\
 &\vdots \\
 q_n &= a_{n1}q_1' + a_{n2}q_2' + \cdots + a_{nn}q_n'
 \end{aligned} \tag{31b}$$

for the charges.

The three fundamental forms of the electric network of n meshes, whose coefficients are determined from the three matrices (31), are, respectively,

$$T = \frac{1}{2} \sum_1^n \lambda_{jk} i_j i_k \tag{32a}$$

$$F = \frac{1}{2} \sum_1^n \rho_{jk} i_j i_k \tag{32b}$$

$$V = \frac{1}{2} \sum_1^n \sigma_{jk} q_j q_k. \tag{32c}$$

The substitution of the transformations (31) in (32), results in three new quadratic forms, namely,

$$T' = \frac{1}{2} \sum_1^n \lambda_{jk}' i_j' i_k' \tag{33a}$$

$$F' = \frac{1}{2} \sum_1^n \rho_{jk}' i_j' i_k' \tag{33b}$$

$$V' = \frac{1}{2} \sum_1^n \sigma_{jk}' q_j' q_k'. \tag{33c}$$

The coefficients of these new quadratic forms, λ_{jk}' , ρ_{jk}' and σ_{jk}' will of course be functions of the elements of the matrices (30) of the original quadratic forms (32) and of the a coefficients of the transformations (31). This has already been noted in the previous two-mesh example.

The transformation matrix, which contains the coefficients of the transformations (31) may be written

$$C = \begin{vmatrix} 1 & 0 & \cdots & 0 \\ a_{21} & & & \\ \vdots & & & \\ \vdots & & & \\ a_{n1} & \cdots & a_{nn} \end{vmatrix} \tag{34}$$

The matrices containing the coefficients of the new quadratic forms (33) are of course

$$\begin{vmatrix} \lambda_{11}' & \cdots & \lambda_{1n}' \\ \vdots & & \vdots \\ \lambda_{1n}' & \cdots & \lambda_{nn}' \end{vmatrix}, \quad \begin{vmatrix} \rho_{11}' & \cdots & \rho_{1n}' \\ \vdots & & \vdots \\ \rho_{1n}' & \cdots & \rho_{nn}' \end{vmatrix}, \quad \begin{vmatrix} \sigma_{11}' & \cdots & \sigma_{1n}' \\ \vdots & & \vdots \\ \sigma_{1n}' & \cdots & \sigma_{nn}' \end{vmatrix}. \tag{35}$$

These matrices contain the complete infinite group of networks having for an impedance function the impedance of the network of (30). The impedance function is thus an *absolute* invariant to a linear transformation of the instantaneous currents or charges of the networks in which the indicial current and corresponding charge are kept invariant.⁶ The matrices (35) include within them the matrices (30), which are obtained by the *identity* transformation, namely,

⁶ See also the Appendix.

$$\begin{aligned}
 i_1 &= i_1' \\
 i_2 &= i_2' \\
 i_3 &= i_3' \\
 &\vdots \\
 i_n &= i_n'
 \end{aligned} \tag{36}$$

The C matrix corresponding to this transformation is the *identity* matrix

$$\begin{vmatrix} 1 & \cdot & \cdot & \cdot & \cdot & \cdot & 0 \\ 0 & 1 & & & & & \cdot \\ & & 1 & & & & \cdot \\ \cdot & & & \cdot & & & \cdot \\ \cdot & & & & \cdot & & \cdot \\ \cdot & & & & & \cdot & \cdot \\ 0 & \cdot & \cdot & \cdot & \cdot & \cdot & 1 \end{vmatrix} \tag{37}$$

As in the two-mesh example, the actual substitution of the transformations (31) in the quadratic forms can be avoided by making use of the transformation theorem (24). Thus, the tensors (35) are obtained from the matrices (30), and the transformation matrix C (34) by the following matrix multiplications:

$$\begin{vmatrix} 1 & a_{21} & \cdot & \cdot & a_{n1} \\ 0 & a_{22} & & & \cdot \\ \cdot & \cdot & & & \cdot \\ \cdot & \cdot & & & \cdot \\ 0 & a_{2n} & \cdot & \cdot & a_{nn} \end{vmatrix} \times \begin{vmatrix} \lambda_{11} & \cdot & \cdot & \cdot & \lambda_{1n} \\ \cdot & & & & \cdot \\ \cdot & & & & \cdot \\ \cdot & & & & \cdot \\ \lambda_{1n} & \cdot & \cdot & \cdot & \lambda_{nn} \end{vmatrix} \times \begin{vmatrix} 1 & 0 & \cdot & \cdot & 0 \\ a_{21} & a_{22} & \cdot & \cdot & a_{2n} \\ \cdot & & & & \cdot \\ \cdot & & & & \cdot \\ a_{n1} & a_{n2} & \cdot & \cdot & a_{nn} \end{vmatrix} \tag{38a}$$

$$\begin{vmatrix} \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \end{vmatrix} \times \begin{vmatrix} \rho_{11} & \cdot & \cdot & \cdot & \rho_{1n} \\ \cdot & & & & \cdot \\ \cdot & & & & \cdot \\ \cdot & & & & \cdot \\ \rho_{1n} & \cdot & \cdot & \cdot & \rho_{nn} \end{vmatrix} \times \begin{vmatrix} \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \end{vmatrix} \tag{38b}$$

$$\begin{vmatrix} \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \end{vmatrix} \times \begin{vmatrix} \sigma_{11} & \cdot & \cdot & \cdot & \sigma_{1n} \\ \cdot & & & & \cdot \\ \cdot & & & & \cdot \\ \cdot & & & & \cdot \\ \sigma_{1n} & \cdot & \cdot & \cdot & \sigma_{nn} \end{vmatrix} \times \begin{vmatrix} \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \end{vmatrix} \tag{38c}$$

The result of the matrix multiplications will be the three tensors (35) where the elements λ' , ρ' and σ' are expressed in terms of the elements of the given network, λ , ρ and σ , and the elements a of the transformation matrix C (34).⁷

⁷ The expressions for λ' , ρ' and σ' in terms of λ , ρ and σ and the elements a of the transformation matrix C may be expressed by the following summations:

$$\begin{aligned}
 \lambda_{ik}' &= \sum_{r,s=1}^n a_{ri} a_{sk} \lambda_{rs} \\
 \rho_{ik}' &= \sum_{r,s=1}^n a_{ri} a_{sk} \rho_{rs} \\
 \sigma_{ik}' &= \sum_{r,s=1}^n a_{ri} a_{sk} \sigma_{rs}
 \end{aligned}$$

where the summation may be carried out in any order.

I am indebted to Professor E. A. Guillemin for these compact expressions which give the transformed parameters directly in terms of the given parameters and the elements of the transformation matrix.

The above network transformations have been made for the purpose of preserving the invariance of the *driving-point* impedance function. These transformations need not be so limited. Transformations may be made whereby the invariance of the transfer-impedance function is preserved. This gives rise to a new notion of equivalence, namely, equivalence with respect to a *definite mesh*.

It has been noted that the number of arbitrary constants in the transformation matrix determined the number of elements which could be eliminated from the network without disturbing the invariance of the impedance function. Thus, the least number of elements necessary in any network to realize a definite driving-point impedance function, or a definite transfer-impedance function, can be readily determined. This is important because one can tell whether a communication network of any number of meshes has superfluous elements.

Instead of imposing conditions on the a coefficients of the transformation to give minimal networks, it may be possible to obtain equivalence with respect to more than one mesh in a network; that is, to make the instantaneous currents in both the k -mesh and r -mesh, for example, invariant for the complete infinite group of networks. Finally, we may obtain equivalence with respect to, say, j -meshes, by using a still more general transformation.

In the foregoing theory, we have limited ourselves to networks of a finite number of meshes, that is, to networks with n degrees of freedom. There is no reason physically why this theory cannot be applied to networks of an infinite number of meshes, that is, an infinite number of degrees of freedom. Here interesting problems arise which bear intimately on mathematical theory, acoustics, electromagnetic wave theory, elastic waves,—in short, all branches of physics involving oscillations. This is also true for the finite problem, since the theory explained above can be applied to any physical vibrational problem involving a finite number of degrees of freedom, not merely to electric circuit theory. The latter province, however, appears to offer the most fertile soil for further investigation, and to provide a physical picture of the phenomena which occur.

In the problem involving networks with an infinite number of degrees of freedom, we have to deal with matrices and tensors containing an infinite number of elements as well as with quadratic forms which are power series or integrals. The matrices containing the coefficients of the three fundamental quadratic forms will contain an infinite number of elements, as will the transformation matrix and the resulting tensors. But for a physical network of an infinite number of degrees of freedom, we know physically that the total instantaneous magnetic energy, the total instantaneous electrostatic energy and the total instantaneous power lost, are finite quantities. Hence the three fundamental quadratic forms, which are now power series or integrals, are properly convergent. Likewise, the linear transformations, which are linear forms of an infinite number of terms, have meaning, as have the infinite transformation matrices which contain the coefficients of the transformations. Finally, the resulting tensors, which contain an infinite number of elements

have physical meaning. They represent the complete infinite group of networks of an infinite number of degrees of freedom, discrete or continuous systems, which are equivalent in one or all the ways defined above.

The network with an infinite number of degrees of freedom may be merely a continuous system such as the smooth transmission or communication line. Thus, not only may there be an infinite number of different terminal networks which may perform the same function in a communication or transmission system, but also an infinite number of communication or transmission lines, which likewise may perform the same function. That is, there exists an infinite group of lines all of which have the same impedance function.

It will be recalled that this investigation has considered essentially two-terminal networks. By the principle of superposition, it should be possible to extend the theory to networks of any number of terminals. This extension is important, since by means of it any section of a communication network can be removed and replaced by an equivalent section.

In conclusion, it may be useful to suggest problems for further investigation. First, it should be mentioned that the conception that networks form a group in which the impedance is an invariant may prove useful in simplifying many problems in network theory. Thus, for example, the solution for the instantaneous currents of a network of the group at once results in the solutions for the instantaneous currents of all of the infinite number of networks in the group, since these currents are obtained from the former by a simple linear transformation. Furthermore, the solution for the instantaneous currents in one network in the group may be much simpler than for another; and there may be one network in the group for which the computations are least complicated. Hence, if it is necessary to obtain currents and voltages in one network, it may be simpler first to transform the network to an equivalent one, for which the computations are much simpler. This is already recognized, for example, when we transform from Y to Δ and vice versa in three-phase alternating-current network problems. Thus it is probable that simplification may result in operational circuit analysis by the above method.

It should be noted that in the matrix multiplication which gives the tensor containing the complete infinite group of equivalent networks, the impedance function vanishes from the scene. This suggests the possibility that the notion of the impedance function, which is a special creation of the electrical engineer, may perhaps disappear in the future. What we have to deal with are networks, currents and energies; and while the impedance function may be helpful for visualization, it may not be necessary to obtain the final important results.

As has been indicated, the problem of currents and charges in an electrical network is identical with the problem of velocities and displacements in a dynamical system. Although this is generally recognized, there is much in classical dynamic theory that remains to be translated in appropriate language for electric circuit theory. Many questions suggest themselves. What in electric circuit theory corresponds to the principal or normal coordinates in dynamic theory? Is it possible to eliminate the cross product terms in the

fundamental quadratic forms of the electric circuit, thereby giving expressions which are sums of squares of the currents or charges? If it is, can a physical network be built which realizes this?

Problems of networks with an infinite number of degrees of freedom, equivalence with respect to transfer-impedance, equivalence with respect to more than one mesh, networks with more than two terminals—these have been merely intimated. Furthermore, it appears that mathematics does not discriminate against negative network elements, which seems to indicate that perhaps they may be realized physically, though not, of course, by coils, resistors and condensers.

Finally, in the study of an electrical network and its response to an impressed electromotive force, one continually encounters many seemingly unrelated branches of mathematics, such as (1) continued fractions, (2) Cauchy residue theory, (3) asymptotic series, (4) fractional and irrational derivatives and integrals, (5) group theory, (6) Fourier series and transforms, (7) integral equations, etc. It seems almost as if something were there, inarticulately trying to make itself understood. But perhaps it must await a modern Euler.

ACKNOWLEDGMENT

The author wishes to acknowledge his gratitude to Professors E. A. Guillemin and D. J. Struik for their interest and encouragement in the preparation of his thesis of which this paper is a part; to Professor V. Bush for his valuable criticism; and to R. M. Foster for his "A Reactance Theorem"⁸ and "Theorems Regarding the Driving-Point Impedance of Two-Mesh Networks";⁹ and to W. Cauer for his "Die Verwirklichung von Wechselstromwiderständen vorgeschriebener Frequenzabhängigkeit"¹⁰ and "Vierpole."¹¹

APPENDIX

Consider the pair of quadratic forms representing, respectively, the inductance and resistance quadratic forms of an n -mesh network containing inductance and resistance elements:

$$\phi(i_1 \cdots i_n) = \sum_1^n \lambda_{jk} i_j i_k \quad (39a)$$

$$\psi(i_1 \cdots i_n) = \sum_1^n \rho_{jk} i_j i_k \quad (39b)$$

and form the pencil of quadratic forms

$$\phi p + \psi = \sum_1^n (\lambda_{jk} p + \rho_{jk}) i_j i_k. \quad (40)$$

The discriminant of this pencil is the determinant of the network:

$$D(p) = \begin{vmatrix} \lambda_{11}p + \rho_{11} & \cdots & \lambda_{1n}p + \rho_{1n} \\ \lambda_{1n}p + \rho_{1n} & \cdots & \lambda_{nn}p + \rho_{nn} \end{vmatrix} \quad (41)$$

This is a polynomial which is in general of degree n and may be written

⁸ Bell System Technical Journal, vol. 3, 1924,

⁹ *Ibid.*

¹⁰ Archiv. für Elektrotechnik, Heft 4, Band 17, 1926.

¹¹ Elektrischen Nachrichtentechnik, Heft 7, Band 6, 1929.

$$D(p) = \Delta(\lambda)p^n + \Delta(\lambda, \rho)p^{n-1} + \Delta_2(\lambda, \rho)p^{n-2} + \cdots + \Delta_2(\rho, \lambda)p^2 + \Delta_1(\rho, \lambda)p + \Delta(\rho) \quad (42)$$

where $\Delta(\lambda)$ and $\Delta(\rho)$ are the discriminants of ϕ and ψ respectively, while $\Delta_k(\lambda, \rho)$ is the sum of the different determinants which can be formed by replacing k columns of the discriminant of ϕ by the corresponding columns of the discriminant of ψ .

Likewise, form the first minor of $D(p)$, namely,

$$M_{11}(p) = \begin{vmatrix} \lambda_{22}p + \rho_{22} & \cdots & \lambda_{2n}p + \rho_{2n} \\ \vdots & & \vdots \\ \lambda_{n2}p + \rho_{n2} & \cdots & \lambda_{nn}p + \rho_{nn} \end{vmatrix}. \quad (43)$$

This may be written as a polynomial in general of degree $n-1$, namely,

$$M_{11}(p) = M_{11}(\lambda)p^{n-1} + M_{11}^{(1)}(\lambda, \rho)p^{n-2} + \cdots + M_{11}^{(1)}(\rho, \lambda)p + M_{11}(\rho) \quad (44)$$

Now it can be shown that the coefficients $\Delta(\lambda) \cdots \Delta(\lambda, \rho) \cdots \Delta(\rho)$ of $D(p)$ are integral rational invariants of weight two of the pair of quadratic forms ϕ and ψ .¹² Similarly, the coefficients $M_{11}(\lambda) \cdots M_{11}^k(\lambda, \rho) \cdots M_{11}(\rho)$ are integral rational invariants of weight two. Thus it is that the linear transformations of the variables of the quadratic forms make the impedance function $Z(p)$, which is the ratio of $D(p)$ and $M_{11}(p)$; that is, the ratio of two relative invariants of the same weight, an absolute invariant. The foregoing is true also of n -mesh networks containing all three kinds of elements, where we now have in addition to the inductance and resistance quadratic forms, the elastance quadratic form. Thus

$$Z(p) = D(p)/M_{11}(p) \quad (45)$$

becomes under a linear transformation with matrix

$$\begin{vmatrix} 1 & 0 & \cdots & 0 \\ a_{21} & \cdots & a_{2n} \\ \vdots & & \vdots \\ a_{n1} & \cdots & a_{nn} \end{vmatrix} \quad (46)$$

$$Z(p) = \frac{\begin{vmatrix} 1 & 0 & \cdots & 0 \\ a_{21} & \cdots & a_{2n} \\ \vdots & & \vdots \\ a_{n1} & \cdots & a_{nn} \end{vmatrix}^2}{\begin{vmatrix} a_{22} & \cdots & a_{2n} \\ \vdots & & \vdots \\ a_{n2} & \cdots & a_{nn} \end{vmatrix}^2} \times \frac{D(p)}{M_{11}(p)} \quad (47)$$

$$= D(p)/M_{11}(p).$$

ACCOMMODATION COEFFICIENTS OF POSITIVE IONS OF ARGON, NEON AND HELIUM

By

C. C. VAN VOORHIS, PRINCETON UNIVERSITY

AND

K. T. COMPTON, MASSACHUSETTS INSTITUTE OF TECHNOLOGY

(Received April 23, 1931)

ABSTRACT

Positive ions of argon, neon and helium produced in a low voltage arc were attracted to a spherical metal collector by regulated potentials up to 140 volts. The resulting heating of the collector was measured by a thermal junction and found to be *considerably less* than the product of the current by the attracting voltage. After taking account of the energy scattering at collisions and of the effect of the secondary electron emission, the following values of the "accommodation coefficients" were obtained: argon 0.75 ± 0.05 , neon 0.65 ± 0.05 (both between 21 and 141 volts), and helium 0.35 ± 0.05 between 21 and 51 volts and 0.55 ± 0.05 between 111 and 141 volts.

WHEN an attempt was made to measure the amount of energy ϕ_+ delivered to a metal electrode when a positive ion with no kinetic energy is neutralized at its surface,¹ collisions between the ions and neutral molecules within the sheath, and comparatively large electron currents were thought to be the principal factors complicating the calculation and interpretation of the results. By making measurements of the heat generated when positive ions were drawn to the collector by fields so large that practically no electrons could reach the collector, and by working with such low gas pressures that very few ions would make collisions within the sheath it was later believed possible to make these complicating factors negligibly small. Under these conditions, since the positive ions reaching the collector are believed to start at or near the sheath edge with only a negligibly small velocity,² ϕ_+ should be easily obtained from the observed heating of the collector at two different negative potentials, if due allowance were made for the kinetic energy of the ions acquired in passing through the sheath. Thus the heating effect H of a current of magnitude j^+ at a given accelerating potential V with respect to the space potential would be

$$H = j^+(V + \phi_+) \quad (1)$$

and the difference between the heating effects at two different accelerating potentials V_f and V_0 would be given by

$$H_f - H_0 = j_f^+(V_f + \phi_+) - j_0^+(V_0 + \phi_+) \quad (2)$$

whence

¹ Van Voorhis, Phys. Rev. 30, 318 (1927).

² Tonks and Langmuir, Phys. Rev. 34, 876 (1929).

$$\phi_+ = \frac{(H_f - H_0) - (j_f^+ V_f - j_0^+ V_0)}{j_f^+ - j_0^+} \quad (3)$$

All of the quantities on the right side of Eq. (3) could then be obtained experimentally by means of our apparatus.

However, the results obtained from the application of this line of reasoning led to the surprising discovery that the heat produced by the positive ions striking a collector and being neutralized at its surface, is *much less* than the equivalent of the kinetic energy which they should acquire from the attracting field. Though this deficiency in heating effect has recently been observed by Found³ and Güntherschulze,⁴ they have ascribed it entirely to the effect which a large secondary electron emission would have upon the apparent and true values of the positive ion currents, and thus have assumed that the effect is only apparent and not real.

Careful measurements over a considerable range of accelerating potentials and gas pressures in argon, neon and helium have led us to conclude that the deficiency in heating effect in these gases is entirely too large to be accounted for by secondary electron emission and consequently at least some of the neutral molecules and metastable atoms formed by the neutralization of the positive ions at a metal surface must have left it with energies much larger than would correspond to the temperature of the metal. This means that positive ions with fairly high velocities may be considered as having accommodation coefficients less than unity just as the gas molecules have at much lower velocities or temperatures.⁵

Some of our measurements have been made under gas pressure conditions such that the effects of collisions of ions with gas molecules within the sheath are no longer negligible; but when these results have been corrected by the use of Runge's⁶ theoretical values for the scattering of ion energy by collisions with neutral molecules, they become, in general, fairly consistent with those obtained at the lower gas pressures and may therefore be used in testing collision theories.

EXPERIMENTAL PROCEDURE AND CALCULATION OF RESULTS

The observations were taken with apparatus of the same type as was described in detail in the earlier paper.¹ A schematic sketch of the parts in the discharge tube and of the electrical connections is given in Fig. 1. A low voltage arc was maintained between the hot tungsten filament *F* and the anode *A* by applying a voltage from the battery *B*₂, this voltage being from 5 to 10 volts higher than the ionizing potential of the gas in use. The collector *C* was a metal sphere in which was imbedded a very small copper-constantan

thermocouple. In the measurements with argon and neon the collector was of molybdenum, 3.1 mm in diameter and with helium it was a 3.0 mm platinum sphere.

The gases were carefully purified by arcs between "misch" metal cathodes and iron anodes in glass reservoirs on the vacuum system, before being admitted to the discharge tube. Observations were made on repeated fillings of a given gas until the results from different fillings were quite reproducible, which condition was taken to indicate that no appreciable impurity was coming from the walls or metal parts of the vacuum tight discharge tube.

Of the quantities on the right side of Eq. (3) j_0^+ and j_f^+ were obtained directly from the readings of the Cambridge Universal Test Set used as A_3 in Fig. 1. To obtain V_0 and V_f it was necessary to find V_s , the space potential

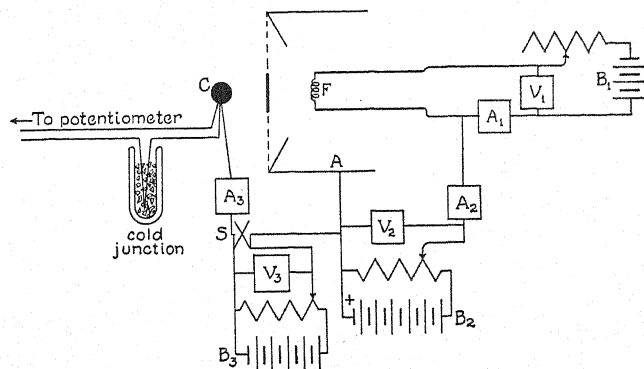

Fig. 1. Schematic sketch of apparatus and arrangement of electrical circuits.

with respect to the anode, by the usual method⁷ and add this to the applied potentials as given by V_3 (Fig. 1). The quantity $H_f - H_0$ was obtained from the product of the heat capacity Q of the collecting sphere C and the rate of temperature change dT/dt of C immediately after its potential was changed from V_0 to V_f . Since the temperature, starting at T_0 when $t=0$, approached a final limiting value exponentially,

$$T - T_0 = (T_f - T_0)(1 - e^{-at}) \quad (4)$$

where T was the temperature at time t , e the Naperian base and a a constant dependent upon the existing experimental conditions. Then it follows from (4) that

$$\left(\frac{dT}{dt}\right)_{t=0} = a(T_f - T_0), \text{ where } a = \frac{2.303}{t} \log_{10} \left(\frac{T_f - T_0}{T_f - T}\right) \quad (5)$$

The data for calculating a were obtained by first noting the electromotive force mV_0 of the thermocouple after the potential of the collector had been

⁷ Langmuir, Gen. Elec. Rev. 26, 731 (1923); Science 58, 290 (1923); Jour. Frank. Inst. 196, 751 (1923); Langmuir and Mott-Smith, Gen. Elec. Rev. 27, 449, 538, 616, 762, 810 (1924).

held at V_0 long enough for it to reach a steady temperature. Then simultaneously the collector potential was changed to V_f and two stop watches started. As the temperature of the collector changed, the drum of the potentiometer was slowly turned so as to keep the galvanometer deflection as near zero as possible. At some instant when the deflection was exactly zero one watch was stopped and its time t_1 and the corresponding mV_1 were recorded, after which mV_2 was noted in the same way for time t_2 obtained by means of the second watch. As soon as the temperature became practically constant, which was generally about 5 minutes after t_0 , record was made of mV_f . From these data two values of a could be calculated and their mean \bar{a} was used in applying Eq. (5).

In Table I are given typical sets of observations and the resulting quantities obtained from various steps in the calculations. To obtain the tempera-

ture differences given in column 5 the corresponding millivolt differences obtained from column 4 were divided by the millivolt differences per degree, of the electromotive force of the thermocouple at the corresponding temperatures. The temperatures and corresponding millivolt differences per degree were readily determined from two curves obtained by plotting against temperature on a large piece of graph paper, the values of mV and $d(mV)/dT$ calculated at 20° intervals from the calibration equation of the thermocouple, $mV_T = 0.0400766T + 0.00004344T^2 - 0.00000002244T^3$.

In column 7 the values of Q are the heat capacities in millijoules per degree for the corresponding mean temperatures. In column 8, MH is the measured heating effect in milliwatts obtained from the observations and calculations, whereas EH is the expected heating on the assumption that all of the kinetic energy gained by the ions from the accelerating field would be delivered to the collector in the form of heat, ϕ_+ being neglected for the present. Thus the value of EH is found from the equation

$$EH = j_f^+(V_f + V_s) - j_0^+(V_0 + V_s). \quad (6)$$

In Tables II, III and IV are given the results obtained in argon, neon and

helium respectively. Column 1 of these tables gives the gas pressure and the assumed positive ion mean free path obtained by taking $2^{1/2}$ times the kinetic theory value for the neutral atoms at the temperature in the discharge tube. In column 2 are given the values of the applied potentials (with respect to the space) after slight adjustment to make the voltage intervals exactly 30 volts, the actual intervals used ranging between 29 and 31 volts since the po-

tential change was made by suddenly changing the position of the slider of a slide wire potential divider and the interval could not be exactly duplicated. The values of the measured currents in column 3 are adjusted to correspond to the potentials given in column 2. These adjustments were deemed advisable in order to shorten the calculations involved in the corrections made as explained later, by making it possible to apply these corrections only to the mean values instead of to each individual result which was obtained under

conditions differing only slightly from those of the three to seven other similar results. However, the values of the ratios of the "measured heating" to the "expected heating" given in column 6 are the means of the four to eight

ratios calculated from the actual observations and are not modified in any way.

In columns 4 and 5 are given values of the collision numbers or the ratios of the sheath thickness S to the mean free path λ . The sheath thicknesses used in column 4 were obtained on the assumption of no collisions within the sheath, i.e., by means of Langmuir's equation,⁸ and Langmuir and Blodgett's⁹ tables, for spherical collectors. The collision numbers in column 5 have been obtained by correcting the sheath thickness for the slowing up of the positive ions by the collisions within the sheath, in accordance with some recent unpublished work of H. P. Robertson and P. M. Morse, assuming that the same fractional shrinkage in thickness takes place in the sheath around the spherical collector as would take place in the sheath of an infinite plane,

Fig. 2. Potential distribution curves, B from space charge equation (no collisions), and S from assumption of kinetic theory collisions between elastic spheres. For the case of a large plane electrode.

for which case the Robertson and Morse calculations have been made. In Fig. 2¹⁰ the solid line gives the distribution of potential for collision numbers up to five and the dashed line the potential distribution for the same sheath thicknesses if there were no collisions. Thus the difference in abscissas of points having the same ordinate on the two curves gives the shrinkage effect resulting from collisions of ions with neutral molecules within the sheath.

In column 6 are given the mean values of MH/EH obtained in the manner described above in connection with Table I. The values given in column 7 were obtained by correcting for the energy so scattered by collisions of the ions with gas molecules within the sheath that it would not be expected to

⁸ Langmuir, Gen. Elec. Rev. 27, 449 (1924).

¹⁰ Published here with the kind permission of Robertson and Morse.

be delivered to the collector. On the assumption of collisions between elastic spheres of equal masses, half of the scattered energy will be delivered to gas molecules on the average, and half will be retained by the ions.¹¹ All of the energy retained by the ions and part of the energy received by the gas molecules will reach the collector and be delivered in full to it if the accommodation coefficient be unity. However, a part of the energy received by the gas molecules will be so directed as to miss the collector, i.e., if collisions take place at a distance PN , Fig. 3, from the spherical collector no neutral molecules receiving velocities directed at an angle from the normal PN greater

Fig. 3.

than the grazing angle θ will deliver any of their energy to the collector (except as the result of further collisions, and it is assumed that this would just balance the loss of energy from within the grazing angle, resulting from the same cause).

To calculate the fraction of energy, called hereafter $F(E)$, which should not be expected to reach the collector, Runge's³ theoretical results were used in the following way. Values of $R \sin \theta$ (from Runge's Fig. 3) were plotted as ordinates against θ , R being the energy radius vector and θ the angle with

the direction of the electric field, i.e., with the direction of the energy at the time of the first collision. We then integrated with a planimeter the areas bounded by the zero ordinate, the curves and the 10° interval abscissa lines and from the integrated values found the $F(E)$ directed outside of given grazing angles after from 1 to 5 collisions. The results thus obtained are given in Table V and plotted in Fig. 4, which has also a plot of the grazing angles from points up to 2 mm distant from our 3.1 mm diameter collector.

Fig. 4. Curves 1, 2, 3, 4 and 5 show fractions of energy directed outside of given angles with the field direction after from 1 to 5 collisions respectively. Curve 6 is a plot of grazing angle against distance from the 3.1 mm collector.

In applying these results we have followed Runge's assumption that it is legitimate to take account of the scattering of the total energy gained in the whole field between sheath edge and collector by considering piecemeal the energy gained in each λ of distance and the scattering of this energy at subsequent collisions on the way to the collector and then taking the sum of the residual energies at the collector as being the total effective applied potential. Thus, for example, in argon at 0.25 mm pressure (see Table II) with 111.3 volts applied potential the collision number was 1.87 and with 141.3 volts it was 2.14. To calculate the effective potentials (hereafter called EP) it was necessary to obtain from the curves in Fig. 4 the grazing angles recorded in column 2, Table VI, corresponding to the distances from the collector given

in column 1 and the $F(E)$'s directed outside of these grazing angles after collisions, as tabulated in columns 3, 4 and 5 of the same table. Then the potentials with respect to the sheath edge at the various integral λ distances from the collector were obtained from the solid potential distribution curve of Fig. 2, the potentials found being tabulated in columns 6 and 7 of Table IV, whose columns 8 and 9 give the potential differences for the whole λ 's and the outside fraction of λ and also, in parentheses, the EP 's found by applying the values given in columns 3, 4 and 5 to the potential differences given in 8 and 9 in the following way.

TABLE VI. Quantities involved in the illustrative example of the calculation of the effective potentials.

1	2	3	4	5	6	7	8	9

1.14 λ	46.8	.224	.457				56.6	(33.3)
1.87 λ	38.5	.376				0.0	(46.6)	
2.00 λ	37.4	.397			3.6		3.6	
2.14 λ	36.2	.422			0.0		(2.5)	

Consider first the potential difference in the first λ distance from the collector. On the assumption that collisions are equally probable all along the path but that all the ions collide once and only once in the distance λ , calculations based on a ten-step division of the first λ for several values of λ , and the resulting potential distributions and energy directions as obtained from the application of the curves in Figs. 2 and 4, showed that the total $F(E)$ received by neutral molecules so directed as to miss the collector is given very accurately by $1/9$ the $F(E)$ lost to such molecules at collisions at a point 0.5λ from the collector. Consequently 81.1 $(1 - .075/9)$ or 80.4 and 71.8 $(1 - 0.075/9)$ or 71.2 are the EP differences in the first λ of our examples. For the fractional loss of the energy applied in the second λ , if the $F(E)$ curve for first collision and the potential distribution curve were straight lines we would take 0.5×0.5 the mean of the fractions at λ and 2λ , the one 0.5 factor to give the mean applied potential between λ and 2λ and the other 0.5 factor to take account of the fact that only half of this $F(E)$ is carried by molecules. However, here again ten-step calculations showed that the factor $1/9$ should be used instead of $1/8$ because of the curvature of the above mentioned curves. For the fractional loss in a given λ of the energy gained outside this λ the fraction $\frac{1}{4}$ was used because the $F(E)$ curves for more than one collision do not differ so greatly from a straight line. Consequently $56.6 [1 - (0.397 + 0.205)/9]$ $[1 - (0.434 + 0.043)/4]$ or 46.6 was found to be the EP in the second λ of our 141.3 volt case. To obtain the effective part of the potential applied in

the outer fractional λ part of the sheath a slightly different method of calculation was used as will appear from the following examples:

$$3.6 \left[1 - \frac{0.14}{9}(0.422 + 0.397) - \frac{0.86}{4}(0.397 + 0.224) \right] = 3.07$$

$$3.07 \left(1 - \frac{0.457 + 0.137}{4} \right) \left[1 - \frac{0.14}{4}(0.25 + 0.12) \right] = 2.5$$

and

$$39.5 \left[1 - \frac{0.87}{9}(0.376 + 0.205) - \frac{0.13}{4}(0.205 + 0.169) \right] = 36.8$$

$$36.8 \left[1 - \frac{0.87}{4}(0.399 + 0.043) \right] = 33.3$$

Thus the total *EP*'s whose energy may be expected to reach the collector are 129.5 and 104.5 volts instead of the actually applied voltages 141.3 and 111.3 respectively, and the use of the former instead of the latter to calculate the expected heating changed the ratio of *MH* to *EH* from 0.67 to 0.77. By this method of correcting for the amount of energy to be expected to reach the collector all the results tabulated in column 7 of Tables II, III and IV were obtained.

When, instead of using the assumption that $\phi_+ = 0$, the Schottky¹² assumption that $\phi_+ = V_i - \phi_-$, where V_i is the ionizing potential of the gas, is taken into account the results are changed from the values of column 7 to those of column 8 (Tables II, III and IV).

After our experimental tube had been set up and most of the data taken, there came to our attention the work of Oliphant¹³ and of Uytterhoeven and Harrington¹⁴ which showed the presence of a fairly large secondary electron emission from negative collectors under conditions somewhat similar to ours. The effect of the secondary electrons would be to make the heating of the collector less than would be expected if all the measured current were carried by positive ions. Since we were not able to measure the secondary emission from the collector directly, although measurements made with an auxiliary Mo plate and Ni collector (added to the discharge tube for this special purpose and not shown in Fig. 1) similar to those used by Uytterhoeven and Harrington¹⁴ showed less than 1 percent secondary emission from the plate under the conditions of our experiments in argon and less than 2 percent in neon (no measurements being made in helium) we have thought it best to show what would be the effect upon our results of secondary electron emissions of about the same magnitude as reported by these investigators. In accordance with Found's suggestion that for different negative collector potentials, other discharge tube conditions remaining the same, the positive ion currents to the collector should be proportional to the sheath areas while the secondary elec-

¹² Schottky, Ann. d. Physik **62**, 143 (1920).

¹³ Oliphant, Proc. Roy. Soc. **124A**, 228 (1929); **127A**, 373 (1930).

¹⁴ Uytterhoeven and Harrington, Phys. Rev. **36**, 709 (1930).

tron emission, since chiefly due to metastable atoms, should remain practically constant, we found by the trial and error method, values of positive currents quite accurately proportional to the sheath areas (recalculated for these smaller currents) when we subtracted some certain constant value from our measured collector currents, these constant values being in general fairly reasonable ones for the secondary electron current when compared with Oliphant's,¹³ and Uytterhoeven and Harrington's¹⁴ results. In column 9 of Tables II, III and IV are tabulated the current values obtained in this way. The value followed by a negative sign and recorded between the first and second positive values is the assumed value of the secondary electron emission for the given discharge condition, since it was the necessary constant amount to be subtracted from the measured currents to give positive ion currents proportional to the corrected sheath areas. The last two positive ion current values in argon are slightly higher than they should be on this theory but this could be accounted for by the fact that under the existing conditions the secondary electrons would produce an appreciable amount of ionization within the sheath. To obtain results consistent with those for the higher accelerating voltages some of the measured currents in neon and helium for the lowest potentials used (about 21 volts) had to be increased by from 1 to 12 percent, amounts practically the same as those obtained by extrapolating the plots of the logarithm of the current against applied voltage, used in determining space potentials, and thus may be ascribed to the fraction of electrons having random energies greater than about 21 volts. The current values marked with a superscript *c* in column 3 are the ones so corrected.

The calculations made as for the results given in columns 7 and 8, Tables II, III and IV but using the positive ion currents given in column 9 instead of those given in column 3 led to the ratios of measured heating to expected heating (or accommodation coefficients) given in columns 10 and 11 for $\phi_+ = 0$ and $\phi_+ = V_i - \phi_-$ respectively.

DISCUSSION OF RESULTS

Of the results given in columns 7, 8, 10 and 11 of Tables, II, III and IV the ones enclosed in parentheses are probably rather inaccurate, the ones with the superscript *E* being uncertain because of poor experimental conditions, the ones with superscript *F* are probably too high because the secondary electron current given by Found's assumption is unreasonably high in this case, and the ones with superscript *H* being probably too high because an assumption used in determining the fraction of energy not to be expected to reach the collector leads to a value for this fraction which is increasingly too high as the mean free paths become shorter, and the collision number increases. The assumption in question is the one given in parenthesis on page 1603 in connection with Fig. 3. Thus the nearer the point *P* is to the collector the greater will be the excess of molecules given direction outside of *PT* when struck by positive ions at *P*, but which later strike the collector as a result of collisions with other molecules, over those going outward across *PT* after being given directions inside *PT* when struck at *P*, since the distances which

the former must go before getting completely away from the collector are considerably greater than the distances the latter must go to reach it.

A study of the remaining values of the results shows that in helium the "accommodation coefficient" (hereafter referred to as A) increases as the positive ions are given higher velocities. This is in accord with the observations of Kingdon and Langmuir¹⁵ that helium ions penetrate to a considerable depth into the metal which they are bombarding, an effect which would increase with increasing energy of the ions. In argon there appears to be no increase in A with increasing energy of the ions and in neon the effect is only very slight and we have neglected it in determining the mean values given for this gas in Table VII.

TABLE VII. Summary of mean values of "accommodation coefficients."

Column	Argon		Neon		Helium	
	Mean	Average variation	Mean	Average variation	21 to 51 V	111 to 141 V
7	0.770	0.023	0.674	0.019	0.40	0.56
8	.725	.029	.591	.038	.20	.47
10	.875	.056	.740	.022	.50	.70
11	.825	.047	.659	.033	.28	.56
Estimate of true value	0.75 ± 0.05		0.65 ± 0.05		0.35 ± 0.05	0.55 ± 0.05

In this table are given the means of the undoubtful values given in columns 7, 8, 10 and 11 of Tables II and III along with the average variations from the means. These average variations from the means are given not because we believe them to be a measure of the absolute accuracy of the results but because they give a concise method of showing the constancy of the results obtained under the four different assumed conditions on which the calculations of the four columns were based.

As judged by constancy, the results in argon would indicate that the actual secondary electron emission from the collector under our experimental conditions in this gas was probably considerably less than the approximately 25 percent given by Found's³ assumption, and thus are in accord with the finding of only about 1 percent by our direct measurements of the emission from the auxiliary plate. Though the assumption of positive ion currents proportional to sheath areas gives in general reasonable values for the secondary electron currents the following considerations indicate that it is probably only an accident that the assumption does give such results. That the positive ion current is *not* controlled by the sheath area as given by the space charge equation but by a much larger volume, is certain. First, it is easily shown that the electrons, which penetrate within such sheaths surrounding our collector, could produce at most only a very small portion of the positive ions which

¹⁵ Kingdon and Langmuir, Phys. Rev. 22, 148 (1923).

are actually observed. Second, recent work of Langmuir,¹⁶ and Tonks and Langmuir² has shown that, whereas most of the potential drop is within these sheaths, the positive ions which are collected are formed within a much larger volume. Hence there is no reason for believing that positive ion currents should be accurately proportional to such sheath areas, and hence the assumptions which underlie columns 10 and 11 of Tables II, III and IV appear to be unjustified. The values and discussion are included principally to illustrate how moderately large secondary electron currents would affect the results, if present.

Though the actual boundary of the region from which positive ions are drawn to the collector, is shown by the above considerations to be far outside of that given by the space charge equation, the latter value is not far from the boundary of the region into which any appreciable number of external electrons penetrate, and the greater part of the potential drop is between this boundary and the collector. Consequently we believe we are justified in using the space charge equation values for the sheath thicknesses in our calculations of the deflections and energy losses at collisions.

By carefully considering the various factors involved and the effect which changes in the assumed values of ϕ_+ and secondary electron emission have upon the results, we arrived at the estimates given for the true values of A for argon, neon and helium positive ions given at the bottom of Table VII. These values are of the same order of magnitude as the values of A found by Knudsen⁵ for cool gases striking a hot filament.

The "Umladung" effect described by Kallmann and Rosen,¹⁷ Penning and Veenemans,¹⁸ and others, i.e., the taking of an electron from a neutral molecule by a positive ion, the now neutralized ion retaining practically all of its kinetic energy and the new ion starting with negligible velocity, would increase the values of A slightly for the conditions giving the larger collision numbers but this effect would probably not be greater than the 0.05 possible error given in our estimates, particularly in argon for in this gas we have values for conditions under which collisions within the sheath are practically negligible.

That the energy given up by positive ions which have been attracted to a metal collector by a field should be less than the total kinetic energy of the ions is to be expected from the explanation of the mechanism of cathode sputtering advanced by Kingdon and Langmuir,¹⁵ and from the observations of Oliphant¹³ and others on the reflection of positive ions and metastable atoms, and the probability of the formation of metastables in the neutralization process. If all of the observed deficiency of energy transfer were due to the formation of metastable atoms all of which left the collector with the velocity of the positive ions from which they were formed, this deficiency would give a measure of the production of metastables in the neutralization

¹⁶ Langmuir, *Phys. Rev.* **33**, 954 (1929).

¹⁷ Kallmann and Rosen, *Zeits. f. Physik* **61**, 61 (1930); **64**, 806 (1930).

¹⁸ Penning and Veenemans, *Zeits. f. Physik* **62**, 746 (1930).

process. However, it is very improbable that the conditions are so simple as this.

velocity of the positive ions from which they are formed, this deficiency would give a measure of the production of metastables in the neutralization process. However, it is very improbable that the conditions are so simple as this.

In conclusion we wish to point out that although there is some uncertainty in the exact values of the accommodation coefficients for argon, neon and helium positive ions as found by us, our measurements seem to show conclusively that they are all considerably less than unity and consequently conclusions which have been reached on the tacit assumption of the unity value need revision to take account of the actual, smaller values.

Since the values of the accommodation coefficient found for neutral molecules⁵ becomes more nearly unity as the molecular weight increases and since the values found by us for ions are of the same general order of magnitude as those found for the neutral molecules, it is suggested tentatively that the values for mercury and other heavy ions are nearly unity. Also the value of A is likely to depend somewhat upon the factors which affect the surface conditions of the metal such as the gas pressure, purity of the gas, roughness of the surface, and kind of metal.

Our thanks are due Mr. Donald C. Archibald for his help in the experimental work of this paper.

PHOTOMETRIC STUDY OF THE APPEARANCE OF
SPECTRAL LINES IN A CONDENSED SPARK

BY H. V. KNORR

MENDENHALL LABORATORY OF PHYSICS, OHIO STATE UNIVERSITY

(Received May 4, 1931)

ABSTRACT

The time interval between the time of appearance in a condensed spark discharge of the arc lines 4678A, 4722A, 4811A ($2^3P_{012} - 2^3S_1$) of zinc, 4680A, 4800A, 5086A ($2^3P_{012} - 2^3S_1$) of cadmium, the air lines 4347A, 4631A and 5001A was measured visually, using the Kerr cell method developed by Beams. A photographic method was developed whereby it was possible to determine from photometric measurements the variation of the intensity of an individual line with the time after the beginning of the spark. The time of first appearance, or zero intensity, is inferred from the extrapolation of the curves showing the intensity as a function of the time. The arc lines of zinc appear simultaneously. The arc lines of cadmium appear simultaneously but definitely earlier than the zinc arc lines. The air lines appear simultaneously but earlier than the arc lines. The spark lines appear simultaneously but earlier than the arc lines and later than the air lines of the respective elements. The results of the visual and photographic methods do not agree. Neither method gives information that in the case of zinc or cadmium, an electron remains in the 2^3S_1 state for a longer time before dropping to the 2^3P_0 state than before dropping to the 2^3P_1 or the 2^3P_2 state.

INTRODUCTION

IN 1925 Beams and Brown,¹ making use of a modified form of the electro-optical shutter of Abraham and Lemoine,² measured the time intervals between the appearance of spectral lines in the spectra of condensed discharges. This early work indicated that in the elements examined, the spark lines appeared before the arc lines. Since the appearance of this first paper, several experimenters^{3,4} have extended the work to other elements. In the elements that were examined in common by various investigators the numerical values for the time difference between the appearance of individual lines did not agree and in some cases the observed order was different. In the case of multiplets, Beams found different lines of the same multiplet appeared at different times, while Locher found that members of a given multiplet appeared simultaneously within the limits of error of the experiment in all cases examined except in the case of the arc triplet of zinc.

The actual existence of these time lags in the appearance of spectral lines has since been questioned by Gaviola.⁵ He believes that the basic assumptions made by the experimenters, namely, that the Kerr cell discharges in-

stantaneously a certain time after the beginning of the spark, that oscillations, if present, have no appreciable effect on the operation of the shutter, and that the capacity in parallel with the spark gap does not modify the time at which the Kerr cell discharges, are incorrect and measurements based on them unreliable.

The purpose of this investigation was to make a comparison of the results obtained by the use of a visual method similar to that employed by other experimenters^{3,4} and the results obtained by use of a photographic method, in which the order of appearance of the spectral lines is inferred from the observations on the way in which the intensity of the individual spectral line

Fig. 1. Diagram of apparatus.

varies with time. By use of the latter method it is possible to eliminate the sensitivity of the eye which is a controlling factor in the visual method. In order that the results might have a possible interpretation as atomic phenomena, the spectral lines, 4678 $2^3P_0 - 2^3S_1$, 4800 $2^3P_1 - 2^3S_1$, 5086 $2^3P_2 - 2^3S_1$, of cadmium and 4680 $2^3P_0 - 2^3S_1$, 4722 $2^3P_1 - 2^3S_1$, 4811 $2^3P_2 - 2^3S_1$, of zinc were selected for the major part of this investigation. In the above triplets the transitions are from the same upper level to different lower levels, so the difference in the length of time that an electron remains in the 2^3S_1 state before the transition takes place to the 2^3P_0 , the 2^3P_1 or the 2^3P_2 state could be measured. In addition to the above lines the spark doublet 5337 $3^2D_{3/2} - 4^2F_{5/2}$, 5378 $3^2D_{5/2} - 4^2F_{7/2}$ of cadmium, the spark doublet 4912 $3^2D_{3/2} - 4^2F_{5/2}$, 4924 $3^2D_{5/2} - 4^2F_{7/2}$ of zinc and the air lines which were excited when the discharge takes place between metallic electrodes in air at atmospheric pressure, were investigated.

APPARATUS AND EXPERIMENTAL METHODS

Fig. 1 gives a diagrammatic representation of the apparatus used in the present experiment. It is essentially the same as that used by previous inves-

tigators. A fixed light path of 14.69 meters was used. A spark gap F with a capacity in parallel was connected across a source of high voltage T_1 . The electro-optical shutter consisting of the two Nicol prisms N_1 and N_2 and the Kerr cell K , was placed between the spark gap and the spectrograph. The source of high voltage was a 25,000 volt 1 KW transformer. Electrodes of various shapes were tried in the spark gap, the shape finally selected being that of the frustrum of a cone, so that the discharge was actually taking place between two circular parallel faces. This type of electrode gave very steady spark conditions over quite long periods of time. The Kerr cell consisted of two parallel brass plates 12 cm long, 1 cm wide and separated at a distance of 3 mm, immersed in carbon disulphide which had been carefully purified. The shutter ordinarily was closed except when sufficient potential was applied to the Kerr cell, then the liquid became doubly refracting and light could pass it.

The circuit FC in Fig. 1 contains the condenser C , a certain amount of inductance in the lead wires, and the spark gap F , hence the discharge of the condenser C through the gap will be oscillatory. The circuit KF contains the Kerr cell, the trolley wires W and the spark gap F , this circuit being directly connected to the circuit FC , so oscillations are undoubtedly present in it. These oscillations if of sufficient amplitude, would reopen the shutter after having closed when the original voltage had fallen to so low a value as to make the shutter inoperative. The discharge of the Kerr cell will not be as sudden as was originally supposed, but its rate of discharge will be determined somewhat from the superposition of the oscillations in the two circuits. The oscillations can be critically damped by insertion of the resistance R_1 , this reducing the rate of fall of voltage on the Kerr cell. Nevertheless it is possible to damp sufficiently these oscillations without delaying the closing time of the shutter appreciably, since it is well established that the relative difference in phase in the components of the ray vibrating parallel and perpendicular to the electric field is given by

$$\theta = 2\pi BLE^2$$

where B is the Kerr constant and θ the phase difference. Now the amount of light passing the prism N_2 at any given instant will be

$$I = A \sin^2 \theta/2 = A \sin^2 (\pi BLE^2).$$

Since the intensity of the light passing the shutter is proportional to the fourth power of the voltage, it is thus possible to damp sufficiently these oscillations and yet not delay the closing time of the shutter. The value of R_2 was found experimentally using a method employed by Lawrence,⁶ that of observing the smallest distances of migration of the metallic vapor from the electrodes. The value of the damping resistance thus found was 2800 ohms (1400 ohms being placed in each lead from the spark gap to the Kerr cell). The effect of this damping resistance was quite evident, for when values of several hundred ohms less than 2800 ohms were used, oscillations were pres-

⁶ Lawrence and Dunnington, Phys. Rev. 35, 396 (1930).

ent, when values of several hundred ohms greater than 2800 ohms were used, a noticeable decrease in the rate of closing of the shutter was observed.

In Fig. 1 the light from the spark gap was rendered approximately parallel by the lens L_1 and was reflected from the concave mirror M_1 , whose focal length was 7 meters, this converging beam was reflected by the right angle prism P through the lens L_2 , the Nicol prism N_1 and focused between the plates of the Kerr cell. The lens L_3 focused the beam after passing through the Nicol prism N_2 on the slit of a constant deviation Gaertner spectrometer, so that the length of the spark was parallel to the slit. A number of diaphragms were placed along the light path and at each end of the Kerr cell so that only light which passed through the Kerr cell between the plates was focused on the slit.

An important modification in the optical path was the introduction of the auxiliary light path $PM_2M_3L_4P_1$, in order to adapt the apparatus to the photographic method. The part of the converging beam which passed the prism P was reflected by the plane mirrors M_2 and M_3 and the right angle prism P_1 and was focused on the slit of the spectrograph by means of the lens L_4 . It was thus possible to have two spectra formed on the plate one directly above the other, the one formed by light which had passed through the Kerr cell and the other formed from the light which came directly from the spark gap. This modification was of utmost importance in the intensity measurements for it was thus possible to determine whether or not the spark conditions had changed appreciably during the time that was necessary to obtain a complete set of exposures.

Visual method. In the visual method in which a fixed light path was used, the time of closing the electro-optical shutter was regulated by changing the effective lengths of the four parallel wires which connect the spark gap with the Kerr cell, by sliding the trolley T along them by means of a string passing over a rather complicated pulley system and operated from the observer's position. When the trolley T is adjusted so that the effective length of wire path is as long as possible the intensity of the line under investigation is at a maximum for this particular time of closing of the shutter. If the position of the trolley is now adjusted so that the length of the wire path is decreased, finally a position is reached where the spectral line is no longer visible; this position of the trolley is noted. In a similar manner when the direction of motion of the trolley is reversed, a point of first appearance of the spectral line is located, which will differ slightly from the first position. The mean of the two positions is taken as the position of first appearance of the line, where the appearance of the line as used here means the position at which the line has become visible through the observing apparatus. The fall of potential produced by the passage of the spark is propagated along the wire to the Kerr cell at approximately the velocity of light,⁷ so that the difference between the times of appearance of two lines is approximately the difference between the lengths of wire as determined above, divided by the velocity of light.

⁷ Fred Allison, Phys. Rev. 30, 66 (1927).

Photographic method. In the photographic method the observing telescope was replaced by a camera attachment converting the spectrometer into a spectrograph. The optical path was modified as previously described. The exposures on the plate were obtained by setting the trolley at a definite position and taking an exposure, then moving the trolley a known distance and taking a second exposure, and so on until five or more exposures had been obtained on each plate. Since the lengths of trolley wire between the spark gap and the Kerr cell correspond to lengths of time after the break down of the

TABLE I. Zinc, cadmium and nitrogen.

The nitrogen lines were obtained by a discharge between zinc electrodes in air. The zinc and cadmium lines were obtained from discharges between electrodes made from the chemically pure metals.

gap, the position of the trolley can be plotted against the intensity of the spectral line and a curve obtained which will show how the intensity of an individual line varies with time. In the present experiment it was possible to obtain spectrograms of the light from the spark beginning at 3.9×10^{-11} seconds after the beginning of the spark to 1.4×10^{-7} seconds after the beginning of the spark, the range being limited by the lengths of wire in the set-up.

Each plate was carefully calibrated by the use of neutral screens.⁸ The calibration curve was obtained by plotting the logarithm of the intensity of the light transmitted by these screens against the reciprocal of the photographic density upon the plate. The reciprocal of the density (the logarithm of the transmission of the plate) was determined from the microphotometer record which was secured from the spectrogram. A Moll microphotometer which records automatically was used. From the measured transmission of the metallic arc and spark lines and the air lines to be investigated, the intensity of the individual lines could be read directly from the calibration curves in arbitrary units.

RESULTS

Results by the visual method. Table I contains the data obtained on the spectral lines which were examined in this experiment. In the case of zinc the order of appearance of the lines obtained in this experiment was the same as that reported by Beams.³ The magnitude obtained for the interval between the first appearance of the spark lines 4912A, 4924A and the arc line 4680A is thirty times smaller than the value obtained by Beams. In cadmium the results for these corresponding lines differ by about the same amount, that is for the interval between the appearance of the spark lines 5337A, 5378A and the first arc line. However the order is not the same, for in this experiment 5086A was observed before 4800A, while Beams observed them in the reverse order. The time intervals between the appearance of the respective arc lines as measured by Beams show somewhat the same magnitude as those determined in this experiment, but the results are still far from agreement. Locher obtained no differences in the times of appearance of the cadmium arc lines.

Results by the photographic method. The data obtained for the arc triplet of zinc 4680A, 4722A, 4811A are plotted in Fig. 2. The intensity which is plotted as the ordinate is expressed in arbitrary units. The lengths of trolley wire, plotted as abscissa, are measured from an arbitrary reference point which corresponds to a time 5×10^{-11} sec., after the beginning of the spark. When the intensity curves for these lines are extrapolated backward they all intersect at a point on the time axis corresponding to a time 1.2×10^{-8} sec., after the beginning of the spark, indicating that the members of this arc triplet appear at the same time. Fig. 3 shows the data on the unresolved air lines 5001A, 5005A, 5007A and 5011A, 4631A, 4347A which were excited when the discharge occurred between zinc electrodes in air at atmospheric pressure. Here as in the case of the metallic arc lines of zinc, when the intensity curve for each of these lines is extrapolated backward to zero intensity, these curves meet at approximately the same point, corresponding to a time 5×10^{-11} sec. after the beginning of the spark. This would indicate that these lines appeared simultaneously, but at a time 1.19×10^{-8} sec. earlier than the metallic arc lines of zinc.

⁸ G. R. Harrison, J.O.S.A. & R.S.I. 18, 492 (1929).

Fig. 4 shows the curves plotted from the data obtained for the arc triplet of cadmium 4678A, 4800A, 5086A. The intensity curves meet at approximately the same point corresponding to a time 0.5×10^{-8} sec., after the beginning of the spark when extrapolated backward to zero intensity, indicating again that the members of this arc triplet all appear at the same time. The time of appearance of the cadmium triplet is 0.7×10^{-8} sec., earlier than the zinc triplet. Fig. 5 shows the data on the air lines 5001A, 5005A, 5007A, 5011A, 4631A, 4347A, which are excited when the discharge takes place between cadmium electrodes in air. When the intensity curve for each of these air lines is extrapolated backward to zero intensity these curves intersect at a point corresponding to the time 5×10^{-11} sec., after the beginning of the spark, which is the same as that obtained for these same air lines which were

Fig. 2. Intensity of zinc arc triplet ($2^3P_{012} - 2^3S_1$).

excited in the zinc spark. This indicates that these air lines just as in the case of zinc all appear at the same time.

In the upper part of Fig. 6 are plotted the data obtained for the unresolved zinc spark doublet 4912A and 4924A, and in the lower part are plotted the data obtained for the cadmium spark doublet 5337A and 5378A. The unresolved zinc doublet extrapolates backward to a point corresponding to 0.5×10^{-8} sec., after the beginning of the spark. The intensity curves for each of the lines of the cadmium doublet, when extrapolated to zero intensity, meet at a point corresponding to a time 0.32×10^{-8} sec., after the beginning of the spark, indicating that each of the members of this spark doublet appeared at the same time. The time of zero intensity or the time of first appearance of

the spark lines is earlier than the arc lines of the same element, but is later than the air lines as shown in Figs. 2, 3, 4, and 5.

DISCUSSION OF RESULTS

The photographic method in the case of the arc triplet of zinc 4680A, 4722A and 4811A, shows that all of these lines appear at the same time. The visual method when applied to this same triplet gives differences between the times of appearance of these same lines. Likewise in the case of the arc triplet of cadmium 4678A, 4800A and 5086A the photographic method gives the same time of appearance for each of these lines, but the visual method gives different times for each line, although the results of different observers using the visual method are not in agreement.

Fig. 3. Intensity of the air lines 5001A, 4631A, and 4347A with zinc spark gap.

The photographic method shows that the air lines 5001A, 5005A, 5007A, and 5011A, 4631A, 4347A whether excited in a zinc or cadmium spark, all appear at the same time, but at a time definitely earlier than the metallic arc lines of the respective element. The visual method on the other hand gives different times of appearance for the individual air lines and it also indicates that the air lines appear before the arc lines in the case of zinc and cadmium. Since in this case the observations were made on groups of lines rather than individual lines, the results are not as convincing as in the case where the observations are made on separate lines.

The photographic method shows that the members of the spark doublet of cadmium 5337A and 5378A appear at the same time and definitely earlier than the metallic arc lines of cadmium, but later than the air lines in the cad-

mium spark. The visual method gave no information on the separate spark lines as it was impossible to resolve them, so the observations were made probably on both lines, the times of appearance being earlier, however, than the arc lines. The result, indicating that the spark lines appeared before the arc lines, is the same for each method. The zinc doublet 4912A and 4924A was unresolved in both the photographic and visual methods so that the data obtained in each case are not satisfactory. However each method shows that this unresolved zinc doublet appears before the zinc arc triplet, hence again the two methods lead to the same result.

There is an evident disagreement between the results obtained by the visual method and those obtained by the photographic method. This diver-

Fig. 4. Intensity of the cadmium arc triplet ($2^3P_{012} - 2^3S_1$).

gence of results is to be expected from the fact that the human eye is not equally sensitive to light of different colors, whereas the photographic plate when properly calibrated should give results on relative intensities which are independent of the sensitivity of the plate for light of different wave-lengths. Hence the zero of intensity inferred from the measurements on the photographic plate would be different from the threshold of visibility detected by the human eye. In reality what one does in the visual method is to observe the line at some intensity considerably above the zero intensity. Examination of the curves, showing the intensity as a function of the time after beginning of the spark, shows that the times when the different lines have the same intensity is variable. The critical intensity which the eye could first detect would be influenced by the sensitivity of the eye for the particular wave-length. The lines which were examined were located in a region of the spectrum

where the sensitivity of the human eye changes quite rapidly with the wavelength. It would be impossible to extrapolate the intensity curves shown in Figs. 2, 3, 4, 5 and 6 in a reasonable manner and obtain values for the relative differences in the times of appearance that were obtained visually. The calibration of the photographic plate made the results obtained by the photographic method independent of the sensitivity of the plate for different colors. The fact that the air lines appeared before the spark and arc lines of the respective elements is probably a result of the natural sequence of events in breakdown of the spark gap. One might suppose as Gaviola⁵ suggested, that the discharge was initiated by ionizing the air between the electrodes. This was followed by evaporation of the metal from the electrodes which was then ionized and excited by collisions. This observed difference between the

Fig. 5. Intensity of air lines 5001A, 4631A, and 4347A with cadmium spark gap.

times of first appearance of the air lines in the zinc and cadmium spark and the metallic arc lines of the same elements may be explained as a characteristic of the spark discharge. Hence if the results of the photographic method are accepted, the data obtained in this type of experiment give no evidence that an electron in the 2^3S_1 state of zinc or cadmium remains there a longer time before the transition takes place to the 2^3P_0 state, than to the 2^3P_1 or the 2^3P_2 state.

CONCLUSIONS

1. The results obtained by the visual and photographic methods are not in agreement.
2. The results obtained by the photographic method indicate that the members of the arc triplet of zinc appear simultaneously. They also indicate

that the members of this same triplet of cadmium appear simultaneously but not at the same time as the members of the arc triplet of zinc. These results therefore seem to verify Gaviola's contention that the apparent time difference between the appearance of spectral lines in such condensed discharges is not an atomic phenomenon.

3. The differences in times of appearance between the air lines which are excited in the spark gap, the spark lines of the element and the arc lines of

Fig. 6. (a) Intensity of unresolved zinc doublet ($3^2D_{3/2}-4^2F_{5/2}$) and ($3^2D_{5/2}-4^2F_{7/2}$).
(b) Intensity of cadmium doublet ($3^2D_{3/2}-4^2F_{5/2}$) and ($3^2D_{5/2}-4^2F_{7/2}$).

the same element, can probably be attributed to the way in which the discharge is formed in the spark gap, i.e. the manner in which the molecules of air or vapor of the element begin to be ionized.

Smith under whose direction this work was carried out and of the valuable suggestions and criticisms received from Dr. M. L. Pool during the course of this work.

THE EFFECT OF PIEZOELECTRIC OSCILLATION ON THE INTENSITY OF X-RAY REFLECTIONS FROM QUARTZ

BY GERALD W. FOX AND PERCY H. CARR
PHYSICS LABORATORY, IOWA STATE COLLEGE

(Received May 1, 1931)

ABSTRACT

In an attempt to determine the amplitude of vibration of the ions in a quartz lattice brought about by piezoelectric oscillations, a series of Laue photographs have been made of both Curie and thirty-degree-cut plates, using the white radiation from a Coolidge universal tube. This tube had a tungsten anode and carried a current of four milliamperes at 95 kilovolts. Eastman duplitized x-ray film was used with no sensitizing screens. On examination, the patterns produced by each plate, oscillating and non-oscillating, appear identical except in one respect; the pattern of the oscillating plate is several times as intense as that of the non-oscillating. A four-hour exposure of a non-oscillating plate to radiation of the above mentioned type, produces but the rudiments of a pattern, whereas, the same plate oscillating produces a very beautiful intense pattern for the same time of exposure. The effect does not depend on the mode of vibration but does depend on the amplitude. Further work is in progress which it is hoped will establish the cause of this peculiar intensity difference.

INTRODUCTION

PIEZOELECTRIC quartz plates used as frequency controllers for vacuum tube oscillators have a visible vibration¹ when in mechanical resonance with the electrical circuit. Such mechanical oscillations must be accompanied by considerable internal movement of the ions of the crystal lattice. It was proposed to investigate this internal motion by shooting a beam of x-rays through a quartz plate both when oscillating and when not oscillating and by observing whether there was any difference in the appearance of the Laue diffraction patterns.

If there was considerable motion of the crystal planes, it might be expected that the spots on the Laue pattern would be altered. Upon first consideration, one might think that this alteration would occur either as a linear smearing of the spots or as a diminution in the intensity of the pattern. The first hypothesis seemed reasonable because of the experiments of Professor Joffé² in which a linear smearing of the spots was produced by a mechanical distortion of the crystal. The second hypothesis appeared reasonable from temperature consideration. The usual result of raising the temperature of a crystal is that the reflection slowly decreases almost linearly with increase in temperature. Backhurst³ gives some data on graphite and ruby, finding a fifteen percent decrease in reflecting power for a rise in temperature of 500° Centigrade.

Gibbs⁴ called attention to the unusual increase in reflecting power of certain planes in crystal quartz which took place at the transition temperature (575°C) when the so-called α form changed over to the β form. Since this large increase was attributed to a relative movement of the ionic planes of only 0.025 Angstrom unit, it seemed possible that oscillations in quartz might produce a change in the relative intensity of the Laue spots.

APPARATUS AND METHODS

Eastman duplitized x-ray films were used throughout. Sensitizing screens were tried at first but were soon discarded for fear they might influence results. The film was placed in a box made of 1/8" lead sheet closed except for a small 1/2" hole in the top. Directly above this hole was mounted in intimate contact, the lower contact plate for the crystal, made of brass and polished flat. In its center was a 1/4" hole. The upper contact plate of the crystal was also made of polished brass. In its center was drilled a 1/8" hole. Radiation from a Coolidge universal tube was delimited by a number 60 drill hole in each of two lead screens mounted approximately five inches apart. Attached to the lower screen and in line with the hole was a two-inch narrow tube of

Fig. 1. Schematic diagram of x-ray tube and crystal circuit.

brass also having a number 50 drill hole in its end. This was merely to facilitate pointing the x-ray beam at the hole in the upper electrode.

The driving circuit is shown in Fig. 1, together with a schematic drawing of the whole layout. The vacuum tube was of the UX210 type employing a filament voltage of 7.5 volts. Plate voltages from 50 to a maximum of 350 volts were used at various times. Resonant conditions in the circuit were determined by observations of the D.C. plate milliammeter A_1 or the radio frequency ammeter A_2 . In this type of circuit using a resistance bias, oscillations are indicated by a large drop in the D.C. plate current and a corresponding increase in the reading of the high frequency ammeter.

⁴ Gibbs, Proc. Roy. Soc. London A107, 561 (1925).

RESULTS

A preliminary run with the non-oscillating crystal showed that at 95 kilovolts peak and 4 milliamperes x-ray tube current at least a four-hour exposure would be necessary to get even a visible pattern. With the same exposure, however, this same plate, oscillating, gave a very beautifully developed Laue pattern. This was curious, and since the exposure on the oscillating crystal had been made in two parts with a lapse of several hours between, and since the film had been developed at a different time and with a different solution than that of its non-oscillating mate, it was assumed that some difference in technique had produced the decided change in intensity. To test this point three different diffraction patterns were made of the same quartz plate; the first, with the plate not oscillating; the second with the plate oscillating; and

Fig. 2. (a) Curie-cut. In use the applied electric field is parallel to an electric axis of the crystal. The optic axis is normal to the plane of the figure. (b) 30-degree-cut. In use the applied electric field makes an angle of 30° with an electric axis of the crystal.

the third with it not oscillating again. In each instance, a four-hour continuous exposure was made at 95 kilovolts and 4 milliamperes. Over a four-hour period slight voltage-current fluctuations were bound to occur but an average current of four milliamperes over the necessary twelve-hour period is probably very close to the truth. All three exposures were then simultaneously developed in a single large tray and were fixed at the same time. Examination of all three films showed beyond doubt that the pattern made by the oscillat-

1900	1875
320	325

ing plate was decidedly more intense than either pattern made by the non-oscillating plate. This discovery made it necessary to go into the phenomenon in more detail.

Six plates were cut from a specimen of optical quality crystal quartz, three of each type of cut as shown in Fig. 2. These plates were then ground down to the following approximate frequencies, as shown in Table I.

The Curie-cut plates have an average wave-length of about 105 meters per millimeter thickness and the 30-degree-cut, about 145 meters per millimeter thickness.

Two four-hour exposures were then made for each plate. Simultaneous development and fixing were carried out. In each case, the same result was obtained, viz.; *an exposure which gave but the rudiments of a pattern with the plate not oscillating, gave an intense pattern when the plate was vibrating.* Visual examination shows the patterns to be identical with the same spots occurring but the intensity is decidedly different. Fig. 3 shows a reproduction of the patterns produced by a 30-degree-cut plate, oscillating and not oscillating. This plate had an approximate frequency of vibration of 1875 kilocycles. It

Fig. 3. (a) oscillating; (b) not oscillating.

was not possible to note any smearing of the spots as was suggested might happen though the method is too crude to detect small changes.

To test the possibility that the effect was due to some sort of an electric strain set up by the applied electric field, a test was run on the same plate whose pattern is shown in Fig. 3. Again two runs were made, the first with no applied field and the second with the line voltage of 120 volts, 60 cycles, applied to the crystal. Both exposures were identical. The two exposures proved to be no different showing that the effect is definitely a resonance phenomenon.

To test this conclusion further, the same piezo-plate was used in a series of three four-hour exposures. The x-ray energy was kept constant and the amplitude of vibration was changed by increasing the plate voltage on the vacuum tube. The voltages used were 50, 150, and 300 volts, respectively. The three exposures show definitely that the intensity of the spots on the patterns depends on the amplitude of vibration of the quartz plate. The 150 volt exposure is decidedly stronger than the 50 volt one and the 300 volt exposure is much stronger than either.

CRYSTAL STRUCTURE OF LITHIUM IODATE

By W. H. ZACHARIASEN AND F. A. BARTA
 RYERSON PHYSICAL LABORATORY, UNIVERSITY OF CHICAGO

(Received April 22, 1931)

ABSTRACT

The structure of lithium iodate was determined by using the oscillation and powder methods. Lithium iodate is hexagonal with 2 molecules per unit cell of $a = 5.469 \pm 0.003\text{A}$, $c = 5.155\text{A} \pm 0.005\text{A}$. The space group assigned is D_6^h and the atom positions are: 2Li in $(001/4)$ $(003/4)$, 2I in $(1/3 \ 2/3 \ 1/4)$ $(2/3 \ 1/3 \ 3/4)$ and 6O in $(uu0)$ $(0\bar{u}0)$ $(\bar{u}u\frac{1}{2})$ $(0u\frac{1}{2})$ $(u0\frac{1}{2})$ $(u0\frac{1}{2})$ with $u = 1/3$. The structure is based on hexagonal closest packing, with the lithium and iodine atoms both lying within oxygen octahedra. The atomic distances are Li-O and I-O = 2.23A with lithium octahedra sharing faces with each other, one lithium and one iodine octahedra sharing only edges and two iodine octahedra only corners.

LITHIUM iodate is the only member of the alkali iodates, whose structure has not yet been determined.¹ In searching the literature no information was found regarding its crystallographic properties. A microscopic examination of the fine crystalline material of chemically pure LiIO_3 as furnished by Kahlbaum, showed that the crystals were short hexagonal prisms. Though LiIO_3 does not crystallize in very large crystals, two crystal splinters were found sufficiently large to be used for the oscillation method. Both crystals were hexagonal prisms and photographs were taken using the principal directions as axes of rotation. In view of the fineness of the material a large number of powder photographs were taken using $\text{MoK}\alpha$, $\text{CuK}\alpha$, and $\text{FeK}\alpha$ radiation.

The photographs were worked out in the usual manner and lead to the following dimensions of the hexagonal cell.

$$a = 5.469\text{A} \pm 0.003\text{A} \quad c = 5.155\text{A} \pm 0.005\text{A} \quad c/a = 0.9427$$

A rough density determination of LiIO_3 gave 1.9 molecules equivalent to 2 molecules per unit cell. The calculated density is 4.48. The greater part of the observations is compiled in Tables I and II. From the tables it is clearly seen that a rhombohedral cell is impossible because of the observed reflections. (The number of molecules in the hexagonal cell also exclude a rhombohedral lattice.) Since the oscillation photographs did not show any deviation from full hexagonal symmetry, consideration of the space group was limited to the following classes: D_{6h}^n , D_6^n , C_{6v}^n and D_{3h}^n . Of these D_6^2 and D_6^5 were ruled out because they have no 2-fold (or 1-fold) positions.

Tables I and II show that whenever $2h+k$ is divisible by 3, exceptionally strong reflections are observed if l is even; whereas the intensity is weak or

nil if l is odd. This observation can only be accounted for by putting the two iodine atoms in positions corresponding to a hexagonal closest packing of these atoms. The only available space groups compatible with such an arrangement are D_{3h}^1 , D_{3h}^4 , C_{6v}^4 , D_6^6 , and D_{6h}^4 . The space groups D_{6h}^4 , C_{6v}^4 ,

The F -curve for iodine was calculated by Thomas' method, the one for oxygen is the experimental one found by J. West in KH_2PO_4 .

and D_{3h}^4 are ruled out because they require that the odd order reflections from all planes $h\ k\ l$ where $2h+k=3n$ and l odd shall be missing, and while many of these reflections are not found, there is evidence in the photographs that some of them are definitely present. This limits the space group selection to D_{3h}^1 and D_6^6 .

In D_{3h}^1 in order to have hexagonal closest packing the necessity for unequivalent iodine atoms arises. The possibility that all oxygen atoms lie in the same plane is unreasonable as that would give too small oxygen to oxygen distances. Likewise this rules out the possibility that they all lie on 3-fold or 6-fold axis of symmetry. The only possible arrangements of the 6 oxygens are therefore: $3j+3k$ or $6n$ with $v=1/4$. None of these possibilities leads to reasonable structures.

In case the 6 oxygens are put in $3j+3k$ and the required oxygen to oxygen distance is greater than 2.50Å, the iodine to oxygen distance is smaller than 1.72Å. It seems improbable that the oxygen to oxygen distance is smaller than 2.50Å, and that the iodine to oxygen distance is as small as 1.72Å. This arrangement must therefore be ruled out and for similar improbabilities placing the 6 oxygens in positions $6n$ can not be considered.

As an additional support for ruling out the considerations of the previous paragraph are the intensity considerations. With the oxygen in $3j+3k$ it is impossible to explain the weak 00.2 reflection. Similarly if the oxygens lie in $6n$ the parameter v must be $1/4$ in order to explain the absent odd orders from the basal plane, which would necessitate the absence of reflections 11.1, which as the tables show are definitely present.

The only remaining space group is D_6^6 .

The 2 iodine atoms are put in positions $(1/3, 2/3, 1/4)$ $(2/3, 1/3, 3/4)$ in accordance with the required hexagonal closest packing. Since all the atoms can not lie on the 3-fold axes of symmetry, the only positions for the oxygens are $(uu0)$ $(0\bar{u}0)$ $(\bar{u}00)$ $(\bar{u}\bar{u}\frac{1}{2})$ $(0u\frac{1}{2})$ $(u0\frac{1}{2})$ or $(u\bar{u}\ 1/4)$ $(2\bar{u}\bar{u}\ 1/4)$ $(u2u\ 1/4)$ $(\bar{u}u\ 3/4)$ $(2uu\ 3/4)$ $(\bar{u}2\bar{u}\ 3/4)$. The latter arrangement does not account for the relative weak 00.2 reflection and therefore the first set is the correct one.

An accurate determination of the oxygen parameter cannot be made due to the small scattering power of these atoms in comparison with that of iodine. The powder photographs show that 30.0 and 30.2 occur with nearly the same intensity although the latter form has twice as many faces as the former. In order to explain this ratio the oxygen atoms must give a large positive contribution to the structure factor for both reflections. This requirement necessitates $u=1/3$. The value $1/3$ is very probable as that gives us hexagonal close packing of the oxygens. A close packed arrangement of the oxygens (using oxygen to oxygen distance=2.7Å) would give us a cell of dimensions $a=4.68\text{Å}$, $c=4.42\text{Å}$ with an axial ratio of 0.944. The fact that the experimental cell is larger than the theoretical one must be attributed to an expansion of the close packing due to the circumstance that both iodine and lithium are too large to fit in the interstices.

The lithium atoms are so light that their positions cannot be determined from the intensities of reflections. There are three sets of available positions

for lithium: (2a) $(000) (00\frac{1}{2})$; (2b) $(00\frac{1}{4}) (00\frac{3}{4})$ and (2d) $(\frac{1}{3}, \frac{2}{3}, \frac{3}{4})$ $(\frac{2}{3}, \frac{1}{3}, \frac{1}{4})$. The set (2a) will put lithium inside of an oxygen triangle with lithium to oxygen distance = 1.83Å. Using (2b) or (2d) lithium will be within an octahedron of oxygens; the lithium to oxygen distance being 2.23Å. The triangular arrangement of oxygens around lithium has never been found in other structures. Lithium either goes inside a tetrahedron of oxygens (Li_2O , KLiSO_4 , Li_2MoO_4) or within an octahedron (LiNO_3). Of the latter two arrangements (2b) is the most plausible one, because this results in a lithium to iodine distance of 3.16Å whereas (2d) would give 2.58Å.

The complete structure thus determined is 2 Li in $(00\frac{1}{4}) (00\frac{3}{4})$, 2I in $(\frac{1}{3} \frac{2}{3} \frac{1}{4}) (\frac{2}{3} \frac{1}{3} \frac{3}{4})$ and 6 O in $(uu0) (0\bar{u}0) (\bar{u}00) (\bar{u}\bar{u}\frac{1}{2}) (0u\frac{1}{2}) (u0\frac{1}{2})$

Fig. 1. Projection on the c -face of the structure of LiIO_3 . The large circles represent oxygens at height 0. The large shaded circles represent oxygens at height $c/2$. The small solid circles represent iodine. The small solid centered circles represent lithium at height $c/4$, $3c/4$.

with $u = 1/3$. The intensities calculated on the basis of this structure agree well with the observed ones, as will be seen from the tables.

DISCUSSION OF THE STRUCTURE

In Fig. 1 is given a projection of the basal plane. The arrangement is a typical coordination lattice, of the hexagonal closed packed type met with in so many cases.

Almost perfect octahedra of oxygen atoms surround the iodine and lithium atoms. The IO_6 -octahedra share only corners with each other. Sharing of the octahedral edges occur between IO_6 and LiO_6 -polyhedra; while the LiO_6 -octahedra share faces with each other. This result is in perfect agree-

ment with what one should expect: The higher charges the central cations have, the fewer are the number of shared corners between two polyhedra.

Although the lithium positions have not been determined from intensity considerations, there is not much doubt about the positions assigned to these atoms. In LiNO_3 , where Li also lies inside an octahedron of oxygens, it was found that the lithium to oxygen distance = 2.15Å. In LiIO_3 the lithium to oxygen distance is 2.23Å.

The distance iodine to oxygen is also 2.23Å. For comparison the iodine to oxygen distance in other crystals of the same coordination number is given. KIO_3 —2.23Å; RbIO_3 —2.26Å, CsIO_3 —2.33Å.

The shortest oxygen to oxygen distance is 3.16Å. In a previous paper by W. H. Zachariasen² it was shown that groups $(\text{XO}_3)^{-n}$ have an unsymmetrical structure if $v = 3 \times 8 + 2$ (v being the total number of valence electrons in the group). In the (IO_6) group there are $50 = 6 \times 8 + 2$ electrons. So that from reasons of analogy it would not be astonishing to find asymmetry in the IO_6 group. This asymmetry probably would result in a slight displacement of iodine away from the center of the octahedron in the direction of one face. However no observations pointing in that direction were observed. The possibility of detecting very small displacements is only possible with extremely accurate intensity determinations.

SUMMARY

Lithium iodate was examined by the oscillation and powder methods. The crystals were found to be hexagonal with 2 molecules in the cell $a = 5.469\text{Å} \pm 0.003\text{Å}$; $c = 5.155\text{Å} \pm 0.005\text{Å}$, $c/a = 0.9427$. The calculated density is 4.48.

The space group was found to be D_6^h with 2 Li in $(001/4)$ $(003/4)$. 2 I in $(1/3 \ 2/3 \ 1/4)$ $(2/3 \ 1/3 \ 3/4)$ and 6 O in $(uu0)$ $(0\bar{u}0)$ $(\bar{u}00)$ $(\bar{u}\bar{u}\frac{1}{2})$ $(0u\frac{1}{2})$ $(u0\frac{1}{2})$ with $u = 1/3$.

The structure is based on the hexagonal closest packing. The lithium and the iodine atoms are both lying within oxygen octahedra. The distances Li-O and I-O are both 2.23Å³. 2 lithium octahedra share faces with each other, one lithium and one iodine octahedra share only edges, two iodine octahedra only corners.

² W. H. Zachariasen, Phys. Rev. 37, 775 (1931).

³ It is probably that a value of u slightly less than $1/3$ is more correct, say $u = 0.314$ which gives Li-O 2.15Å and I-O = 2.28Å.

THE APPLICATION OF THE GEIGER-MÜLLER ION COUNTER
TO THE STUDY OF THE SPACE DISTRIBUTION
OF X-RAY PHOTOELECTRONS

BY J. A. VAN DEN AKKER AND E. C. WATSON

NORMAN BRIDGE LABORATORY OF PHYSICS, CALIFORNIA INSTITUTE OF
TECHNOLOGY, PASADENA, CALIFORNIA

(Received May 4, 1931)

ABSTRACT

The photographic plate in the apparatus for the magnetic analysis of x-ray photoelectrons has been replaced by a Geiger-Müller ion counter and the magnetic spectrum of the photoelectrons ejected from a thin film of gold by primary x-ray from molybdenum has been studied. Very great resolving power is obtained and considerable precision in determining the exact position of the lines (i.e. the energies of the photoelectrons). The numbers of L_{III} electrons of gold ejected by the $K\alpha_1$ x-ray of molybdenum have been plotted as a function of the angle of ejection and compared with the theoretical longitudinal distribution predicted by Schur.

INTRODUCTION

IN THE past many investigators¹ have observed the space distribution of x-ray photoelectrons in cloud expansion chambers. This method is powerful because one may observe directly the path taken by an individual photoelectron after ejection from the parent atom. In actual practice, however, the method has several shortcomings,² one of which is that except in a very few special cases the electrons coming from one level of the parent atom cannot be differentiated from those coming from another level.³

The method developed by one of the writers⁴ enabled the longitudinal distribution of the photoelectrons to be studied as a function of both the energy of the incident photons and the level from which the electrons are ejected. While the change in relative intensities of "lines" in the "magnetic spectra" taken at various angles by this method yielded valuable information, the actual longitudinal distribution of a given group of photoelectrons could be obtained only qualitatively, because the photoelectrons were recorded photographically. With the aim of obtaining distribution curves of a more accurate nature, a new magnetic spectrograph has been constructed, in which the photographic plate has been replaced by a small Geiger-Müller tube.⁵

APPARATUS

In Fig. 1 is shown the horizontal section through the centers of the slits of the new spectrograph. The photoelectrons are ejected from an exceedingly

⁴ Watson, *Phys. Rev.* **30**, 479 (1927).

⁵ For a bibliography of work done on this extremely sensitive detector of ions see, e.g., Van den Akker, *Rev. Sci. Instr.* **1**, 672 (1930).

thin film of the element studied, which is deposited on a strip of celluloid 2 mm wide. This strip is supported with its length vertical, and so arranged at the axis of rotation of the apparatus that the electrons always leave the film normally to its surface. The width of the x-ray beam at the axis of rotation is about 4 mm, so that the film is included in the beam at all angular settings of the spectrograph. Each of the slits shown is $1/64$ inch wide and $1/4$ inch long. The slits S_1 and S_2 are 3 inches apart, and thus ρ , the radius of curvature of the electron orbits, is fixed at 1.5 inches. The slit S_3 and the windows W_2 and W_3 in the Geiger-Muller tube aid in setting the angular dial shown in Fig. 2. Once this setting has been made, the Geiger-Muller tube is shifted to a new position, axis at O' , where the entrance window W_1 is more directly behind S_2 .

Fig. 1. Horizontal section of apparatus, showing arrangement of slits.

Rotation of the spectrograph from outside the chamber may be accomplished by means of a large brass taper, which is shown in Fig. 2. The lead-in B is a small brass pipe which connects the chamber of the Geiger-Müller tube to a gas system, while A is an electrical lead-in to the anode wire of the tube. A pointer fastened to the top of the taper enables one to read θ , the angle between the x-ray beam and the initial direction of the photoelectrons which enter S_1 .

The entrance window W_1 is a set of five holes, each of 0.8 mm diameter, and arranged in a vertical line. A small disk fits into the wall of the tube, and this disk possesses five holes which fall over the five holes in the wall of the tube. This is shown in Fig. 3, in which is given a cross section of a tube of design later than that of the tube depicted in Fig. 2. A film of celluloid of the

order of 10^{-6} cm thick covers the holes of the small disk. This film must satisfy two requirements: It must be sufficiently thin to pass an appreciable fraction of the slowest photoelectrons, and yet it must be sufficiently strong to withstand the difference in pressure which exists between the interior and exterior of the tube (approximately 5 cm of mercury).

Fig. 2. Vertical section of apparatus.

A description of the specialized form of Geiger-Müller tube used in this research and of its operation has been given elsewhere.⁶ The most important detail is the limitation of the active volume by the use of hard rubber plugs. This limitation of volume results in a very low "residual count;" and, when the anode wire is satisfactory, the electron count is independent of the potential of the anode over a range of about 50 volts. (When the whole of the

⁶ Van den Akker, Rev. Sci. Instr. 1, 672 (1930).

volume of the chamber is active the effect of the ends of the tube is to make the residual count a function of the potential of the anode).

The wiring diagram for the Geiger-Müller tube is given in Fig. 4. The tube is earthed, while the anode is connected to a source of high potential through

Fig. 3. Diagram of small electron counter, showing limitation of active volume by means of solid hard rubber plugs.

a resistance of 5×10^9 ohms. Since the spectrograph is placed at the center of a long, vertical solenoid, the connector between the anode and the amplifier

Fig. 4. General scheme of electrical connections for the Geiger-Müller tube.

is necessarily long. The strong electrical disturbances which come from the x-ray outfit make it necessary to shield this connector carefully; to satisfy this requirement, and an additional restriction on the total capacity to earth of the connector, the shielded connector is a very fine wire strung through a large lead pipe.

The results given in this paper were obtained when the x-rays were the primary rays of molybdenum, generated in a water-cooled Coolidge tube

driven at 30 kv and 20 m.a., and the electrons were ejected from a barely visible sputtered film of gold.

THE NATURE OF THE MAGNETIC SPECTRA

The results of two exploratory runs at $\theta = 80^\circ$ are given in Figs. 5 and 6. In Fig. 5 is shown a small part of the whole spectrum which includes the double peak due to L_{III} electrons ejected from gold by $MoK\alpha_{1,2}$. In each

Fig. 5. A small part of the electron "spectrum" taken at 80° , showing the double peak due to L_{III} electrons of gold ejected by $MoK\alpha_{1,2}$.

figure the number of impulses occurring in the Geiger-Müller tube per minute is plotted against the solenoid current. The spectrograph was calibrated with respect to the position of the $K\alpha_1: L_{III}$ peak, the $H\rho$ value being that given by Robinson and Cassie.⁷ All other positions indicated by vertical dashed lines were calculated. Where the precision measurements made by Robinson and

⁷ Robinson and Cassie, Proc. Roy. Soc. A113, 282 (1928).

Cassie have been used, the letters "R-C" have been appended. In the calculation of the remaining positions, level values given in Vol. XXI of the *Handbuch fur Physik* were used. In all cases the ν/R values of the emission lines of molybdenum and gold and the values of the fundamental constants were those selected by Robinson and Cassie.

The sharpness of the peaks in Fig. 5 indicates good resolution, and shows that few electrons lost appreciable energy in getting out of the sputtered film. Each point shown was obtained by a ten minute period of counting, and hence the probable error for each point was not small, being one electron per minute for points in the neighborhood of 25 per minute. The heavy vertical dashes at the extreme right of Figs. 5 and 6 represent twice the probable error of individual points. The probable error of the curves drawn is in general

Fig. 6. The low velocity end of the electron "spectrum" showing peaks due to electrons from the L_I and L_{II} levels of gold.

somewhat smaller, being as small as 0.4 electrons per minute at certain points. The count obtained at zero magnetic field, the "residual count," was about 4.5 per minute. This count was not noticeably changed when the source of x-rays was cut off, showing that the effect of scattered x-rays was negligible.

The small peak at 2.555 amp can be attributed to electrons ejected from the M_{III} levels of gold atoms in which the transition ($M_I \rightarrow L_{III}$) may occur. Thus, while the M_{III} level in the normal gold atom has the value $\nu/R = 202.8$, the value of this level in an atom in which the above transition may occur is 206.7. The two peaks at 1.900 and 1.930 could not be attributed to electrons coming from gold. The sputtered film of gold had been exposed to mercury vapor at room temperature, however, and hence one might reasonably expect to find peaks due to electrons from mercury. The calculated positions of electrons ejected from the mercury L_{II} level by $MoK\alpha_{1,2}$ were, respectively, 1.931 and 1.899 amp.

THE LONGITUDINAL DISTRIBUTION OF THE L_{III} ELECTRONS

In an attempt to measure the longitudinal distribution of electrons ejected from the L_{III} level of the gold atom by $K\alpha_1$, the $K\alpha_{1,2}:L_{III}$ peaks were obtained at various angles. The difference between the ordinate of the peak at 2.528 amp and the ordinate of the valley at 2.551 amp was taken as a measure of the number of electrons ejected from the L_{III} level. This difference is plotted against the angle of ejection, θ , in Fig. 7. The deviation of the experimental curve from the points at 60° and 80° is a correction due to the loss of $K\alpha$ rays in passing through the celluloid strip which supported the sputtered film. This correction is negligible for all angles excepting those slightly less than 90° . It should be noted that this correction is not accurately known, and that an error in this correction will shift the maximum of the experimental curve through several degrees.

Fig. 7. The longitudinal distribution of L_{III} electrons of gold ejected by $MoK\alpha_1$.

Schur⁸ has recently given a theoretical expression for the longitudinal distribution of the L electrons taken collectively. This expression is divided into two parts, one giving the distribution of the L_I electrons, and the other giving the distribution of the L_{II} and L_{III} electrons combined. The latter part is

$$J(\theta, \phi) \sim \left\{ 1 + \frac{8I_L}{h\nu} \sin^2 \theta \cos^2 \phi + \frac{2v}{c} \cos \theta \left[1 + 2 \left(1 + \frac{11I_L}{h\nu} \right) \sin^2 \theta \cos^2 \phi \right] \right\}$$

where $J(\theta, \phi)$ is the probability per unit solid angle that an electron will leave the parent atom in a direction making an angle θ with the forward direction of the x-ray beam, and the angle ϕ with the direction of the electric vector, ϕ being measured in a plane perpendicular to the beam of x-rays. The quantities I_L , ν , and v are respectively the mean energy of binding of the L_{II} and L_{III} electrons, the frequency of the incident radiation, and the speed of ejection of the photoelectrons. Since unpolarized rays were used, we integrate with respect to ϕ from 0 to π , and obtain

⁸ Schur, Ann. d. Physik 4, 433 (1930).

$$P(\theta) \sim \left\{ 1 + \frac{4I_L}{h\nu} \sin^2 \theta + \frac{2v}{c} \cos \theta \left[1 + \left(1 + \frac{11I_L}{h\nu} \right) \sin^2 \theta \right] \right\}.$$

This function is represented in Fig. 7 by the dashed curve. The wide departure of the experimental curve from the theoretical at small and large angles can be explained in part by nuclear scattering of the electrons in the sputtered film. Scattering can not explain the larger part of this departure, however, as spectra obtained in the past⁹ reveal the important fact that certain lines, strong at 80°, fall to nearly zero intensity at 0°. On the other hand, the theoretical distribution is that of the L_{II} and L_{III} electrons combined, and it may be that the distribution of the L_{II} electrons is less isotropic than that of the L_{III} electrons. The maxima of the curves are both well forward of 90°, being at about 70°, and the ratio of the ordinates at 0° and 180° of the experimental curve is nearly the same as that of the theoretical curve. The experimental value of this ratio is 1.60, while Schur's function gives

$$P(0)/P(\pi) = (1 + 2v/c)/(1 - 2v/c) = 1.82.$$

ON THE PROBLEM OF THE ENTROPY OF THE UNIVERSE AS A WHOLE

BY RICHARD C. TOLMAN

NORMAN BRIDGE LABORATORY, CALIFORNIA INSTITUTE OF TECHNOLOGY

(Received May 6, 1931)

ABSTRACT

The well-known problem of the entropy of the universe as a whole arises from the difficulties encountered by classical thermodynamics—first in failing to account for the presumed fact that the entropy of the universe has always been increasing at an enormous rate and nevertheless has not yet reached its maximum value—and second in failing to allow an emotionally satisfactory feeling towards our universe whose ultimate fate would be the stagnation of “heat-death.” The purpose of the present article is to examine this problem from the point of view of the extension of thermodynamics to general relativity which has previously been made by the author.

A number of earlier contributions to the solution of the problem, which have been made from the standpoint of classical thermodynamics or statistical mechanics, are first briefly described in order to emphasize the very different character of the contribution to the problem made in the present article. It is then pointed out that the problem of the entropy of the universe arises in the classical thermodynamics because of the presumption that thermodynamic processes cannot take place both reversibly and at a finite rate, and that the general nature of the contribution to the problem offered by relativistic thermodynamics consists in showing the possibility of thermodynamic changes which could take place at a finite rate and at the same time reversibly without increase in entropy.

The principles of relativistic thermodynamics are then reviewed, and this difference between the classical and relativistic thermodynamics is shown by considering the possibilities of carrying out reversible changes at a finite rate in the properties of a thermodynamic fluid. In the classical thermodynamics it is found that no change in the thermodynamic properties could be allowed to take place at a finite rate, the entropy density of the fluid necessarily remaining constant in accordance with the equation

$$\frac{d\phi_0}{dt} = 0.$$

On the other hand, in relativistic thermodynamics it is found possible to allow changes to take place at a finite rate in the proper volume of the fluid, due to changes in the gravitational potentials $g_{\mu\nu}$, and still maintain reversibility provided the changes satisfy the relation

$$\frac{\partial}{\partial x_4} \left(\phi_0 \sqrt{-g} \frac{dx_4}{ds} \right) = 0.$$

To exhibit the nature of the reversible changes at a finite rate thus permitted in relativistic thermodynamics, consideration is given to the highly idealized model of a non-static universe filled with black-body radiation as a thermodynamic fluid, and it is shown that the radius, total proper volume, and entropy density of such a universe could be changing at a finite rate and yet reversibly without increase in entropy. Furthermore, in the case of an expanding model of the kind considered, it is shown that an ordinary observer, who marks out with rigid meter sticks a small region of

this universe in his immediate vicinity for study, would find the energy density, energy content, and the temperature of this region decreasing with the time, and would find the number of quanta leaving the region per second greater than the number entering, and the average frequency of the quanta that leave greater than that of those that return. These phenomena would be interpreted by the observer, from a classical point of view, as due to radiation from his neighborhood into the colder surroundings of space and hence as leading to an increase in entropy, in spite of the fact that all the processes taking place in such a model would actually be reversible from the point of view of the relativistic thermodynamics which should be applied to such a problem.

In conclusion remarks are made concerning the disparity between the above model, which was chosen for purposes of illustration because of its mathematical simplicity, and models which would be more suitable to serve as representations of the actual universe. And some indication is given of the further developments that should be undertaken.

PART I. INTRODUCTION

§1. Purpose of present article.

IN A number of previous articles I have endeavored to present the principles for an extension of thermodynamics to general relativity¹ and to consider some of the applications of the new system of relativistic thermodynamics based on these principles.² The purpose of the present article is to examine the bearings of relativistic thermodynamics on the well-known problem of the entropy of the universe as a whole. It will be found that this extended thermodynamics provides new possibilities for thermodynamic processes to take place at a finite rate without increase in entropy. And it will be shown that the recognition of these new possibilities not only appears to be essential for a true understanding of the problem of the entropy of the universe, but may even provide to a greater or lesser extent the basis for its solution.

§2. The nature of the problem of the entropy of the universe.

In accordance with the views of the classical thermodynamics all thermodynamic processes, actually taking place in the universe at a finite rate, were regarded as accompanied by an increase in entropy. Among these processes appeared a wide variety of immediately appreciated terrestrial occurrences of a meteorological, biological or technological nature in which the increase of entropy depended for the most part on the degradation of energy originally received as radiation from the sun,—in addition, various tidal actions in which the increase of entropy resulted from the degradation into heat of mechanical energy of astronomical motions;—and quantitatively most important of all, the continuous flow of radiation from the stars with a great increase in entropy due to the presumable drop in temperature in passing from the hot interior of the stars to the cold depths of intergalactic space.

In general the view was held that entropy was everywhere increasing at an enormous rate and that this would continue until the entropy of the universe

¹ Tolman, *Proc. Nat. Acad.* **14**, 268 (1928); *ibid.* **14**, 701 (1928); *Phys. Rev.* **35**, 875 (1930); *ibid.* **35**, 896 (1930).

² Tolman, *Proc. Nat. Acad.* **14**, 348 (1928); *ibid.* **14**, 353 (1928); *ibid.* **17**, 153 (1931); *Phys. Rev.* **35**, 904 (1930); Tolman and Ehrenfest, *Phys. Rev.* **36**, 1791 (1930).

had reached its maximum,—the sun and stars cold, all of creation dead and unchanging.

Such a view, however, carries with it two difficulties. The first difficulty has genuine intellectual validity and can be expressed by the question: Why has not the entropy of the universe already reached its maximum value in the infinite past time which has presumably been available? The second difficulty has perhaps only emotional validity and can be expressed by the question: What significance can we ascribe to a universe whose ultimate fate is merely the "heat-death" of maximum entropy? These are the difficulties which constitute the problem of the entropy of the universe.

§3. Nature of earlier contributions to the solution of the problem.

Various suggestions have been made with regard to the solution of the problem. It will be profitable to consider some of them briefly in order to emphasize the very different nature of the suggestion which will be made in this article.

a. Finite time since creation. The most obvious treatment of the problem is to assume that the universe was indeed created at a finite time in the past with sufficient available energy so that the entropy has not yet reached its maximum value. In the future this maximum would be reached and all significant changes would cease. A modification of the treatment could be made by assuming an infinite past during which the universe was in a quiescent metastable state of large available energy, and a disturbance at a finite time in the past which initiated the process of degradation.

These suggestions depend too greatly on special *ad hoc* assumptions to be scientifically satisfying.

b. Continuous regeneration. A second type of suggestion depends on the assumption of the existence of regenerative processes of such a nature as to maintain the universe in an approximately steady condition. Thus Millikan³ has suggested the four-step cycle: (1) Matter in the stars is transformed into radiation which flows out into intergalactic space; (2) the radiation in intergalactic space is transformed into electrons and protons; (3) the electrons and protons combine to form helium and other elements, giving rise to the production of the observed cosmic rays; (4) the matter thus formed drifts back into the stars, thus completing the cycle. The evidence for step (2) is completely lacking at present; steps (2) and (3) assume the occurrence of processes of synthesis under the theoretically unfavorable conditions of extremely low concentration; and the cycle contradicts the principle of microscopic reversibility.⁴ The evidence for step (1), however, is very strong, the evidence for step (3) cannot be dismissed as trivial, and there is no inherent improbability in step (4).

c. Continuous approach to maximum entropy. A third type of suggestion

³ Millikan and Cameron, *Proc. Nat. Acad.* **14**, 637 (1928).

⁴ For a partial historical account of this principle, see Tolman, *Proc. Nat. Acad.* **11**, 436 (1925). For a discussion of the principle, see for example Tolman, "Statistical Mechanics" Chap. 15, Chemical Catalog Co., New York, 1927.

would be to assume an infinite past for the universe, coupled with ever decreasing values for the entropy of the universe as we examine backwards in the past and a continuous asymptotic approach to the maximum of entropy in the future.⁵ If such an assumption were allowable, it would avoid the difficulty of a limited past time for the existence of the universe, but the difficulties of a practical exhaustion of the energy available for human needs within a finite time in the future would not appear to be avoided. The assumption would perhaps not be a possible one for a finite universe of finite energy content, for which we have some evidence.

d. Fluctuations in entropy in accordance with its statistical-mechanical interpretation. A fourth of type of contribution to the problem depends on the statistical mechanical interpretation of entropy, as given most clearly by Boltzmann's famous *H*-theorem. In accordance with this theorem it is found that, although there is a great probability for the entropy of a system to increase when it has less than its maximum value, it is not certain that this will take place and fluctuations away from the maximum of entropy will occur. This furnishes the possibility that the universe has existed for an infinite time in the past and that we are now experiencing a return of the universe or of that portion which is within our range of observation towards a condition of maximum entropy after a major fluctuation away from that value.

This important possibility was clearly presented by Boltzmann⁶ over thirty years ago. The enormous improbability of a major fluctuation of the kind assumed does not necessarily furnish a valid argument against the explanation, since, as pointed out to me in conversation by Mrs. Ehrenfest-Afanassjewa, the existence of sentient beings to observe the rare phenomenon could presumably only occur at the time of decay of such a fluctuation. From the point of view of human wishes, however, the explanation is not entirely satisfying, since it implies that man himself is a transitory and improbable phenomenon, that our surroundings are now headed with almost complete certainty towards a condition at least close to that of maximum entropy, and that the conditions under which life, as we know it, is possible are almost never present. Nevertheless, these objections have emotional rather than intellectual validity and the part played by the theory of statistical fluctuations in a relatively complete solution of the problem of the entropy of the universe may prove to be no mean one.

§4. Nature of the present contribution to the solution of the problem.

The present contribution to the problem of the entropy of the universe is based on the system of relativistic thermodynamics which I have developed. The general nature of the contribution depends on an extension given by this relativistic thermodynamics in our ideas as to the kind of processes which can occur at a finite rate without producing any increase in entropy.

As an illustration of this extension in our ideas, it would be impossible

⁵ This possibility was suggested to me by some remarks of the late Professor William James which were told me in conversation by Professor Gilbert N. Lewis.

⁶ Boltzmann, Wied. Ann. 60, 392 (1897).

from the point of view of classical thermodynamics to carry out an actual expansion of a thermodynamic fluid reversibly and at a finite rate, since the friction of moving parts and the deficiency between the actual pressure exerted by the fluid and that which could be exerted with an infinitely slow rate of expansion would lead to an increase in entropy. Nevertheless, in relativistic thermodynamics we shall find that the *proper* volume associated with a thermodynamic fluid could increase at a finite rate, owing to a finite rate of change in the gravitational potentials $g_{\mu\nu}$, without involving any increase in entropy.

In further illustration, it appeared impossible in the classical thermodynamics for a flow of heat to take place reversibly and at a finite rate, owing to the increase in entropy connected with the finite temperature drop necessary to maintain the finite rate of flow. Nevertheless, in relativistic thermodynamics, we shall find that the reversible increase in proper volume, mentioned in the paragraph above, would make it possible for heat radiation to be regarded by an ordinary observer as flowing out of a given region of interest at a finite rate, without any increase in the entropy of the system as a whole.

It is evident from these examples, that relativistic thermodynamics increases in an important manner the variety of changes which could be taking place in a universe which is actually in a state of maximum entropy, and makes it necessary to re-examine processes which we have formerly taken as evidence that the entropy of our own universe is actually increasing at an enormous rate.

In Part II, we shall first consider the general bearing of relativistic thermodynamics on changes in thermodynamic condition without increase in entropy. In Part III, we shall then apply relativistic thermodynamics to the very special model of a non-static universe filled solely with radiation. Such a model ignores very characteristic features of the actual universe, but mathematically is relatively simple to handle and will present some features which appear analogous to phenomena in the actual universe. Finally in Part IV, we shall try to give some criticism of the role that the new ideas might play in the general solution of the problem of the entropy of the universe.

PART II. RELATIVISTIC THERMODYNAMICS

§5. The first and second laws of relativistic thermodynamics.

The extension of thermodynamics to general relativity can be based on two principles which may be regarded as the relativistic generalization of the first and second laws of classical thermodynamics.

In accordance with the first of these principles, any thermodynamic process occurring in the universe must take place in such a way as to agree with the principles of relativistic mechanics as given by the tensor density equation

$$\frac{\partial \mathfrak{T}_\mu^\nu}{\partial x_\nu} - \frac{1}{2} \mathfrak{T}^{\alpha\beta} \frac{\partial g_{\alpha\beta}}{\partial x_\mu} = 0 \quad (1)$$

or the equivalent non-tensorial yet nevertheless covariant equation

$$\frac{\partial(\mathfrak{T}_\mu^\nu + t_\mu^\nu)}{\partial x_\nu} = 0 \quad (2)$$

where \mathfrak{T}_μ^ν is the tensor density of material energy and momentum, t_μ^ν the pseudo tensor density of potential energy and the $g_{\alpha\beta}$ the gravitational potentials.

Since these equations reduce to the ordinary energy-momentum principle in flat space-time where the gravitational field is negligible, the analogy of this first principle to the ordinary first law of thermodynamics is evident. In applying the principle to thermodynamic considerations, the system involved will of course be treated from a macroscopic point of view, and this is an advantage since the applicability of these equations to microscopic phenomena would certainly not be in accord with the development of quantum mechanics, which has taken place since their formulation.

The second principle of relativistic thermodynamics may be stated in the form

$$\frac{\partial}{\partial x_\mu} \left(\phi_0 \sqrt{-g} \frac{dx_\mu}{ds} \right) dx_1 dx_2 dx_3 dx_4 \geq \frac{dQ_0}{T_0} \quad (3)$$

where ϕ_0 is the proper density of entropy as measured by a local observer, using Galilean coordinates which are at rest with respect to the mass motion of the thermodynamic fluid at the point of interest, the quantities dx_μ/ds are the macroscopic "velocities" of the fluid at the point of interest as measured in the coordinate system x_1, x_2, x_3, x_4 , the quantity dQ_0 is the heat flowing through the boundary into the infinitesimal region *and* during the infinitesimal time, denoted by $dx_1 dx_2 dx_3 dx_4$, as measured in proper coordinates, and T_0 the temperature of the boundary also measured in proper coordinates.

The justification for the principle lies in the fact that it has been shown to be a natural covariant generalization of the ordinary second law of thermodynamics valid in flat space-time, Eq. (3) being a tensor equation of rank zero which reduces in flat space-time and Galilean coordinates to

$$\left[\frac{\partial \phi}{\partial t} + \frac{\partial}{\partial x} (\phi u) + \frac{\partial}{\partial y} (\phi v) + \frac{\partial}{\partial z} (\phi w) \right] dx dy dz dt \geq \frac{dQ}{T} \quad (4)$$

where ϕ is the density of entropy, u, v and w are the component velocities of the fluid, dQ is the heat flowing into the region $dx dy dz$ in the time dt , and T is the temperature, all these quantities now being measured in the particular set of Galilean coordinates x, y, z, t which is being used.

§6. Application of the relativistic second law to a finite adiabatic system.

Let us now apply our new form of the second law as given by Eq. (3) to a finite thermodynamic system, by taking x_1, x_2, x_3 as being the space-like coordinates and carrying out an integration over the spatial region of interest. If we carry out such an integration, using coordinates such that the limits

of integration necessary to include the system fall on the boundary which separates the system from its surroundings, it is evident that the summation of dQ_0/T_0 over the interior of the system will cancel out, since any heat entering a given element of volume is abstracted from neighboring elements. Hence dividing Eq. (3) by dx_4 , writing out the separate terms corresponding to the different values of μ , and performing the integration we obtain, with some rearrangement in order,

$$\begin{aligned} & \iiint \frac{\partial}{\partial x_4} \left(\phi_0 \sqrt{-g} \frac{dx_4}{ds} \right) dx_1 dx_2 dx_3 \\ & \geq - \iiint \left[\frac{\partial}{\partial x_1} \left(\phi_0 \sqrt{-g} \frac{dx_1}{ds} \right) + \frac{\partial}{\partial x_2} \left(\phi_0 \sqrt{-g} \frac{dx_2}{ds} \right) \right. \\ & \quad \left. + \frac{\partial}{\partial x_3} \left(\phi_0 \sqrt{-g} \frac{dx_3}{ds} \right) \right] dx_1 dx_2 dx_3 + \sum \left(\frac{1}{T_0} \frac{dQ_0}{dx_4} \right)_{\text{BOUNDARY}} \end{aligned} \quad (5)$$

The last term on the right hand side of the above inequality is the total value of the quantity $(1/T_0)(dQ_0/dx_4)$ taken over the boundary which separates the system from its surroundings, and by performing the indicated integrations the other terms on the right hand side of the expression can also be seen to depend solely on conditions at the boundary. We obtain

$$\begin{aligned} & \iiint \frac{\partial}{\partial x_4} \left(\phi_0 \sqrt{-g} \frac{dx_4}{ds} \right) dx_1 dx_2 dx_3 \\ & \geq - \int \int \left| \phi_0 \sqrt{-g} \frac{dx_1}{ds} \right|_{x_1}^{x_1'} dx_2 dx_3 - \int \int \left| \phi_0 \sqrt{-g} \frac{dx_2}{ds} \right|_{x_2}^{x_2'} dx_1 dx_3 \\ & \quad - \int \int \left| \phi_0 \sqrt{-g} \frac{dx_3}{ds} \right|_{x_3}^{x_3'} dx_1 dx_2 + \sum \left(\frac{1}{T_0} \frac{dQ_0}{dx_4} \right)_{\text{BOUNDARY}} \end{aligned} \quad (6)$$

where the limits of integration at the boundary are denoted by x_1, x_1' etc.

This expression (6) may be regarded as a general statement of the relativistic second law of thermodynamics as applied to finite systems. Defining the entropy of the system as

$$S = \iiint \left(\phi_0 \sqrt{-g} \frac{dx_4}{ds} \right) dx_1 dx_2 dx_3 \quad (7)$$

it gives the relation which must hold between the rate at which the entropy of a finite system is changing with the time x_4 and those conditions at the boundary which determine the flux of matter and the flow of heat between the system and its surroundings.

For an adiabatic system with no flux of matter or flow of heat between the system and its surroundings we shall have the quantities $dx_1/ds, dx_2/ds, dx_3/ds$, and dQ_0/dx_4 equal to zero at the boundary and the expression will then reduce to

$$\frac{dS}{dx_4} = \iiint \frac{\partial}{\partial x_4} \left(\phi_0 \sqrt{-g} \frac{\partial x_4}{\partial s} \right) dx_1 dx_2 dx_3 \geq 0. \quad (8)$$

In accordance with this expression the entropy of an adiabatic system cannot decrease with the time but can only increase or remain constant. As in the classical thermodynamics, adiabatic processes in which the entropy increases with the time may be called irreversible, since neglecting improbable fluctuations the system after such a process could not of itself return to the original state of lower entropy; while processes in which the entropy remains constant may be called reversible.

§7. Increased possibility for reversible processes in relativistic thermodynamics.

With the help of the foregoing considerations we may now compare the conditions which would be imposed by classical and by relativistic thermodynamics on the occurrence of reversible processes. In the present section we shall show that the new thermodynamics offers the possibility for a kind of thermodynamic change which was not contemplated in the classical thermodynamics, and which might take place at a finite rate without increase in entropy, in contrast to the conclusion of classical thermodynamics that reversible thermodynamic processes could not take place at a finite rate. And in later sections we shall show by a simple specific example that such reversible processes taking place at a finite rate might actually be realized, and play a possible part in cosmological happenings.

a. Classical treatment of entropy changes in a thermodynamic fluid. Let us first illustrate the kinds of classical considerations which have formerly lead to the conclusion that thermodynamic processes could not take place both reversibly and at a finite rate.⁷ To do this we may consider the conditions which would be imposed by classical thermodynamics on reversible changes in the condition of a thermodynamic fluid.

In the classical thermodynamics we could evidently write for the entropy of a finite portion of thermodynamic fluid enclosed in a suitable container the expression

$$S = \iiint \phi \, dx \, dy \, dz \quad (9)$$

where ϕ is the density of entropy as measured in the particular set of (Galilean) coordinates x, y, z, t which the observer uses, and the integration is to be taken over the whole volume of the container.

If now we consider the possible reversible changes which could take place in this thermodynamic fluid, it is evident in the first place that we could permit no relative motion between different portions of the fluid, since the decay of this motion would lead to an increase in entropy, and we may hence

⁷ Of course the classical thermodynamics permitted ideal *mechanical* processes to take place at a finite rate without increase in entropy, but the distinction between mechanical and thermodynamic processes was clear enough so that this did not prove to be a source of confusion.

use a set of coordinates in which the thermodynamic fluid as a whole would be at rest and rewrite our expression for the entropy in the form

$$S = \iiint \phi_0 dx dy dz \quad (10)$$

where ϕ_0 is the proper density of entropy. In the second place, it is evident that we could only permit adiabatic changes, since if we allowed heat flow in our system at a finite rate we should have increases in entropy arising from the finite temperature gradient which would be necessary to maintain this flow. Hence in accordance with the classical thermodynamics the condition for our contemplated process to be reversible would be that of constant entropy as given by the equation

$$\frac{d}{dt} \iiint \phi_0 dx dy dz = 0. \quad (11)$$

In the third place, it is evident that our process could not involve a change in volume at a finite rate, for example by the withdrawal of a piston, since this would involve mass flow of portions of the fluid which would lead to an increase in entropy that could be calculated from the difference between the pressure actually exerted by the fluid on the moving piston and that which would be exerted at an infinitesimally slow rate of expansion. Hence the condition given by Eq. (11) for our contemplated reversible process might now be rewritten with the differentiation inside the integral sign in the form

$$\iiint \frac{d\phi_0}{dt} dx dy dz = 0. \quad (12)$$

This final condition, moreover, could evidently be satisfied in our case only by taking

$$\frac{d\phi_0}{dt} = 0 \quad (13)$$

at all points of the fluid, since for a stationary fluid with no flow of heat there would be no possibility at any point for negative values of the quantity $d\phi_0/dt$.

This, however, completes the considerations necessary for the classical conclusion that there could be no thermodynamic change at all in our fluid which takes place both reversibly and at a finite rate. Indeed we see that no changes could take place in the system as a whole through interaction with its surroundings, since we have found that its volume could not be allowed to change at a finite rate and heat could not be allowed to flow through its boundary at a finite rate, and no changes could take place in the interior condition of the fluid since we have found that it could have no macroscopic internal motions, no internal flow of heat, and no changes in local entropy density which take place at a finite rate.

b. Relativistic treatment of entropy changes in a thermodynamic fluid. We

must now compare this conclusion with that which we would obtain by applying relativistic thermodynamics to the same system, namely a finite portion of thermodynamic fluid. In this case in accordance with expression (8) in the preceding section §6, the condition for a reversible adiabatic change in the condition of the fluid would be

$$\iiint \frac{\partial}{\partial x_4} \left(\phi_0 \sqrt{-g} \frac{dx_4}{ds} \right) dx_1 dx_2 dx_3 = 0 \quad (14)$$

where x_4 is the time like coordinate and the integration is to be taken over the whole range of spatial coordinates x_1, x_2, x_3 necessary to include the fluid. And this condition can evidently be satisfied if we have the equality holding at each point in the fluid

$$\frac{\partial}{\partial x_4} \left(\phi_0 \sqrt{-g} \frac{dx_4}{ds} \right) = 0 \quad (15a)$$

or

$$\frac{1}{\phi_0} \frac{\partial \phi_0}{\partial x_4} = - \frac{1}{\sqrt{-g} \frac{dx_4}{ds}} \frac{\partial}{\partial x_4} \left(\sqrt{-g} \frac{dx_4}{ds} \right). \quad (15b)$$

This expression gives a relation between the percentage rate at which the proper entropy density ϕ_0 is changing with the time x_4 at a given point and the percentage rate at which the quantity $(\sqrt{-g} dx_4/ds)$ is changing with the time at that same point. The value of this latter quantity, however, is determined by the gravitational field at the point in question, and by the kind of coordinate system $x_1 \cdots x_4$ which is being used.

If now we assumed the gravitational field negligible, as is tacitly done in the classical thermodynamics, and had a fluid with no relative motion between its parts, we could choose a system of Galilean coordinates x, y, z, t in which the fluid as a whole would be at rest. In this system of coordinates the quantities $\sqrt{-g}$ and dx_4/ds would have the constant value unity and the condition given by Eqs. (15) would reduce to the result

$$\frac{d\phi_0}{dt} = 0 \quad (16)$$

which we have already found to be characteristic of the classical thermodynamics. It is thus by a neglect of the gravitational field and its possible change with time that the classical thermodynamics has been led to the conclusion that no reversible processes can occur at a finite rate.

On the other hand in relativistic thermodynamics we must not assume that the gravitational field is necessarily negligible but must specifically consider the part which it plays in thermodynamic processes. Hence in relativistic thermodynamics we must consider the condition for reversibility given by Eq. (15) in its full form, and retain the possibility of mutual changes in gravitational field and entropy density taking place together at a finite rate in such a way as to satisfy this condition for reversibility.

In Part III we shall consider a definite model which exhibits such a mutual change in gravitational field and entropy density taking place at a finite rate and satisfying the condition for reversibility. To conclude the present section, however, we may first investigate somewhat further the general nature of the reversibility requirement given by Eq. (15).

Consider the case of a thermodynamic fluid which is at rest with respect to the spatial coordinates x_1, x_2, x_3 which are being used. Since the macroscopic velocities $dx_1/ds, dx_2/ds$, and dx_3/ds are everywhere zero by hypothesis, it is evident that the amount of fluid in any given coordinate range $dx_1 dx_2 dx_3$ would not be changing with the time since there is no flow across the boundary. In accordance with the principles of relativity, however, we can then write for the proper volume dV_0 of the small element of fluid in such a coordinate range the well-known equation

$$dV_0 = \sqrt{-g} dx_1 dx_2 dx_3 \frac{dx_4}{ds} \quad (17)$$

and substituting this expression into the condition for reversibility, as given by Eq. (15a), we can rewrite this condition in the new form

$$\frac{\partial}{\partial x_4} \left(\phi_0 \sqrt{-g} dx_1 dx_2 dx_3 \frac{dx_4}{ds} \right) = \frac{\partial}{\partial x_4} (\phi_0 dV_0) = 0 \quad (18)$$

since the coordinates x_1, x_2 and x_3 are independent of the coordinate x_4 .

This equation, however, states that the total entropy for each given small element of fluid shall be constant as measured by a local observer, and this is merely the condition for a change in the proper volume of the element with no flow of heat and with balance between internal and external pressures. Hence if we had a fluid with no flow of heat and constant proper pressure throughout, a finite rate of alteration in the gravitational field which produced no flow of heat and changed the proper pressure at the same rate throughout the fluid would satisfy the condition of reversibility. This alteration in gravitational field, however, would lead to an alteration in proper volume and thus to alteration in the entropy density, so that the thermodynamic state of the fluid would be changing reversibly and at a finite rate. It is this dependence of proper volume on gravitational field, which was quite outside of the considerations of the classical thermodynamics, which leads in relativistic thermodynamics to the possibility of reversible processes which take place at a finite rate.

PART III. APPLICATION TO A SPECIFIC MODEL

§8. The general nature of the model.

We may now apply the foregoing considerations to a specific model. For this purpose we shall take a non-static universe⁸ filled with a uniform density of black-body radiation. The choice of this model is not made because it is

⁸ For an account of various treatments which have been given to the non-static line element for the universe, see Tolman, *Proc. Nat. Acad.* **16**, 582 (1930).

thought to give a close approximation to the actual state of the universe but because the mathematical treatment will be relatively simple. The model neglects the presence of matter and its agglomeration into stellar systems which are very characteristic features of the actual universe. Nevertheless, we shall find that the behaviour of the radiation in such a universe furnishes a surprising possibility of insight into the flow of radiation from the stars which is such a puzzling feature of the actual universe.

§9. The line element for the non-static universe.

The line element for a non-static universe filled with a uniform distribution of matter and energy can be derived⁹ by treating the contents of the universe for the purposes of large-scale considerations as though filled with a perfect fluid, on the basis of the two requirements, (a) that the fluid shall at all times be uniformly distributed spatially, and (b) that particles (nebulae) which are stationary in the coordinate system used shall fulfill the stability requirement of not being subject to acceleration.

The line element so obtained can be written in a variety of forms depending on the choice of coordinates, and for the purpose of the discussions in the present article it will be most convenient to write it in the form¹⁰

$$ds^2 = -e^{g(t)} \left(\frac{dr^2}{1 - r^2/R^2} + r^2 d\theta^2 + r^2 \sin^2 \theta d\phi^2 \right) + dt^2 \quad (19)$$

where r , θ and ϕ are the spatial coordinates, t is the time coordinate, R is a constant, and the dependence of the line element on the time is given by the exponent $g(t)$.

§10. Certain general properties of the non-static universe.

Before proceeding to our special model, it will be desirable to recall certain properties which are implied in general for the non-static universe by the form of the line element and which will be needed in our later discussion.

In accordance with the requirement (a) on which the line element was derived, the proper macroscopic density ρ_{00} and the proper pressure p_0 of the fluid which fills the universe will be independent of the position r , θ , ϕ , but may be changing with the time t . And indeed working out the components of the energy-momentum tensor T_μ^ν which correspond to the line element (19) and equating to those for a perfect fluid we obtain as the only non-vanishing components¹¹

$$8\pi T_1^1 = 8\pi T_2^2 = 8\pi T_3^3 = -8\pi p_0 = \frac{1}{R^2} e^{-g} + \ddot{g} + \frac{3}{4} \dot{g}^2 - \Lambda \quad (20)$$

$$8\pi T_4^4 = 8\pi \rho_{00} = \frac{3}{R^2} e^{-g} + \frac{3}{4} \dot{g}^2 - \Lambda \quad (21)$$

⁹ Tolman, Proc. Nat. Acad. **16**, 320 (1930). See also Ibid. **16**, 409 (1930), and note that the five assumptions mentioned in §2 of that article can be included under the heading of the two requirements (a) and (b) given above.

¹⁰ Tolman, Proc. Nat. Acad. **16**, 511 (1930). Eq. (5). Note that the \bar{r} of that article is our present r .

¹¹ Tolman, Proc. Nat. Acad. **16**, 409 (1930). Eq. (2).

where Λ is the cosmological constant; and these equations give the dependence of pressure and density on the exponent g and its time derivatives \dot{g} and \ddot{g} , and thus on the time itself.

With the help of these expressions for the components of the energy-momentum tensor we can now easily apply the principles of relativistic mechanics in the well-known form

$$\frac{\partial \mathfrak{T}_\mu}{\partial x_\nu} - \frac{1}{2} \mathfrak{T}^{\alpha\beta} \frac{\partial g_{\alpha\beta}}{\partial x_\mu} = 0. \quad (22)$$

With $\mu = 1, 2, 3$ we merely obtain identities, but substituting into this equation for the case $\mu = 4$ we can easily obtain after dividing through by a constant factor¹²

$$\frac{d}{dt}(\rho_{00} e^{3g/2}) + p_0 \frac{d}{dt} e^{3g/2} = 0. \quad (23)$$

This important result can evidently also be obtained directly by combining Eqs. (20) and (21).

In accordance with the requirement (b) on which the line element was derived, particles which are at rest with respect to the coordinate system r, θ, ϕ will not be subject to acceleration but will remain at rest. And this can be directly verified by calculating the Christoffel three-index symbols which correspond to the line element (19) and substituting in the geodesic equation which governs the motions of particles in general relativity.

As a result of the foregoing, observers who are at rest with respect to the coordinate system will remain permanently so. And in accordance with the form of the line element (19), for such observers, the proper time as measured by local clocks will evidently agree with the coordinate time t . On the other hand, for the proper distance dl_0 as measured with rigid meter sticks we shall evidently have

$$dl_0 = \frac{e^{g/2} dr}{\sqrt{1 - r^2/R^2}} \quad (24)$$

for points at the coordinate distance dr in the radial direction, and

$$dl_0 = r e^{g/2} d\theta \quad \text{and} \quad dl_0 = r \sin \theta e^{g/2} d\phi \quad (25)$$

for the θ and ϕ directions. For the proper volume dV_0 associated with a given small range of coordinates we shall have

$$dV_0 = \frac{r^2 \sin \theta e^{3g/2}}{\sqrt{1 - r^2/R^2}} dr d\theta d\phi. \quad (26)$$

Although particles which are at rest in the coordinate system r, θ, ϕ will remain so, nevertheless it is evident from Eqs. (24) and (25), that the proper distance between such particles as measured with rigid meter sticks will in general be changing with the time, since the exponent g is itself a function of

¹² See reference 11, Eq. (4).

the time. Thus for the proper distance between a particle located at the origin $r=0$ and a particle permanently located at the coordinate distance $r=r$, we shall have

$$l_0 = \int_0^r \frac{e^{g/2} dr}{\sqrt{1 - r^2/R^2}} = e^{g/2} R \sin^{-1} \frac{r}{R} \quad (27)$$

and this will be increasing or decreasing with the time in accordance with the dependence of g on the time. Also in accordance with Eq. (26), the proper volume associated with a given coordinate range will be a function of the time, and for the proper volume of the universe as a whole we shall have

$$V_0 = \int_0^{2\pi} \int_0^\pi \int_0^R \frac{r^2 \sin \theta e^{3g/2}}{\sqrt{1 - r^2/R^2}} dr d\theta d\phi = \pi^2 R^3 e^{3g/2}. \quad (28)$$

In accordance with this result it is natural to consider $Re^{g/2}$ as the radius of the universe and to speak of an expanding universe if g is increasing with the time and of a contracting universe if g is decreasing with the time.

The change with time in the proper distance between objects in the universe leads to a shift in the observed wave-length of light coming from distant objects, a shift towards the red in an expanding universe and a shift towards the violet in a contracting universe. The magnitude of this shift is given by the formula¹³

$$\frac{\lambda_0 + \delta\lambda}{\lambda_0} = e^{(g - g_0)/2} \quad (29)$$

where g_0 is the value of the exponent occurring in the general expression for the line element at the time when the light was emitted with the original wave-length λ_0 , and g is its value at the time the light is received and observed to have the wave-length $\lambda_0 + \delta\lambda$.

In accordance with this formula we may regard the wave-length, which would be found by a local observer for any given quantum of light, as a quantity which is changing with the time in accordance with the change of g with the time. And, indeed, differentiating Eq. (29) with respect to the time we can evidently write

$$\frac{1}{\lambda} \frac{d\lambda}{dt} = \frac{1}{\lambda_0 + \delta\lambda} \frac{d}{dt} (\lambda_0 + \delta\lambda) = \frac{1}{2} \frac{dg}{dt} \quad (30)$$

as an expression for the fractional change in the wave-length of any given quantum with the time. Or in terms of frequency we can write

$$\frac{1}{\nu} \frac{d\nu}{dt} = - \frac{1}{2} \frac{dg}{dt} \quad (31)$$

as an expression for the change in the frequency of radiation with the time, ν being, of course, the frequency as measured by proper observers who are at rest with respect to the fluid in the universe and hence also at rest with respect to the coordinates r, θ, ϕ .

¹³ See reference 11, Eq. (21).

This completes the statement of general properties of the non-static universe which we shall need in discussing our special model.

§11. Properties of non-static universe filled with black-body radiation.

We may now turn to the discussion of the special model in which we take the thermodynamic fluid filling the universe to be a uniform distribution of black-body radiation of the same proper density throughout, a proper observer being one who finds no net flow of radiation.

Under these circumstances we can obtain a great simplification in treatment since it is evident that the proper macroscopic density of the fluid ρ_{00} and its proper pressure p_0 will be related by the well-known expression connecting the density and pressure of radiation

$$\rho_{00} = 3p_0. \quad (32)$$

And this permits us to obtain an immediate relation between the pressure of radiation in such a universe and the time variable g , since by substituting in the general Eq. (23) we have

$$3 \frac{d}{dt}(p_0 e^{3g/2}) + p_0 \frac{d}{dt} e^{3g/2} = 0 \quad (33)$$

and this can at once be integrated to give

$$p_0 = A e^{-2g} \quad \text{and} \quad \rho_{00} = 3A e^{-2g} \quad (34)$$

where A is the constant of integration, the pressure and density of radiation thus being quantities which decrease as the radius of the universe $R e^{g/2}$ increases.

As an important consequence of this result it now becomes possible to obtain a solution for g as a function of t . Substituting the expression for proper density given by Eq. (34) into Eq. (21) we obtain after some rearrangement

$$\frac{d}{dt}(e^g) = \pm \sqrt{32\pi A - \frac{4}{R^2} e^g + \frac{4}{3} \Lambda e^{2g}} \quad (35)$$

as a differential equation for the dependence of g on t , where the plus sign corresponds to an expanding universe and the negative sign to a contracting universe. Eq. (35) can itself then easily be integrated to give an explicit solution for g as a function of t . The form of the solution will depend on the sign of the cosmological constant Λ , and it is merely of interest for our present purposes to remark that for the case of a universe containing nothing but radiation there appears to be no solution, having physical reality, which would make g a periodic function of t .

As the most important consequence, however, of the expression for density given by Eq. (34), we can now show that the changes taking place in such a universe on account of the changing value of g are thermodynamically reversible. In accordance with Eq. (34) and the well known relation of Boltz-

mann connecting the density of black-body radiation with its temperature, we can write

$$\rho_{00} = 3Ae^{-2g} = aT_0^4 \quad (36)$$

where a is the Stefan-Boltzmann constant and T_0 is the proper temperature. Solving this for the temperature and substituting in the known expression for the entropy density of black-body radiation, we obtain

$$\phi_0 = \frac{4}{3} aT_0^3 = 4 \left(\frac{a}{3} \right)^{1/4} A^{3/4} e^{-3g/2} \quad (37)$$

as an expression for the proper entropy density of our fluid.¹⁴ On the other hand in accordance with Eq. (26) we have

$$dV_0 = \frac{r^2 \sin \theta e^{3g/2}}{\sqrt{1 - n^2/R^2}} dr d\theta d\phi \quad (38)$$

as an expression for the proper volume associated with the coordinate range $dr d\theta d\phi$. Hence combining the two expressions (37) and (38), we can evidently write

$$\frac{\partial}{\partial t} (\phi_0 dV_0) = 0 \quad (39)$$

since g is the only quantity involved which depends on the time and this is seen to cancel out from the product.

The final result, however, is the very expression which we obtained in Part II (§7, Eq. (18)) as a general condition for a reversible process in relativistic thermodynamics. And since g and hence ϕ_0 will in general be changing in such a universe at a finite rate, we have thus actually illustrated by a specific example the possibility provided by relativistic thermodynamics for reversible processes to take place at a finite rate.

§12. Interpretation by an ordinary observer of phenomena in an expanding universe filled with radiation.

Turning our attention now in particular to the case of expansion, with the radius $Re^{g/2}$ increasing with the time, we can show that the special model of a universe, filled with black-body radiation and expanding reversibly without increase in entropy, would nevertheless exhibit important phenomena which

¹⁴ The relations connecting energy density and entropy density with temperature, used in (36) and (37), presuppose that the frequency distribution of the radiation remains that for black-body radiation for all values of g . This introduces no difficulty, however, since even if there were a tendency for the frequency distribution to change away from that for black-body radiation, as the size of the universe changes, this could be prevented by the introduction of a small amount of material to act as a catalyst; and in actuality there is of course no such tendency since it would involve a decrease in entropy. In addition it can be shown in detail that the dependencies of frequency and energy density on g given by Eqs. (31) and (34) are such as to preserve the black-body distribution of frequency for all values of g , if we have such a distribution for one value of g .

would be interpreted by an ordinary observer as similar to phenomena in the actual universe which have been regarded in the past as important evidence for an increasing entropy of the universe. To obtain a description of these phenomena, we shall consider that the observer in question marks out a small region of the universe in his immediate vicinity, using rigid meter sticks, and then studies the changes taking place in this region. We shall then show that the observer will find the density of energy in this region and the total energy content of the region continually decreasing with the time, its temperature dropping, the number of light quanta leaving the region always greater than the number entering, and the average frequency of the quanta which leave greater than the average frequency of those that enter. Evidently our ordinary unsophisticated observer would interpret these findings as evidence that his immediate neighborhood was cooling off by radiation into the colder depths of space, and with a knowledge only of the classical thermodynamics he would conclude that the entropy of the universe was increasing at an enormous rate, in spite of the fact that the relativistic thermodynamics, which must be used under the circumstances, actually shows that there would be no increase in entropy in such a universe. The analogy between the phenomena interpreted by this unsophisticated observer as leading to an increase of entropy and phenomena in the actual universe which have hitherto been interpreted in a similar manner is close enough so that we must certainly be cautious lest we draw too hasty conclusions as to increases in entropy in our actual universe.

To proceed now to the detailed exposition, let us consider that the observer in our idealized model of the universe is located for convenience at the origin of the r, θ, ϕ system of coordinates and is provided with a rigid scale of proper length dl_0 . With the help of this scale he marks out a small sphere around the origin of constant proper radius l_0 , which gives him a small region of the universe in his immediate vicinity to serve as the subject of his studies.

For the relation between the constant proper radius of this sphere and the coordinate r of its boundary we may evidently write in accordance with Eq. (24)

$$l_0 = \int_0^r \frac{e^{g/2} dr}{\sqrt{1 - r^2/R^2}} = e^{g/2} R \sin^{-1} \frac{r}{R} \quad (40)$$

and for the case in hand where the sphere considered is very small compared with the whole universe, so that r is small compared with R , we obtain from this the approximate relation

$$r \approx l_0 e^{-g/2}. \quad (41)$$

Since the proper radius of the sphere l_0 is constant by hypothesis, we note that the coordinate r of its boundary is a quantity which is decreasing with the time in an expanding universe owing to the increase in g with time.

For the proper volume of this sphere contained within the radius l_0 we can evidently write in accordance with Eq. (26)

$$\begin{aligned}
 V_0 &= \int_0^r \frac{4\pi r^2 e^{3g/2} dr}{\sqrt{1 - r^2/R^2}} \\
 &= 4\pi e^{3g/2} R \left[-\frac{r}{2} \sqrt{R^2 - r^2} + \frac{R^2}{2} \sin^{-1} \frac{r}{R} \right]_0^r.
 \end{aligned} \tag{42}$$

Developing this in the form of a series in r/R and neglecting higher powers, we obtain

$$\begin{aligned}
 V_0 &= 4\pi e^{3g/2} R^3 \left(-\frac{1}{2} \frac{r}{R} + \frac{1}{4} \frac{r^3}{R^3} + \frac{1}{16} \frac{r^5}{R^5} + \cdots \right. \\
 &\quad \left. + \frac{1}{2} \frac{r}{R} + \frac{1}{12} \frac{r^3}{R^3} + \frac{3}{80} \frac{r^5}{R^5} + \cdots \right) \approx \frac{4}{3} \pi r^3 e^{3g/2}. \tag{43}
 \end{aligned}$$

And substituting the value of r given by Eq. (41), we obtain for the proper volume of the sphere in terms of its proper radius l_0 , as a close approximation, the result which might be expected

$$V_0 = \frac{4}{3} \pi l_0^3 \tag{44}$$

which is a constant independent of the time.

We may now consider the nature of the observations which our observer would find in studying this sphere of constant measured radius which he has marked off.

As a result of Eq. (34), the proper energy density at every point in our special model of the universe would be changing with the time t in accordance with the expression

$$\frac{1}{\rho_{00}} \frac{d\rho_{00}}{dt} = -2 \frac{dg}{dt}. \tag{45}$$

Moreover, the measurements of energy density which our observer would make in his immediate neighborhood would actually be measurements of proper energy density, and from the form of the line element (19) the proper time which he uses would agree with the coordinate time t . Hence it is evident that our observer would find the energy density in his vicinity to be decreasing with the time in accordance with Eq. (45).

Furthermore, in accordance with Eq. (44), the proper volume of his sphere of constant measured radius is itself independent of the time. Hence it is evident that our observer would find the total energy content E_0 of his sphere decreasing at the rate

$$\frac{1}{E_0} \frac{dE_0}{dt} = -2 \frac{dg}{dt}. \tag{46}$$

In addition, owing to the relation between energy density and temperature for black-body radiation given by Eq. (36), it is evident that our observer would find the temperature in his vicinity to be dropping at the rate

$$\frac{1}{T_0} \frac{dT_0}{dt} = -\frac{1}{2} \frac{dg}{dt}. \tag{47}$$

Still further, since the total number of light quanta in the universe would be independent of the time, and the proper volume of the universe as a whole would be increasing with the time while the proper volume of the observer's sphere remained constant, it is evident that the observer would find a larger number of light quanta leaving his sphere per second than entering. To calculate this excess we may evidently write for the number of quanta n inside the sphere in terms of the total number of quanta N in the universe

$$n = \frac{\frac{4}{3} \pi l_0^3}{\pi^2 R^3 e^{3g/2}} N \quad (48)$$

where the numerator of the fraction is the proper volume of the sphere as given by Eq. (44) and the denominator is the total proper volume of the universe as given by Eq. (28). And carrying out a logarithmic differentiation of this with respect to the time we obtain

$$\frac{1}{n} \frac{dn}{dt} = - \frac{3}{2} \frac{dg}{dt} \quad (49)$$

which gives the net loss per unit time in the number of quanta within the observer's sphere. The result so obtained, when combined with the rate at which the frequencies of the quanta are decreasing with the time as given by Eq. (31), is just sufficient to account for the rate of decrease in the proper energy of the observer's sphere as given by Eq. (46).

Finally, we may point out a curious circumstance which would reinforce our unsophisticated observer in his interpretation of the above phenomena as radiation into surroundings of lower temperature. Let us suppose that our observer, ever active in his scientific investigations, stations one of his assistants on the boundary of his sphere at the fixed distance l_0 from the origin as measured with rigid meter sticks, and instructs him to observe the average frequency of the light entering and leaving the sphere through its surface. This assistant will not be at rest in the coordinate system r, θ, ϕ , but in accordance with Eq. (41) will have the coordinate velocity

$$\frac{dr}{dt} = - \frac{1}{2} l_0 e^{-g/2} \frac{dg}{dt} = - \frac{1}{2} r \frac{dg}{dt}. \quad (50)$$

Hence, since it is evident that the average frequency of the radiation would be independent of direction for an observer at rest in the coordinate system, this assistant will find the average frequency of the radiation entering the sphere less than that of the radiation leaving the sphere, as a result of the Doppler effect corresponding to the velocity given by Eq. (50).

This completes a considerable chain of evidence which would lead an ordinary observer, unfamiliar with the expansion of the universe, to conclude that the region in his immediate neighborhood was cooling off by radiation into surroundings of lower temperature, in spite of the fact that the changes taking place in the model actually involve no increase in entropy. The analogy

between the findings of this observer in the hypothetical model and those of the classical thermodynamist in the actual universe is very striking.

PART IV. CONCLUSION

§13. Summary.

In the foregoing article an attempt has been made to show the bearing of relativistic thermodynamics on the well-known problem of the entropy of the universe as a whole. The origin of this problem lies in the difficulties encountered by the classical thermodynamics,—first in failing to account for the presumed fact that the entropy of the universe has always been increasing at an enormous rate and nevertheless has not yet reached its maximum value,—and second in failing to allow an emotionally satisfactory feeling towards our universe whose ultimate fate would be the stagnation of “heat-death.”

In the present article a brief description was first given of various older contributions to the solution of this problem, which have been based on the standpoints of the classical thermodynamics and statistical mechanics. This was done in order to show the very different character of the new contribution proposed in this article. A summarized account of the nature of this contribution may now be given.

The problem of the entropy of the universe arises because of the commonly accepted conclusion that the entropy of the universe is actually increasing at an enormous rate, and this conclusion is in turn based on the presumption, familiar in classical thermodynamics, that thermodynamic processes cannot be taking place at a finite rate, as observed, and at the same time reversibly without increase in entropy. The general nature of the contribution to the problem offered by relativistic thermodynamics lies in showing that there can be thermodynamic processes which take place both reversibly and at a finite rate.

To illustrate this difference between the classical and relativistic thermodynamics, we may consider the possibility of carrying out a reversible change in the thermodynamic properties of a finite portion of thermodynamic fluid. In the classical mechanics it is found that no internal motions of the fluid, no flow of heat, and no change in volume can be allowed to take place at a finite rate and hence that no change at all in the thermodynamic properties of the fluid can take place at a finite rate, the entropy density of the fluid remaining constant in accordance with the equation

$$\frac{d\phi_0}{dt} = 0.$$

On the other hand, in relativistic thermodynamics it appears possible to allow changes in the proper volume of the fluid, due to changes in the gravitational potentials, to take place at a finite rate and still maintain reversibility. Indeed, the condition for reversibility is found to be satisfied if we have at each point in the fluid the relation

$$\frac{\partial}{\partial x_4} \left(\phi_0 \sqrt{-g} \frac{dx_4}{ds} dx_1 dx_2 dx_3 \right) = \frac{\partial}{\partial x_4} (\phi_0 dV_0) = 0$$

and this permits a finite rate of change in the proper entropy density ϕ_0 with the time x_4 , provided it satisfies the equation

$$\left(\sqrt{-g} \frac{dx_4}{ds} \right) \frac{\partial \phi_0}{\partial x_4} + \phi_0 \frac{\partial}{\partial x_4} \left(\sqrt{-g} \frac{dx_4}{ds} \right) = 0.$$

To exhibit the nature of the reversible changes at a finite rate thus permitted in relativistic thermodynamics, we may consider the highly idealized model of a non-static universe filled with black-body radiation as our thermodynamic fluid. It is found that the radius and total proper volume of such a universe could be changing at a finite rate with the time and yet reversibly without increase in entropy.

Furthermore, if we take the case of an expanding universe and consider an observer who marks out with rigid meter sticks a small region of the universe in his vicinity, it can be shown that he would find the energy density, the energy content, and the temperature of this region decreasing with the time, and in addition would find the number of light quanta leaving the region per second greater than the number returning and the average frequency of those passing outward through the boundary greater than that of those returning. He would thus be led to interpret the phenomena taking place in such a universe as a flow of radiation from his immediate neighborhood out into the colder regions of space, in spite of the fact that the changes in the universe would in reality be taking place without any increase in entropy.

The general nature of the contribution to the problem of entropy made in this article has thus been to show that phenomena which have hitherto been regarded from the point of view of classical thermodynamics as furnishing unmistakable evidence for an increasing entropy in the universe are not necessarily leading to any increase in entropy at all, and to emphasize the necessity for analyzing the phenomena of the universe from the more acceptable point of view of relativistic thermodynamics before conclusions are drawn as to what extent the entropy of the universe is increasing if at all.

§14. Critique.

Finally a few words of criticism will not be out of place. The foregoing statement as to the nature of the contribution made in this article carries with it at least the possible implication that an analysis of the phenomena of the actual universe from the standpoint of relativistic thermodynamics would show that there are in reality no important changes at all taking place in the entropy of the universe.

I feel, however, that although the article has clearly demonstrated the necessity of using relativistic thermodynamics in analyzing the entropy changes of the universe as a whole, it would be premature to assert too precisely what is to be expected as the result of such an analysis until it has been applied to a model of the universe which is not so over-simplified as the one

employed in this article. This model of a universe, containing nothing but radiation, neglects two of the most characteristic features of the actual universe, namely the presence of matter and its high degree of concentration into stellar systems. At a later time I hope to give more consideration to these properties of the universe. They appear, however, greatly to increase the mathematical complexity of the problem and for this reason I have contented myself for the present with a very simple model, which can nevertheless give us considerable insight into the problem of the entropy of the universe.

One feature of the model which was mentioned in §11 should perhaps be emphasized, namely that there appear to be no periodic solutions of Eq. (35) for g as a function of t which would have physical interest. Hence if we had an expanding model of the kind considered it would continue to expand, reversibly to be sure, but without actual return to its original condition. Our model is so over-simplified, however, that we must not conclude therefrom that periodic solutions would not be of interest for the actual universe.

Further it should perhaps also be emphasized again that the theory of fluctuations may play an important part in a relatively complete treatment of the entropy of the universe. At the present time, however, we cannot say just how large this part may be.

In conclusion then, it has apparently been definitely demonstrated that the problem of the entropy of the universe as a whole must be treated with the help of relativistic rather than classical thermodynamics, and it has been shown that the application of relativistic thermodynamics to a highly over-simplified model of the universe gives results of great interest. It remains for the future, however, to consider the application of relativistic thermodynamics to more complicated models which would give a better approximation to the actual universe.

ON THE RESOLVING POWER OF A PRISM SPECTROMETER
FOR THE INFRARED

BY JOHN STRONG*

CALIFORNIA INSTITUTE OF TECHNOLOGY, PASADENA

(Received January 15, 1931)

ABSTRACT

The resolving power of a spectrometer in the infrared is limited by the rate at which energy passes through the exit slit of the spectrometer. Calculation of the energy available for activating a thermocouple, under condition that the exit slit embrace the same frequency range $\Delta\nu$ of spectrum at all times, gives information on the attainable resolving power at various wave-lengths and with various prisms. The best dispersing angle for a sylvine prism to be used from 8 to 22μ is from 70° to 75° . A lamellar prism construction is described.

INTRODUCTION

IN THE spectral region where a photographic plate, which measures the energy received during the time of exposure, is used, the resolving power of a spectrometer is limited by interference effects. However, in the infrared where a thermocouple or radiometer is used one does not measure the energy received over an arbitrary period of time but the rate at which energy is received. This available energy rather than interference effects places the limit on the resolving power of the spectrometer.

It was the purpose of this investigation to make calculations of the energy available for activating a receiver (such as a thermocouple). The energy of a continuous spectrum passing through the exit slit, with both slits equal, is proportional to the square of the slit width, so that if the value for the available energy at any particular wave-length and for a particular dispersing prism is greater, by a factor α , than the energy necessary to give a definite response of the receiving device, then the spectrometer slits may be closed by a factor $1/\alpha^{1/2}$ and still give a practical deflection. The available energy is therefore a measure of the resolving power which is attainable under varying conditions as long as the limit set by interference effects is not exceeded.

The calculation of available energy is instructive on account of the information that it gives regarding the resolving power attainable in various regions of the spectrum. The determination of the absorption spectrum of a gas in the infrared consists of a study of the heat radiations emitted from some convenient source and the changes in spectral energy distribution which result from the introduction of the gas into the radiation path. The spectrum emitted from a heated body possesses very little energy at long wave-lengths since the emission cannot exceed that from a black body which varies inversely with the fourth power of the wave-length. This scarcity of available

* National Research Fellow.

energy at long wave-lengths would seem to place a serious limitation upon the character of experimental work that might be done at long wave-lengths. However, the results of Robertson and Fox¹ with a rocksalt prism on the oscillation-rotation spectrum of ammonia and similar molecules shows a definite improvement in resolution at the longer wave-lengths. These calculations will show in a quantitative way that similar improvement at long wave-lengths is to be expected for a sylvine prism.

The calculation of available energy for various prisms shows the best prism to use for a particular spectral region. For the entire spectral range for which sylvine is a useful prism material, it is best to have as the dispersing angle of the prism 70 to 75 degrees. Usually a 60° prism is considered best but this is neither obvious nor a consequence of the classical works of Pickering² and of Wadsworth.³ These authors made calculations of the best dimensions for prisms made from materials having values for the refractive index varying between 1.5 and 1.8. Their calculations do not hold because sylvine has refractive indices below 1.5 in the infrared, also the formula used by Pickering and Wadsworth for the transmission of a prism is invalid except when the absorption is very low.

PRILIMINARY CONSIDERATIONS

When a band system in the infrared is plotted with wave number rather than wave-length as the abscissa one gets a more natural picture, since the fineness of structure is then approximately the same throughout the spectrum. On the other hand, if wave-length is used as abscissa, the structure appears coarser at longer wave-lengths and in fact if $\Delta\nu$ is taken as a measure of the fine structure of the band system the corresponding $\Delta\lambda$ becomes greater at longer wave-lengths according to the formula

$$\Delta\lambda = \frac{\lambda^2 \Delta\nu}{c}.$$

This means that if the slit of the spectrometer is adjusted so that the wave-length interval in the slit is increased proportionally with λ^2 it will embrace the same frequency range of spectrum. The energy passing through the exit slit is proportional to the spectral energy density of illumination of the slit, E_λ , multiplied by the square of the slit width. For a black body at long wave-lengths E_λ is proportional to λ^{-4} while for an ideal spectrometer having constant dispersion and constant efficiency the slit width, s , would be proportional to λ^2 and $E_\lambda s^2$, the energy passing through the exit slit, would be independent of λ . By constant efficiency it is meant that the same fraction of the energy of various wave-lengths is lost by reflection at the various surfaces in the optical path and by absorption in the prism. This means that the resolving power measured by the rational magnitude $\Delta\nu$ will be the same throughout the spectrum.

¹ R. Robertson and J. J. Fox, *Proc. Roy. Soc. A* **120**, 128 (1928).

² Pickering, *Phil. Mag.* (4), **36**, 39 (1868).

³ F. L. O. Wadsworth, *Astrophys. J.* **2**, 264 (1895).

For a spectrometer which is not ideal the energy passing through the exit slit increases as the dispersion increases and decreases as the efficiency decreases. $\delta n/\delta \lambda$ for the materials transparent in the infrared increases at longer wave-lengths while the transparency decreases. The dispersion factor predominates at first and so the available energy (when the slit width is constant as measured by $\Delta \nu$) increases and greater resolving power is attainable at longer wave-lengths. This for sylvine is a result similar to the experimental results of Robertson and Fox. The available energy passes through a maximum and rapidly decreases as the transparency factor becomes predominate. When the dispersing angle of the prism increases the dispersion increases, at first slowly, then rapidly, while the light lost by reflection increases. It was for the purpose of arriving at the best compromise between these varying factors that the following calculations were made.

ENERGY AVAILABLE TO ACTIVATE RECEIVER

For a simple prism spectrometer the energy, e , passing through the exit slit is given by the following expression

$$e = E_{\lambda} s_1 l_1 \frac{A}{f_1^2} \frac{s_2}{f_2} \frac{d\theta}{d\lambda} TFR.$$

The symbols are defined by the following formulas:

E_{λ} is the spectral energy density of illumination of the entrance slit and for long wave-lengths this is given by the Rayleigh-Jeans formula.

$$E_{\lambda} = \frac{4\pi k t}{\lambda^4}.$$

s_1 and l_1 , are width and length respectively of the entrance slit.

A is the effective area of the collimating mirror of the spectrometer. For a large collimating mirror this is the area of the prism face ($h \times b$ if h is the height of prism face and b the length) projected on the plane of the mirror face. If i is the angle of incidence of the light on the prism face, A is defined by the equation $A = h \times b \cos i$.

f_1 and f_2 are the focal lengths respectively of the collimating and telescope mirrors.

s_2 is the width of the exit slit.

$d\theta/d\lambda$ is the dispersion of the prism and it may be broken up into two factors $(\partial\theta/\partial n) \times \partial n/\partial \lambda$. For a prism at minimum deviation $\partial\theta/\partial n$ is given by $2 \sin(\phi/2)/\cos i$ where ϕ is the dispersing angle of the prism. Values of $\partial n/\partial \lambda$ are defined by the empirical formula given by Rubens⁴ for the index of refraction of sylvine.

T is the transmission of the prism. This is given by the formula

$$T = \frac{1}{k\tau} (1 - e^{-k\tau})$$

⁴ Rubens, Ann. d. Physik 54, 476 (1895); 60, 724 (1897).

The absorption coefficient is represented by κ and the width of the prism opposite the dispersing angle is represented by τ . For values of $\kappa\tau$ less than 0.1 the values of T are given approximately by the formula used by Pickering and Wadsworth in their work, $T = e^{-\kappa\tau/2}$. For values of $\kappa\tau$ greater than 5 the values of T are given approximately by $1/\kappa\tau$. Table I gives values of T for various values of $\kappa\tau$.

TABLE I.

$\kappa\tau$	T	$\kappa\tau$	T	$\kappa\tau$	T	$\kappa\tau$	T
0.01	0.995	0.11	0.946	0.1	0.952	1	0.632
.02	.989	.12	.943	.2	.906	2	.432
.03	.985	.13	.938	.3	.864	3	.317
.04	.980	.14	.934	.4	.824	4	.245
.05	.975	.15	.929	.5	.787	5	.198
.06	.970	.16	.924	.6	.752	6	.166
.07	.966	.17	.919	.7	.719	7	.143
.08	.961	.18	.915	.8	.688	8	.125

.10	.952	.20	.906	1.0	.632	10	.100

F is a factor which takes account of the loss of light due to reflections at the two prism surfaces and is represented by the following formula,

$$F = \left\{ \frac{1}{2} \left[1 - \frac{\sin^2(i-r)}{\sin^2(i+r)} \right] + \frac{1}{2} \left[1 - \frac{\tan^2(i-r)}{\tan^2(i+r)} \right] \right\}^2$$

where r is the angle of refraction at the prism face.

R is the total reflectivity of all the spectrometer mirrors and is considered constant. For eight normal reflections from polished silver the loss of light is 8 percent at 10μ and 4 percent at 20μ .

If $f_1 = f_2$ and if the spectrometer slits are equal and always adjusted so that the frequency interval they subtend is constant then s_1 and s_2 may be substituted for by the expression

$$s_2 = s_1 = f_1 \frac{d\theta}{d\lambda} \frac{\lambda^2 \Delta\nu_0}{c}$$

where $\Delta\nu_0$ corresponds to the constant frequency interval embraced by the slits.

Substituting in the formula for e gives

$$e = \frac{8\pi k t \Delta\nu_0^2 h b R}{c^2 f_1} T F \frac{\partial n}{\partial \lambda} \sin \frac{\phi}{2}$$

or

$$e \propto \epsilon = T F \frac{\partial n}{\partial \lambda} \sin \frac{\phi}{2}.$$

Values of F for various prism angles, ϕ , and various wave-lengths are given in Table II. For the calculation of ϵ given in Table III, τ was given the value 10 centimeters.

85°	8.2	10.7	14.6	16.5	18.1	18.9	15.5	5.4	5.2

It would seem impractical to narrow the slits narrower than the frequency interval $\Delta\nu'$ corresponding to the theoretical resolving power of the spectrometer. For a prism spectrometer this is given by the Rayleigh formula.

$$\Delta\nu' = \frac{-c}{\lambda(\partial n/\partial\lambda)\tau}$$

If the absorption coefficient is high only the apex of the prism will transmit radiation and the value of τ to be substituted in the formula is much less than the actual value of τ . In order to get an idea of how this limiting frequency interval, $\Delta\nu'$, varies as one goes deeper into the infrared it may be calculated using a value corresponding, for that wave-length in question, to a prism having a transmission of 95 percent. The values of $\tau_{T=.95}$ are given in Table IV

TABLE IV. Values of $\tau_{T=.95}$ and $\Delta\nu'$ for various wave-lengths.

λ	11.79 μ	12.96 μ	14.14 μ	15.91 μ	17.68 μ	20.6 μ	22.5 μ
κ	0.004	0.0175	0.0270	0.065	0.135	0.515	1.00 cm ⁻¹
$\tau_{T=.95}$	25	5.72	3.71	1.54	.74	.19	.10 cm
$\Delta\nu'$.75	2.6	3.4	6.2	9.9	26.4	38.4 cm ⁻¹

together with corresponding values of $\Delta\nu'$. It is interesting to compare these limiting frequencies with the resolving power successively realized by Burmeister, Eva von Bahr, Brinsmade and Kemble, Imes and Randall, and Meyer and Bronk in their classical investigations of the fundamental oscillation band of HCl. Their slit widths reduced to the same units used in Table IV are respectively 40, 10, 7, 4 and 3 cm⁻¹.

When only the apex of the prism transmits appreciably and it is not possible to realize the limiting resolving power on account of the insensitivity of

the receiver one may double or quadruple the energy passing through the exit slit by using two or four identical prisms side by side which are tall compared with τ . Such an arrangement is shown in Fig. 1. Since it is much easier to make a plane parallel plate than to make a prism whose faces make a prescribed angle with each other, an alternative arrangement is illustrated by Fig. 2. The back of each parallel plate is silvered by evaporation, the plates

Fig. 1.

Fig. 2.

are waxed together and the ensemble cut and polished along the dotted line so as to give a lamellar prism with dispersing angle 35° to 37.5° . This will form a Littrow half prism into which the light will not need to penetrate deeper than the thickness of the parallel plates used. It is, however, more advisable to use a prism which is more transparent in the desired spectral region.

CONCLUSION

From the values of ϵ given in Table III and the values of $\tau_{T=0.95}$ and $\Delta\nu'$ given in Table IV, we may draw the following conclusions.

1. A dispersing angle of 70° to 75° is best for a sylvine prism to be used from 8 to 22μ . Table III shows the available energy for these prism angles to be greater for all wave-lengths out to 18μ . Beyond 18μ , there is so little difference in the available energy that the construction of a special 15° prism for this region is not justified.

2. A sylvine prism with a 10 cm base is useful to 18μ . In spite of the fact that the energy for illuminating the entrance slit of the spectrometer decreases with the fourth power of the wave-length, it will be observed from Table III that the energy available for activating a thermocouple increases. This means that the resolving power increases at longer wave-lengths as long as the available energy, rather than interference effects, places the limit on the resolving power of the spectrometer.

3. Values of $\tau_{T=0.95}$ in Table IV show that only the apex of the prism transmits radiations. The available energy may be increased several fold by the use of a lamellar prism construction. This should make it possible to realize approximately the theoretical resolving power of one of the lamella. Such a lamellar prism would be particularly useful when the radiations are to be further dispersed with a grating. It is possible that the use of another prism material, such as potassium iodide (transparent to wave-lengths greater than 33μ) would be better. However, since no material is yet known which is more transparent than potassium iodide it may be advisable to use a lamellar

prism of this material in order to extend the region open to prism spectroscopy as far as possible. The optical properties of potassium bromide and potassium iodide are being investigated by the author so that a set of values of ϵ for all the infrared prism materials may be compiled.

4. An examination of the proportionality factor between e and ϵ shows the available energy is inversely proportional to the focal length of the spectrometer collimator. This result indicates that a spectrometer of the Pfund type would give the best resolution.

**The Effect of Meteors on Radio Transmission Through the
Kennelly-Heaviside Layer**

A consideration of the available data on meteor trains indicates (1) that meteors expend the larger part of their energy in the Kennelly-Heaviside layer,¹ that is, in that region of the upper atmosphere which controls the propagation of all long distance radio waves; (2) that a large fraction of the energy of a meteor goes into ionization of the air around its path;^{2,3} (3) that this ionization extends to a considerable distance from the actual path⁴—in some cases, several kilometers or more—and (4) that it lasts for some minutes after the meteor has passed.⁴

It is interesting to calculate the order of magnitude of the ionic concentration which may be produced and to compare it with the concentration which is generally assumed in order to explain short wave radio phenomena. Meteors are believed to vary in mass from a few milligrams to several kilograms and larger, according to different estimators. If the mass of a meteor is taken as one gram, its velocity as 40 km/sec., its length of path as 200 km and the range of ionization around the path as 1/2 km, the concentration of ionization on the above assumptions would be of the order of 10^6 ions per cc. The maximum ionization deduced from radio data is of the order of 10^5 electrons per cc. It is therefore apparent that transmission of radio signals might be markedly affected by the presence of meteors along the path.

Data taken during radio measurements of the heights of the ionized layer, furnish evidence for such an effect. Thus Heising⁵ finds that the deflecting layer seems to experience very sudden drops as though a large amount of ionization suddenly appeared, accompanied for a moment by turbulence, after which the layer gradually returns to the normal height. The frequency of such sudden variations is

reasonably consistent with the number which would be expected for the particular length of path used, on the assumption of 10^9 meteors of random direction per day for the whole earth.⁶

The orbital motion of the earth increases the relative velocity of the meteors which are observed after midnight and it is an observed fact that the number of meteors has a maximum between 2:00 and 3:00 A.M. Both of these facts would increase the contribution of ionization which is due to meteors and might even result in a lowering of the Kennelly-Heaviside layer after midnight. A number of investigators have observed such a drop after midnight. Moreover, on the basis of the above calculations and assuming that the ions produced have an average life of one hour, the total ionization produced by meteors is of the correct order of magnitude to produce the effect observed.

The foregoing evidence, while admittedly sketchy, indicates that the ionizing effect of meteors in the Kennelly-Heaviside regions may be an important factor in short wave radio propagation through the upper atmosphere. It is planned to make tests during future meteoric showers in order to obtain further information on the subject.

Raman Spectrum of the Hydroxyl Ion with High Dispersion

The Raman spectrum of a 10*N* aqueous solution of potassium hydroxide was photographed with a Hilger E1 large quartz spectrograph, using for excitation a hot-cathode helium arc of length 45 cm. The Pyrex tube which contained the solution was surrounded by a filter tube of nickel oxide glass, and the light was focused on it by an elliptical reflector. An exposure time of 100 hours was required.

The spectrum obtained consists of a single broad line having a fairly well defined intensity-maximum which corresponds to a frequency shift of $3603 \pm 4 \text{ cm}^{-1}$. This is in good agreement with the value of $3615 \pm 25 \text{ cm}^{-1}$ recently reported by Woodward.¹ It is somewhat lower than the shift of 3630 cm^{-1} found by Krishnamurti² in crystalline sodium hy-

droxide. The line has a width of about 30 cm^{-1} . That it must be attributed to the hydroxyl ion is beyond doubt.

It was observed that the presence of dissolved sodium or potassium hydroxide greatly influences the structure and the intensity of the water band. We have studied this effect in solutions of various concentrations, using a spectrograph of smaller dispersion. The results will soon be reported in detail.

The Relative Abundance of the Oxygen Isotopes, and the Basis of the Atomic Weight System

Mecke and Childs,¹ as the result of a detailed quantitative investigation of the *A* and *A'* bands of oxygen, find the relative abundance of the oxygen isotopes O^{16} and O^{18} to be 630:1, in sharp contrast to the value 1250:1 found by Babcock² and 1075:1 found by Naudé.³ We have made a careful study of Mecke and Childs' paper, and find several rather doubtful theoretical assumptions. We have accordingly recalculated a portion of their data, using a method that appears to us to be more reliable. Their final result is, however, not essentially changed, and it therefore seems unnecessary to publish the details.

We have also examined Babcock's assumptions, and find two sources of possible error, one due to the fact that the rotational energy levels of the $\text{O}^{16}\text{O}^{18}$ molecule differ from those of the $\text{O}^{16}\text{O}^{16}$ molecule, and the other due to the fact that, in Babcock's work, the mean temperature of the $\text{O}^{16}\text{O}^{18}$ molecule (in the atmosphere) differs from the temperature of the $\text{O}^{16}\text{O}^{16}$ molecule (in the laboratory). Both the energy and the temperature affect the Boltzmann factor, but fortunately the two errors thus introduced by Babcock's neglect of this factor tend to cancel. We find that for the lines used by Babcock,⁴ the maximum resulting error is not more than about ten percent, and so is quite negligible.

Mecke and Childs suggest several possible sources of error in the work of Naudé, but we do not have the information necessary in order to discuss these suggestions. As far as the work of Babcock and of Mecke and Childs is concerned, it would appear that the discrepancy must be due mainly to experimental and not to theoretical errors. It would also appear that the Mecke and Childs result is entitled to much greater weight.

Assuming for the sake of argument that the abundance ratio is really 630 to 1, it follows, as noted by Mecke and Childs, that atomic masses based on $\text{O}^{16}=16$ should be 2.2 parts in 10^4 greater than those based on the chemical system $\text{O}=16$. It is accordingly of importance to test Aston's mass-spectrograph results⁵ on this new basis. Aston,⁶ Birge,⁷ and Naudé³ have previously considered this mat-

¹ R. Mecke and W. H. J. Childs, *Zeits. f. Physik* **68**, 362 (1931).

² H. D. Babcock, *Proc. Nat. Acad. Sci.* **15**, 471 (1929).

³ S. M. Naudé, *Phys. Rev.* **36**, 333 (1930).

⁴ According to a personal communication from Babcock, only the first few lines of the *P* branch were used.

⁵ F. W. Aston, *Proc. Roy. Soc. A* **115**, 487 (1927).

⁶ F. W. Aston, *Nature* **123**, 488 (1929).

ter, but the conclusions depend markedly on the values adopted for the chemical atomic weights. One of us⁷ has already found that the rounded values ordinarily published in atomic-weight tables are not sufficiently accurate for a discussion like this.

Nearly all of Aston's precision measurements are concerned, unfortunately, with elements that are known to consist of a mixture of isotopes. In such cases it is necessary to know the relative abundance of the isotopes of the element in question, as well as of oxygen, in order to compare Aston's result with the chemical atomic weight. For elements like carbon and nitrogen, the two resulting corrections (for oxygen, and for the element in question) tend to cancel, so that Aston's result should agree closely with the chemical atomic weight. Thus in the case of carbon the most probable atomic weight⁷ is 12.0025. Aston's mass C^{12} is 12.0036, which becomes 12.0010 on division by 1.00022 in order to reduce to the chemical scale. Then to obtain an atomic weight of 12.0025, the relative abundance C^{12}/C^{13} should be 650. King and Birge⁸ give 400 for this figure, but their discussion shows that 650 is an equally possible value.

The best atomic weight of nitrogen⁹ is 14.008. Aston finds $N^{14} = 14.008$. To bring the two results into agreement requires a relative abundance $N^{14}/N^{15} = 320$. Naudé found that the abundance $N^{14}/N^{15} = 0.65$ of O^{16}/O^{18} . Using Mecke and Childs' value of O^{16}/O^{18} , one obtains $N^{14}/N^{15} = 409$, a very satisfactory agreement.

The best atomic weight of helium appears to be⁷ 4.0018. Aston obtained 4.00216, or 4.00127 on the chemical scale. The discrepancy is only 1.1 parts in 10^4 , which is within the published limits of error. The most accurate atomic weight of fluorine is due to Moles and Batuecas¹⁰, from the molecular weight of FCH_3 . Using the present best values for C and H, their result is 18.995 ± 0.005 . Aston obtains 19.000, or 18.996 when reduced to the chemical scale. The agreement is entirely satisfactory. In the case of iodine, Aston's result is identical with the best chemical value. The connection with oxygen, in the mass-spectrograph work, is rather indirect, and it is therefore doubtful if this result can be considered to furnish independent evidence on the question. In the case of phosphorus it is the chemical value that is uncertain.

Of the elements that permit an accurate

comparison of the chemical and mass-spectrograph results, there remains only hydrogen. The chemical value⁷ is 1.00777 ± 0.00002 (probable error), as compared with Aston's 1.00778 ± 0.00015 (*limit* of error). Aston's value, reduced to the chemical scale, is 1.00756 and the discrepancy appears to be outside the limits of error. It could be removed by postulating the existence of an isotope of hydrogen of mass 2, with a relative abundance $H^1/H^2 = 4500$. It should be possible, although difficult, to detect such an isotope by means of band spectra.

The above discussion shows that, with the exception of hydrogen, the new Mecke and Childs' abundance ratio gives a satisfactory agreement between the mass-spectrograph and the chemical results. The agreement is in fact somewhat better than that obtained with an assumed abundance ratio of 1250 to 1, or of 1070 to 1. The case of hydrogen, however, distinctly calls for further investigation.

Aston¹¹ has asked for suggestions as to the best basis for chemical atomic weights and atomic masses. We believe that the facts presented in this letter indicate that, from the experimental standpoint, the quantitative relation between the *mean* atomic weight of oxygen, and the mass of the atomic species O^{16} is rather uncertain at the present time, and is likely to remain so for the present. It should also be pointed out that there is as yet no *proof* that the relative abundance of the oxygen isotopes, in different sources, is strictly constant.¹² The possibility that the relative abundance is *not* constant is the most compelling argument for a change in the basis of the atomic-weight system. What that change should be can best be decided by chemists, but we believe that further data are needed before any change is seriously considered. The one point we wish to emphasize here is that there

¹² The mass-spectrograph is perhaps the most reliable method for investigating this question.

now exist two systems for the measurement of atomic masses, connected by a relatively *uncertain* factor. For that reason it seems best, for the present, not to convert results obtained on one system into the other system, by

the use of some assumed conversion factor.

The Masses of O^{17}

The writers have recently built a new accurate apparatus, in order to obtain, among other values, more exact masses for the nucleus of O^{17} , since they had concluded that additional data were needed in order to establish definite relations. Urey,¹ however, considers that the data already available demonstrate the existence of three quantum states for this nucleus.

The purpose of this letter is (1) to give, as a minor change, a different set of values for the

ranges of the protons; (2) what is more important, to point out that while we do not disagree with Urey's conclusion above, it seems to us that the few available data should be classified in a slightly different way; (3) and to add a calculation, omitted by Urey, of an inelastic collision between an α -particle and a nitrogen atom as obtained by Harkins and Shadduck.²

The data given in this paper lead to the following calculated values:

TABLE I.

M_0 (nucleus)	M_0 (atom)	$\Delta M_1 \times 10^5$	$\Delta M_2 \times 10^5$
16.99891	17.00328	1	12

Here M_0 represents the rest mass of the oxygen, ΔM_1 is the error of M_0 introduced by a 1 percent error in the energy of the α -particle, and ΔM_2 that due to an error of 10° in the angle ω between the track of the α -particle

and that of the oxygen nucleus. In the calculation, the value 14.00800 (Aston) is taken as the rest mass of the nitrogen atom, as was presumably done also by Urey. The values are collected as follows:

TABLE II. *Mass of O^{17} .*

Track	M_0 (atom)	Average M_0 (atom)
B4	17.00508	High level 17.00508
B5	17.00330	Middle level 17.00319 0.00189
H+S 1	17.00328	
B3	17.00300	
B2	17.00148	Low level 17.00148 0.00171

The values differ somewhat from those of Urey, who omits track H+S 1.

We have excluded from this table the cal-

culated values for the following four tracks as not having a sufficient bearing upon the division into the above three groups.

TABLE III.

Track	M_0 (atom)	Reason for rejection from Table II
H+S 3	17.0050	Agrees well with the value 17.00508 for the B4 track, but one of the pair of photographs of the event was not clear
B7	17.00402	Tracks curved (rejected by Urey)
B6	17.00293	Angle ω too small to give accuracy in M_0
B1	17.00370	Probably as accurate as those listed in Table II, but deviates too far from mean of other three in middle level to offer evidence in favor of the existence of this level

¹ Urey, Phys. Rev. (2) 37, 923 (1931).

² Harkins and Shadduck, Proc. Nat. Acad. Sci. 12, 707 (1926).

Thus, according to our classification,

- (1) the lowest level is represented by only one value,
- (2) the middle level by three values, and
- (3) the high level by only one value.

The ranges of the protons emitted are given

in Table IV. Urey assumes that the range varies as the cube of the initial velocity, but a closer approximation is probably given by use of the 3.5 power, as is done by Chadwick, Constable and Pollard.³ On this basis, the ranges in cm at 15° and 760 mm are:

TABLE IV.

B4	B6	H+S 1	B3	B5	B1	B7	B2
17.3	18.8	20.4	25.0	25.0	31.9	38.6	59.7

Except for the highest values, this change of power does not give a great increase of range.

It may be noted that the values of ω , the

angle between the extension of the track of the α -particle and that of the oxygen nucleus, is always small. The observed values are:

TABLE V.

B6	H+S 1	B4	B7	B3	B1	B5	B2
7° 54'	15° 21'	19° 24'	21°	21° 13'	22° 0'	22° 12'	28° 51'

This angle is always small because (1) the initial velocity of the proton is limited, (2) the mass of the oxygen is relatively high, and (3) no disintegration has as yet been observed with certainty by the photographic method were the velocity of the α -particle at impact is less than 1.83×10^9 cm per sec.

Some additional evidence for the validity of the three levels in the O^{17} nucleus seems to be given by the fact that the differences between the average masses are moderately

nearly equal, as shown in Table II by the values 0.00189 and 0.00171. However, additional experimental evidence is needed for the definite determination of the energy levels.

The Electrical State of the Sun. A Correction

Dr. H. B. Maris of this laboratory has kindly brought to my attention an error in the above entitled paper (Phys. Rev. 37, 983 (1931)) which effectively nullifies the paragraph containing arguments and calculations purporting to show that the sun is electrically neutral. In Eq. (3), Q represents the free electrical charge per unit length of the equivalent circuit rather than the total free electrical charge. On making the correction we find that, although other evidence indicates that the sun is electrically neutral, our magnetic calculation, alone, is quite incapable of establishing that fact.

The corrected calculated value of the galactic magnetic field according to Anderson's hypothesis of the annihilation of positive electrical charge is still so large (10^3 gauss) as to be impossible and our original conclusion is therefore unchanged. The incorrect assignment of the value of Q did not affect the detailed calculations in other sections of the paper.

ERRATA

RADIATION OF MULTIPOLES

BY KARL F. HERZFELD

Department of Physics, The Johns Hopkins University

(Phys. Rev. 37, 253, 1931)

In a paper which appeared under this title there are unfortunately some mistakes, the correct formulas are given below:

On page 256 the following formula (9)

$$\psi = \sum c_k \psi_k e^{-2\pi i k \nu t} \quad \psi_k = e^{-\xi^2/2} H_k(\xi) b_k$$

Same page, before formula (10)

$$b_k = \left(2^{-k} \frac{1}{k!} \left(\frac{4\pi M \nu}{h} \right)^{1/2} \right)^{1/2}$$

Instead of formula (16) on page 258

$$a_i^{(k)} = \frac{k!}{i!} 2^i (-1)^{(k-i)/2} \frac{1}{\left(\frac{k-i}{2}\right)!} \text{ for } k-i \text{ even.} \quad (16)$$

At the bottom of page 258 and on top of 259.

$$\begin{aligned} I_{k,s}^{(n)} &= 0 \text{ if } s-n \text{ odd} \\ &= \pi^{1/2} \sum_{j=0}^{(n-s)/2} \frac{(4j)!}{2^j (2j)!} (2j+k+s) \cdots (2j+1) \\ &\quad (-1)^{j+(s-n)/2} 2^{2j+k+s-n} k! \frac{1}{\left(\frac{n-s}{2}-j\right)!} \frac{1}{(2j+k+s-n)!} \\ &= \pi^{1/2} (-1)^{(s-n)/2} 2^{k+s-n} k! \sum_{j=0}^q (-1)^j \frac{(4j)!}{(2j)!^2} \frac{1}{4^j} (2j+k+s)! \\ &\quad \times \frac{1}{(q-j)!} \frac{1}{(2j+k-q)!} \end{aligned} \quad (17)$$

with $n-s=2q$.

Finally for the formulas which occur in the middle of page 259

$$I_{k,2}^{(2)} = (\pi)^{1/2} 2^k k! \frac{(k+2)!}{(k!)} = (\pi)^{1/2} 2^k (k+2)!$$

If $n=3$ (tetraeder) there are possible two transitions

$s=1$, frequency ν

$$\begin{aligned} I_{k,1}^{(3)} &= -(\pi)^{1/2} 2^{k-2} k! \left\{ \frac{(k+1)!}{(k-1)!} - \frac{4!}{(2!)^2} \frac{1}{4} \frac{(k+3)!}{(k+1)!} \right\} \\ &= +(\pi)^{1/2} 2^{k-2} \left\{ \frac{3}{2} (k+2)(k+3) - k(k+1) \right\} k! \end{aligned}$$

$s=3$ frequency 3ν

$$I_{k,3}^{(3)} = (\pi)^{1/2} 2^k \frac{k!(k+3)!}{k!} = (\pi)^{1/2} (k+3)! 2^k.$$

In general, we have for $s=n$, frequency $n\nu$

$$I_{k,n}^{(n)} = (\pi)^{1/2} 2^k \frac{k!(k+s)!}{k!} = (\pi)^{1/2} 2^k (k+j)! \quad (18)$$

HYPERFINE STRUCTURE IN IONIZED BISMUTH

BY RUSSELL A. FISHER AND S. GOUDSMIT
Department of Physics, University of Michigan

(Phys. Rev. **37**, 1057, 1931)

The photograph of the hyperfine structure of Bi II 4705 (Fig. 2b) was unfortunately inverted. The complete Fig. 2 should appear as follows:

Fig. 2. Diagram for transition $J=2$ to $J=1$ compared with Bi II $\lambda 4705$. $\mu = +0.457$, total $\Delta\nu = 2.71 \text{ cm}^{-1}$. The arrow indicates where the line pattern fits the diagram.

THE SCATTERING OF UNPOLARIZED X-RAYS

BY G. E. M. JAUNCEY AND G. G. HARVEY
Washington University, St. Louis, Missouri

(Phys. Rev. **37**, 698, 1931)

The denominator of the right side of Eq. (12) should be raised to the fourth power. The corrected equation is

$$I_{unm} = 4I_e / (1 + 0.022x^2)^4 \quad (12)$$

SURFACE TENSION OF MERCURY

BY MARIE KERNAGHAN
Department of Physics, The Saint Louis University

(Phys. Rev. **37**, 990, 1931)

The ordinate of Fig. 3 should read "Surface tension (dynes) Corrected values".

BOOK REVIEWS

Veröffentlichungen Des Wissenschaftlichen Zentral-Laboratoriums der Photographischen Abteilung-Agfa- Band I. Pp. 155, figs. 94. S. Hirzel, Leipzig, 1930. Price RM10.

The photographic division (Agfa) of the I. G. Farben industrie has inaugurated an annual publication in which the results of technical and theoretical photographic investigations of that laboratory are gathered together. In general each volume will consist both of articles which have appeared in other places and of some which have not been previously published. The annual should prove a great benefit to the photographic research world by helping to keep important photographic knowledge collected.

The first volume contains an article on the existing theories of the latent image, several papers on sensitometry with special reference to color sensitivity, an announcement of new sensitizers for the extreme red and infrared photography. An article on the testing of sound film is particularly good in that clear and complete picture of the physical problems involved in photographic sound recording is given. Articles on x-ray photography and on cellulose and its derivatives complete the volume.

M. E. RUSSELL

Molecular Spectra in Gases. Report of the Committee on Radiation in Gases and Bulletin 57 of the National Research Council. E. C. KEMBLE, R. T. BIRGE, W. F. COLBY, F. W. LOOMIS, L. PAGE. Second printing 1930. Pp. 366. Price \$3.50 (paper binding).

This bulletin originally issued in December 1926 has been reprinted with minor corrections and the addition of an index. Separate copies of the index are available for distribution.

E. C. KEMBLE

An Outline of Wave Mechanics. N. F. MOTT. Pp. 156, figs. 21. The Macmillan Company, New York, 1930. Price \$2.80.

New sciences are complicated when they start, and grow simpler as we understand them better. Wave mechanics is no exception. The first papers, the first books, on the subject were mathematics and not much else. But now, with increased understanding, it is possible to dispense with more and more of the detail, and yet to become continually clearer and more comprehensible. Mott's admirable little book is an excellent illustration of this tendency. To the reviewer it seems singularly successful in its attempt to present enough detail to enable the principles of the subject to be accurately understood, and yet not enough to burden the reader. After reading it, one does not have the too common feeling that it could not be understood except by one who knew the whole subject beforehand.

It should not be supposed that Mott's book is intended for the general reader. It is distinctly for physicists, advanced students and research workers. It presupposes a considerable background of physics and mathematics. But it can honestly be recommended, for example, to the experimental physicists who want some idea of wave mechanics. The examples and illustrations are of a physical sort, and of a remarkable variety for such a small book. Particularly good, as one would expect from Mott's research, are the sections on collisions, scattering and such problems. Questions of stationary states, of atomic and molecular structure, are treated, but not in any great detail, as must be obvious from the small compass of the book. No problems, of course, are carried through in a complete manner, and yet one feels that the fundamentals are so adequately presented that the reader will be set thinking along the right line. As an elementary and readable account of wave mechanics, the reviewer feels that the book can be highly recommended. An idea of the actual contents can be obtained from the chapter headings: Waves and Particles, The Wave Equation, Group Velocity and the Uncertainty Principle, The Theory of Stationary State, The Absorption of Radiation, The Helium Atom and the Hydrogen Molecule, Dynamics of Systems containing many Electrons, The Spin of the Electron and the Exclusion Principle.

Principles of Electrical Engineering (Second Edition). W. H. TIMBIE AND V. BUSH. Pp. 595, figs. 270. John Wiley and Sons, New York, 1930. Price \$4.50.

We regret that in the review of this book which appeared in the May 15 issue of this journal, page 1374, the name of the publisher was erroneously given.

PROCEEDINGS
OF THE
AMERICAN PHYSICAL SOCIETY
MINUTES OF THE WASHINGTON MEETING, APRIL
30, MAY 1 AND 2, 1931

The 170th regular meeting of the American Physical Society was held in Washington, D.C., at the Bureau of Standards on Thursday and Friday, April 30 and May 1, and at the National Academy of Sciences on Saturday, May 2, 1931. The first session began at ten o'clock on Thursday morning. The presiding officers were W. F. G. Swann, President of the Society, Paul D. Foote, Vice-president, Joseph A. Becker, Lyman J. Briggs, Arthur H. Compton, Karl K. Darrow, Henry G. Gale, Enoch Karrer and L. P. Sieg. At the Bureau of Standards on the first and second days of the meeting the registration was 388. A fair estimate of the total attendance at the sessions was between four and five hundred.

On Thursday afternoon the Society omitted its regular sessions from one-thirty to three-thirty o'clock to meet with the newly formed American Association of Physics Teachers. At this session Dr. A. W. Hull of the General Electric Company presented an invited address on "Qualifications of a Research Physicist."

On Thursday evening a public forum was called at the National Academy Building to discuss methods of promoting interest in all branches of physics. This meeting was called by L. W. McKeehan, chairman of the Committee on Sections and was presided over by F. K. Richtmyer.

On Friday evening the Society held a dinner at the Hotel Washington. The President presided at this dinner and the after-dinner speakers were George K. Burgess, Arthur H. Compton, Charles Darwin and F. Henning. R. H. Fowler was also a guest of the Society at the speakers table. The attendance at this dinner was 243.

On Saturday afternoon at the National Academy Building there was held a special colloid program. The papers at this session were invited. The presiding officer of this meeting was Enoch Karrer of the B. F. Goodrich Company.

Meeting of the Council. At its meeting held on Thursday, April 30, 1931, sixteen persons were transferred from membership to fellowship and thirty-seven were elected to membership. *Transferred from Membership to Fellowship:* James H. Bartlett, Jr., David G. Bourgin, V. L. Chrisler, S. Goudsmit, Robert J. Havighurst, Paul Kirkpatrick, W. W. Nicholas, Linus Pauling, Shirley L. Quimby, Richard Ruedy, A. G. Shenstone, Ernest C. G. Stückelberg, George E. Uhlenbeck, N. H. Williams, Mark W. Zemansky and R. V. Zumstein. *Elected to Membership:* Edward B. Baker, M. C. Banca, William E. Berkey, Margaret F. Blackford, Robert L. Boyer, Percy H. Carr, Nickola

Chako, Thomas A. Elkins, David W. Epstein, Richard Evans, O. Rex Ford, Gladys M. Francis, Garret A. Hobart 3rd, Cleveland B. Hollabaugh, Howard B. Holroyd, Jun Koana, C. M. Lewis, Walter G. Marburger, A. T. McPherson, Paul C. Mitchell, George C. Munro, Robert J. K. Murray, Leon S. Nergaard, Paul A. Northrop, Syoten Oka, Allan E. Parker, Clifford M. Potter, Norman A. Shepard, William B. Shockley, Leland B. Snoddy, Daniel S. Stevens, G. R. Tatum, Sigeo Uneno, Forrest Western, John A. Wheeler, E. P. Wigner and Robert L. Womer.

The regular scientific program of the Society consisted of 163 papers, numbers 11, 25, 34, 40, 44, 47, 48, 49, 50, 68, 71, 95, 108, 120, 127, 131, 144, 152, 153, 155, 157, 158 and 163 were read by title. The abstracts of these papers are given in the following pages. An **Author Index** will be found at the end.

W. L. SEVERINGHAUS, *Secretary*

1. Dissociation of water vapor in electrical discharge. ERNEST G. LINDER, *Cornell University*.—By use of Townsend's ionization equation and Aston's result for the potential distribution in the Crookes dark space, the number of electrons produced at each point in the dark space can be obtained. From this, may be calculated the total energy of all the electrons generated by each primary electron, i.e., $\int_0^S (V_1 - V) dn$, where S =length of dark space, V_1 =cathode potential drop, V =space potential, n =number of electrons. Using experimental values of S and V_1 and Townsend's constants, it is thus found that for discharge currents of 1–25 m.a. the average energy per electron runs from 53.8 to 79.2 volts, these values being from 17.8 to 14.3 percent of the corresponding total cathode drop energies. The amount of dissociation in the dark space and negative glow for the above currents is from 4.78 to 5.90 molecules of water per electron, which gives an almost constant value of 11 volts per dissociation. The results suggest that dissociation is due to excitation of the molecule. Probe measurements in the positive column give an electron density of 7.4×10^7 electrons per cm^3 , and a mean energy of 3.71 volts. If a probability of dissociation by electron impact equal to 0.0024 be assumed, the dissociation in the positive column can be accounted for.

2. The electro-optical shutter and spark breakdown. FRANK G. DUNNINGTON, *University of California*. (*Introduced by Ernest O. Lawrence*).—The use of the electro-optical shutter in investigations of rapidly varying phenomena necessitates knowledge regarding its manner of functioning and limitations. Using a typical experimental set-up as an example, theoretical cut-off curves have been calculated: 1st, assuming an instantaneous drop of the controlling voltage (i.e. spark gap), and 2nd, assuming the controlling voltage decays according to a definite law. These indicate an effective cut-off time (90% to 10% transmission) of from 2.5 to 4×10^{-9} sec. and a total lag of 4 to 9×10^{-9} sec. Experimental results show a complete change in the appearance of the spark in 5×10^{-9} sec., thus indicating an effective cut-off time somewhat less than this value. Other results set a lower limit on the total lag of about 7×10^{-9} sec. The effective working of the shutter is dependent on the following major factors: (1) purity of nitrobenzene used in Kerr cell; (2) resistance of leads to cell; (3) voltage applied; (4) capacity of cell; (5) steepness of voltage wave used to control shutter. Contrary to previous beliefs, theory and experiment show the best control voltage is only slightly under that giving 100% transmission. A graphical survey giving the step by step development of the breakdown of a gap in an initially homogeneous field has been made for pressures from 20 to 76 cm and gap lengths from 1 to 10 mm.

3. The effect of pressure on the rate of fall of potential in condensed discharges. J. C. STREET AND J. W. BEAMS, *University of Virginia*.—The experimental method was essentially the same as one recently described (Street, *Bulletin American Phys. Soc.* Feb. 1931) and somewhat similar to Toepler's (*Archiv für Elektrot.* 14, 305, 1925) though different in important essentials. Electrical impulses produced by the discharge under investigation traveled along two

parallel symmetrical lead wires to their open ends where they were reflected. The maximum potential across the two ends when measured as a function of the length of lead wires gave a curve from which the rate of fall of potential across the discharge was determined. Our results show that in the first part of the breakdown the resistance can best be represented as a function which decreases exponentially with time. When the potential was very slowly applied (static breakdown) the following are some of the results obtained for the decrease of potential with time:

Pressure in cm of Hg	Time of fall from 100 to 20%
38	4.7×10^{-8} sec.
54	2.5
75	1.7
95	1.1
115	.8
139	.8

The results are in general accord with the calculations of Schilling (Archiv für Elektrot. 25, 97, 1931). Incidentally they indicate how to obtain a maximum rate of discharge for Kerr cells and illustrate how they are damped when used with short leads.

4. On the formation of an arc or spark on interrupting an electric circuit. THOMAS J. KILLIAN, *Massachusetts Institute of Technology*.—There seem to be two possible sources of the spark or arc which results when a physical circuit, carrying unidirectional current, is opened. J. Slepian (J.A.I.E.E., Oct., 1926) has suggested that the initial ionization is due to the temperature rise of the last contact point of the separating electrodes. At high breaking speeds this theory is subject to certain theoretical and experimental difficulties. If no conduction current flows immediately after the contacts are opened the charging current will cause the potential difference and the electric intensity between the contacts to increase. It is shown that the electric field may attain 10^6 to 10^7 volts cm^{-1} at which values "field" currents may flow. When the potential difference between the electrodes is such that the electrons, which have been drawn from the metal by these intense fields, may produce ionization an arc or spark results. An analysis of oscillograms taken at various current densities and opening speeds seems to show that this mechanism may initiate the discharge. This may indicate a method of studying "field" currents at high densities which until now have only been studied at extremely low densities.

5. Vacuum spark discharge. L. B. SNODDY, *General Electric Co.* (Introduced by A. W. Hull.)—Impulsive breakdown between pure copper electrodes in high vacuum has been investigated by means of the cathode ray oscillograph and the rotating mirror. (See J. W. Beams, Review of Scientific Inst. 1, 667, 1930). The mirror photographs of the discharge show a luminous spot at the anode lasting from 1 to 4×10^{-7} sec. and luminosity at the cathode starting slightly later (1 to 2×10^{-7} sec.) than that at the anode and continuing throughout the discharge. The anode does not remain luminous unless the current is very large. The breakdown has two stages; the first a pure electron discharge, lasting less than 5×10^{-7} sec., followed by a low voltage copper vapor arc. The volt-ampere characteristic of the high voltage stage follows the well known law for auto-electronic emission. From the volt-ampere curves the area of emission at the cathode can be computed (Stern, Gossling and Fowler, Proc. Royal. Soc. 124, 699, 1929). For two gaps investigated the areas were approximately $3 \times 10^{-3} \text{ cm}^2$ and $1 \times 10^{-3} \text{ cm}^2$. Using these areas and the rate of potential rise as determined by the oscillograph it is shown that in each case the anode spot at the time of breakdown reaches a temperature of approximately 2600°C . Photomicrographs of the anode show craters of area agreeing well with the computed areas. Current densities, determined from the circuit constants and measured areas of the cathode craters, range from 10^8 amps/ cm^2 , at 5×10^{-7} sec. after breakdown, to 8×10^8 amp/ cm^2 , at which value the arc goes out.

6. On the temperature of cathode in vacuum arc. R. TANBERG AND W. E. BERKEY, *Westinghouse Elec. & Mfg. Co., East Pittsburgh*. (Introduced by Thomas Spooner.)—Pyrometric and spectroscopic tests show that the metal cathode spot in a vacuum arc is not at an extremely high temperature. The temperature of a copper cathode is measured by an optical pyrometer and found to be about 3000°K in a 20 ampere arc. Spectroscopic examination of the cathode spot shows only a faint continuous spectrum indicating that the temperature of the cathode is not high. A temperature of the above magnitude is shown to be sufficient to give the rate of vaporization required under extreme assumptions. The results show that the high speed of the vapor stream issuing from the cathode region cannot be due to high temperature of the cathode itself.

7. The cathode fall of an arc. R. C. MASON, *Westinghouse Elec. & Mfg. Co., East Pittsburgh*.—To explain the mechanism of a mercury-pool arc, in which the cathode is at a relatively low temperature, Langmuir has suggested that electrons are extracted from the cathode by a very high field. Presumably, the same theory will apply to all arcs in which the cathode is not hot enough for appreciable thermionic emission. An analysis is presented in this paper showing that, under the same conditions, an arc in which the high field is operative should have a cathode fall several volts greater than an arc with a thermionic cathode. Upon either the classical Schottky theory, or the quantum mechanical theory of high field emission, the energies of electrons at the boundary of the cathode fall space will be several volts less in the high field arc than in the thermionic arc; so, to produce sufficient positive ions for space charge purposes, the cathode fall of the former must be greater than that of the latter. A test is thus suggested for the Langmuir theory of an arc.

8. Measurements on the vapor stream from the cathode of a vacuum arc. W. E. BERKEY AND R. C. MASON, *Westinghouse Elec. & Mfg. Co., East Pittsburgh*.—The velocity of the vapor stream issuing from the cathode region of a vacuum arc between copper electrodes is calculated from (1) the energy received by a vane 3 cm in front of the cathode, as measured by the rate of rise of temperature; (2) the momentum imparted to the vane, as determined by the deflection of the vane. The mass used in the calculations is that of the copper deposited on the vane. The average velocity of the vapor, computed from data obtained by either method, is over 10^6 cm per second, confirming Tanberg's momentum measurements. There is some evidence that the vapor is ionized to a considerable degree. Radiation from the arc, or energy of recombination on the vane, can account for only a small part of the total energy received by the vane.

9. A method for the comparison of magnetic susceptibilities of feebly magnetic salts. L. G. HECTOR AND ALBIN N. BENSON, *The University of Buffalo*.—A method depending upon induced current phenomena may be employed for comparing the magnetic susceptibilities of substances whose electrical conductivity is small. The present method depends upon the comparison of the alternating electromotive forces developed in two coils each of which is coupled to a field coil. A tube filled with the salt to be examined is then placed in one of the pick-up coils and a change in the coupling between the pick-up coil and the field coil is thereby produced. By means of a variable resistor shunted about one field coil a balance between the induced e.m.f. is restored. Comparison of the two induced alternating e.m.f. was first attempted by means of a vacuum tube voltmeter, but slight irregularities in wave form and shifts in phase resulted in uncertainty in the readings. In the latest method, current from each pick-up coil is rectified by thermionic tubes and the rectified current is further smoothed out by filters. The potentials developed across the last condenser bank in each filter are then compared by means of a direct current galvanometer.

10. Block structure and magnetic viscosity. FRANCIS BITTER, *Westinghouse Elec. & Mfg. Co., East Pittsburgh*.—As a result of the work of Becker (*Zeits. f. Physik* 62, 253, 1930) and Powell (*Proc. Roy. Soc.* 130, 167, 1930) it is now possible to write the expression for the potential energy of a single crystal as a function of the direction of magnetization in the crystal, say $\Phi(\theta, H)$. This expression depends on the crystalline field, or (s, l) interaction, and on the distortion of the lattice, and has, in general, several minima as a function of θ . If the crystal is made up of regions of spontaneous magnetization, the equilibrium distribution of orientations is

given by an expression of the form $\exp. (-\Phi_0(\theta, H)/KT)$ where Φ_0 represents the potential energy of such a region. This distribution cannot in general be established in a reasonable time because of the existence of several maxima of Φ_0 . If, however, we know the distribution of orientations, f , at a time $t=0$ (say complete demagnetization, or saturation) then the distribution at a time t resulting from a change in H is given by the diffusion equation

$$a\nabla \cdot (f\nabla\Phi_0) + b\nabla^2 f = df/dt.$$

This equation has not been solved except for special and simple forms of Φ_0 . A closer inspection, however, shows that a gradual "creeping" of magnetization will not, in general, occur unless the depth of the Φ_0 minima is comparable with KT . Since the depth of these minima depends on the volume of a region, magnetic viscosity phenomena in single crystals may eventually be used to determine the volume of the regions of spontaneous magnetization and so check the hypothesis (Phys. Rev. 37, 91, (1931)) that they are identical with Zwicky's blocks.

11. Magnetic properties of magnetite crystals at low temperature. CHING-HSIEN LI, *University of Illinois*.—Thin circular plates cut parallel to the 100, 110, and 111 planes of the magnetite crystal were prepared. Both the perpendicular and parallel components of magnetization at low temperatures down to that of liquid air were investigated by the method of torsion. It was found that the magnetic property of the crystal was abruptly changed at about -160 degrees centigrade. It seems that the elementary magnetic elements within the crystal are very easily rotated in the magnetic field at that particular temperature. This particular temperature corresponds exactly to the temperature at which the heat capacity of magnetite is suddenly increased to a maximum point as was found experimentally by R. W. Millar two years ago. Weiss' theory of the molecular field as applied to this change of specific heat and the corresponding change of magnetic property is in the process of investigation.

12. Effect of heating on residual magnetism. R. L. SANFORD, *Bureau of Standards, Washington, D. C.*—Experiments with a 0.63 percent carbon steel show that if the structure is lamellar pearlite, consisting of alternate plates of iron and iron carbide, the residual induction reverses sign at a temperature of approximately 200°C and regains part of the magnetization in the original direction upon cooling. If the temperature is raised to 800°C , the residual induction disappears and does not reappear on cooling. If the material is remagnetized in the original direction while at a temperature of approximately 265°C , the residual induction decreases upon cooling and finally reverses at a temperature of about 30°C . Hardened steel does not reverse but the presence of very fine lamellar pearlite produces a reversal. Precipitated carbide produced by reheating a hardened specimen does not cause the reversal. The lamellar structure appears to be necessary for the reversal. The first reversal can be satisfactorily explained as the result of the thermomagnetic transformation of the carbide plates which first reverse the magnetization in the adjacent iron plates and then become nonmagnetic at the so-called A_0 point. The reversal after remagnetization at the high temperature is not so easy to explain.

13. Annual variations in magnetic storms. H. B. MARIS, *Naval Research Laboratory, Bellevue, Anacostia, D. C.*—A new list of magnetic storms for the years 1839 to 1930 shows an annual variation in the frequency of disturbances with two equal maxima about a week following the equinoxes and two equal minima at the solstices. The ratio of the maximum to the minimum frequency is nearly two to one. The distribution of frequency F is given approximately by the equation, $F = k(3 + \cos 2\theta)$, where θ is the position of the sun on the ecliptic. Three groups of storms showing annual recurrence interrupt the normal distribution curve. The first, 1840 to 1865 had a maximum about February 20, the second group started April 10, 1854, and was intermittently persistent with a two year period till 1875 and the third group started May 16, 1913, and is almost unbroken since then. The change from maximum to minimum frequency between equinox and solstice is explained as the result of three effects. The ultraviolet flair, which is assumed to come from the solar latitude where sun-spots are observed, should increase in intensity as the earth increases its solar latitude. This would be expected to give a ten percent change in storm intensity. Expansion of the upper atmosphere as it is heated by the solar flair causing the storm will move the conducting Heaviside layer across the earth's magnetic field with a dynamo effect which will decrease by about fifteen percent from equinox to solstice.

Winds blowing from day toward night will have a maximum dynamo effect in driving atmospheric electric currents at equinox.

14. Magnetic properties of copper-nickel alloys. E. H. WILLIAMS, *University of Illinois*.—The magnetic susceptibility of alloys of copper and nickel in proportions ranging from 0.1 to 70 percent nickel have been studied. Although copper is only weakly diamagnetic it requires 0.8 or 0.9 percent nickel to neutralize this diamagnetic effect and 56 percent nickel is required before the alloy shows ferromagnetic properties at ordinary temperatures. For amounts of nickel from one percent up to 30 percent the alloy, while paramagnetic in most respect, does not obey any law of paramagnetism with regard to temperature. As the temperature is increased the susceptibility first increases and then decreases, the maximum occurring in the neighborhood of the Curie point for nickel. In the case of alloys containing more than 30 percent nickel the susceptibility decreases with increase of temperature for temperatures above 20°C. So far as the phenomena of increasing paramagnetic susceptibility are concerned there is at present no explanation. It has been suggested that a few atoms or molecules of nickel do not lose their magnetic identity in the alloy and that these atoms with their spinning electrons become more mobile as the temperature is increased. One objection to this is that the susceptibility is independent of the field.

15. The origin of thermionic electrons from oxide coated filaments, R. W. SEARS AND J. A. BECKER, *Bell Telephone Laboratories, Inc.*—The following experiments show that the emission is determined by the condition of the oxide surface and not the core-metal surface as proposed recently by Lowry (*Phys. Rev.* 35, 1367, (1930)) and also Riemann and Murgoci (*Phil. Mag.* 9, 440, 1930). (1) When barium is deposited on the oxide surface either by evaporation from an external source or by electrolysis of the oxide itself, the emission changes even though the temperature is so low that the barium could not diffuse to the core surface. (2) A removal of the oxide coating while the filament is at room temperature causes the emission as determined at low temperatures, to decrease by a factor of 6000 or more. (3). When space charge limited current is drawn to a plate, the potential of a point in the oxide is always positive with respect to the core surface by an amount directly proportional to the current. If the current were determined by the core surface this potential should be negative and should not vary linearly with the current. The experimental facts adduced to prove a limitation by the core surface are not conclusive and can be explained on the view proposed here.

16. Theoretical interpretation of experimental Richardson plots. W. H. BRATTAIN AND J. A. BECKER, *Bell Telephone Laboratories, Inc., New York*.—The theoretical equation for the saturation current is

$$\ln i - 2\ln T = \ln A + \int_1^T \frac{b}{T^2} dT - (b)_{T=1} = \ln A - \frac{a}{T} \quad (1)$$

$A = 4(1-r)\pi mk^2e/h^3$, " b " is defined in terms of L_p , the total heat of evaporation per mole at constant pressure. $b = (L_p/R) - (5T/2)$ " a " is defined by Eq. (1). It is related to the free energy. If " a " and " b " are functions of T , an experimental plot of $\ln i - 2\ln T$ vs. $1/T$ will, in general, not be a perfect straight line. At any value of $1/T$ a tangent can be drawn. Its slope is $-b$ or $[-a + T da/dT]$ and the intercept is $[\ln A - da/dT]$ or $[\ln A + (b-a)/T]$. Actually, db/dT is usually so small that the mean straight line through the experimental points is practically coincident with the tangent at the mean value of $1/T$. If, as Herzfeld suggests, " a " = $h\nu_0/k$; the slope of the Richardson plot equals $-(h/k)[\nu_0 - T d\nu_0/dT]$ where the slope, ν_0 , and $d\nu_0/dT$ all refer to values taken at the same temperature; the logarithm of the universal constant A is equal to the intercept $+(h/k)(d\nu_0/dT)$; also, the term "work function" cannot, in general, be used for both the slope of the Richardson plot and $h\nu_0$.

17. Influence of space charge on current fluctuations. E. W. THATCHER AND N. H. WILLIAMS, *University of Michigan*.—Current fluctuations of two fundamental types are recognized in a circuit containing a thermionic element: (1) Those due to the discreteness of the carriers, governed by probability relations applied to their departure from the cathode and collection at the anode. (2) Those due to thermal agitation of electricity in the circuit, analogous

to the Brownian fluctuation of particles in colloidal suspension. The influence of electron space charge on these fluctuations has been investigated with especially designed tubes. Precise measurements in this region have hitherto been unattainable on account of the inherent "mixed" nature of the emission from metal surfaces. Abnormalities arising from this source in tungsten and thoriated tungsten have been studied and controlled. A new treatment of the shot effect as applied to pure electron emission yields an expression for the ratio of the mean square value of the fluctuation voltage under given space charge conditions to that under strict temperature limitation of the current:

$$\frac{\overline{V_s^2}}{\overline{V_t^2}} = f(i_0/i) e^{-\omega^2/2\alpha^2}$$

I_0 is the space current, i the saturation current associated with a particular emitter temperature, and their ratio characterizes the space charge situation. The influence of the frequency term has been shown to be vanishingly small over a range of frequencies from 50,000 pps. to 500,000 pps. The function " f " has been experimentally determined for various situations of current limitation.

18. Supersonic satellites. W. H. PIELEMEIER, *Pennsylvania State College*.—As the path length in a Pierce acoustic interferometer was increased, satellites, or minor peaks, became more prominent in the curves which correlate the *excess of plate current over bias current*, ($I_p - I_B$), and the *mirror position*, (x). With the exception of the satellites these curves have a striking resemblance to the curves which correlate the *calculated square of the pressure amplitude in the air at the crystal surface* and the *mirror position*. A wave velocity independent of intensity was assumed for the calculation. If it is assumed that the velocity of the waves decreases to the limiting value, $V = (\gamma p/d)^{1/2}$, with diminishing intensity, not only the shape of the satellites, but also their position is thereby explained. Measurements were made with several crystals. For each of the frequencies tested the acoustic velocity as determined by the satellite positions differed by less than 0.06 percent from the above limiting value. In every case the velocity, as determined by the major peaks, *exceeds* the theoretical value by more than 0.5 percent. Such a large shift could scarcely be a frequency shift as the resonance positions are approached.

19. Canonical transformations and the vibrations of a loaded string. R. B. LINDSAY, *Brown University*.—The classical method of discussing the transverse motion of a finite string of negligible weight fastened at the ends with tension τ and loaded with particles of equal mass m and equally spaced at distances a is that in which the Lagrangian equations for a system of n degrees of freedom are set up and integrated by means of determinant analysis. It is here shown that if we denote the coordinate and conjugate momentum of the s th particle by q_s, p_s and perform the transformation to the new system Q_s, P_s defined by the transformation function

$$S = \sum_{k=1}^n (m/2)^{1/2} \omega_k^2 \cot Q_k \left[\sum_{s=1}^n a_{sk} q_s \right]^2,$$

where $a_{sk} = 2 \sin (sk\pi/n+1)/(m(n+1)\omega_k)^{1/2}$ and the ω_k form a set of parameters, the Hamiltonian

$$H = 1/2m \cdot \sum_{k=1}^n \dot{p}_k^2 + \tau/2a \cdot \sum_{k=1}^{n+1} (q_k - q_{k-1})^2$$

(with $q_0 = q_{n+1} = 0$) transforms into $K = \sum_{k=1}^n \omega_k P_k$ with $\omega_k = 2(\tau/ma)^{1/2} \sin k\pi/2(n+1)$. The canonical equations now lead to $P_k = \text{const}$, $Q_k = \omega_k t + \beta_k$ and the usual solution is at once obtained from $\dot{p}_k = \partial S / \partial q_k$ in the form

$$q_s = \sum_{k=1}^n a_{sk} P_k^{1/2} \sin (\omega_k t + \beta_k)$$

$$\dot{p}_s = m \sum_{k=1}^n \omega_k a_{sk} P_k^{1/2} \cos (\omega_k t + \beta_k) \quad \text{where}$$

the ω_k appear as the characteristic frequencies (multiplied by 2π). The generalization to the continuous string is immediate. The transformation $q(x) = 2/M^{1/2} \cdot \sum_{k=1}^{\infty} (P_k/\omega_k)^{1/2} \sin Q_k$.

$\sin k\pi x/l$ where l is the length and M the mass of the whole string, carries the Hamiltonian functional into $H = \sum_{k=1}^{\infty} \omega_k P_k$ where now $\omega_k = k\pi(\tau/Ml)^{1/2}$. The energy fluctuation and quantization of the loaded and continuous strings are investigated.

20. The elastic constants and the thermal expansion of a sample of rubber between room temperature and -30°C . W. W. STIFLER, *Amherst College*, AND PAUL C. MITCHELL, *Missouri Valley College*.—A method has been developed by which the coefficient of linear expansion, Young's modulus, and the coefficient of rigidity can be measured on the same sample of rubber at any temperature from that of the room down to -30°C . For a particular sample, the thermal expansion proceeds quite regularly in this range but the coefficients of elasticity increase rapidly as the temperature is lowered. For example, at 22°C , Young's modulus is 1.30×10^8 dynes per cm^2 and at -30°C it is 3.56×10^8 dynes per cm^2 .

21. Columns with variable end restraints. L. B. TUCKERMAN AND WM. R. OSGOOD, *Bureau of Standards*.—Because of its importance in aircraft construction, the Bureau of Aeronautics of the United States Navy has supported an investigation of the strength of columns with variable elastic end restraints, the investigation covering the range of lengths for which the failure is partly elastic and partly plastic. A theoretical analysis led to the conclusion that satisfactory corrections could be made for a rigid end mounting, which greatly simplified the test apparatus. The test results are found to be expressed advantageously in terms of the dimensionless variables

$$\sigma = P/(F_0 A), \quad \lambda = [l/(\pi r)](F_0/E)^{1/2}, \quad \kappa = [(2K)/(Pl)] + 2s/l,$$

where P = the maximum axial load which can be carried by the column. A = the cross-sectional area of the column, F_0 = the short-column strength of the material, E = the modulus of elasticity of the material, l = the length of the column, r = the radius of gyration of the cross-section with reference to the gravity axis perpendicular to the plane of bending, K = the coefficient representing the end restraint, s = the length of the rigid portion at each end of the column. The dimensionless variables σ , λ , and κ render comparable test results on materials with different but affine stress-strain curves. Only by the use of these variables has it been found possible to coordinate all the test results which have been obtained. The variables λ and σ have been used previously in other column investigations. (L. B. Tuckerman, S. N. Petrenko, and C. D. Johnson, "Strength of Tubing under Combined Axial and Transverse Loading," N.A.C.A. Technical Note No. 307, pp. 3, 4, June, 1929.)

22. Methods for measuring the coefficient of restitution. LYMAN J. BRIGGS, *Bureau of Standards*.—A comparison is made of the following methods for determining the coefficient of restitution of elastic spheres, such as golf balls, when subjected to large deformations: 1. Ballistic method, in which the ball is struck by a flat-nosed projectile, and ball and projectile are caught in separate ballistic pendulums (Thomas). 2. Normal rebound of a ball dropped from a known height onto a massive flat plate, correction being made for air resistance during both fall and rebound. 3. Photographic method, in which the relative speed of ball and projectile after impact is determined from two spark photographs. 4. Rebound from a smooth inclined plate, involving measurement of the angles of incidence and reflection.

23. Velocity of sound in metal rods by a resonance method. LEHMAN C. SHUGART, *Lehigh University* (Introduced by C. C. Bidwell).—A small coil is fastened to the end of the test rod and placed in a strong radial magnetic field. The coil is connected to the output of an audio-frequency oscillator. To the other end of the rod is fastened a carbon microphone button. At resonance frequencies corresponding to the fundamental or any overtone of the rod very sharp peaks are obtained in the microphone current. A correction must be made for the effective length of the rod due to the attachment of the driving coil and the microphone button. To get this correction, observation of the first overtone for a rod of twice the original length is made. The slight change in frequency enables the computation of the effective length. The equation is $v = 2nl + 4\Delta nl$. Value of velocity of sound for brass, steel and aluminum check very closely with the best published data. The method is being used for the determination of values in other

materials where data are lacking and especially for liquid metals. These may be contained in thin steel tubes, the peak for the resonance frequency in the liquid being easily distinguishable from that for the steel tube.

24. The vibrations of a plate with fixed center. ROBERT CAMERON COLWELL, *West Virginia University*.—A Chladni plate clamped at the center is usually set in vibration by bowing it at the edges. The sand figures formed in this way have been known for many years. If, however, a mechanical oscillator actuated by a vacuum tube is applied at different points on the plate, many new figures are formed. A few of these will be shown and a brief mathematical treatment given.

25. The arc spectrum of nitrogen. O. E. ANDERSON AND K. R. MORE, *University of British Columbia*. (Introduced by G. M. Shrum.)—The arc spectrum of nitrogen has been excited with low voltage, hot cathode arcs in mixtures of nitrogen with helium, neon and argon. Duffendack and Wolfe (Phys. Rev. 34, 409, 1929) have used helium for the excitation of this spectrum, but it has usually been assumed that the lines could not be excited in argon. Since in these experiments the lines were observed in argon with an intensity of the same order as with helium, it has been necessary to revise the usual explanation of the excitation processes. When currents of the order of 1.5 amperes were used, the best results were obtained with 0.1 mm of nitrogen in 1.5 mm of argon. The spectrum has been examined in the region 3400–6000Å. As some of the weaker lines were obscured by the nitrogen band structure, which varied with the nature of the admixed gas, it has not been possible to show that all the lines excited by helium were present in the argon mixture. A comparison of the intensities of the lines carried out with a Moll registering microphotometer showed that the strong NI lines were as intense as the moderately intense argon lines.

26. Activation of N_2 -Hg mixtures by illumination with light from a quartz Hg arc. B. L. SNAVELY AND LOUIS A. TURNER, *Princeton University*.—Illumination of a mixture of nitrogen and mercury (5 mm N_2 , 0.001 mm Hg) in a quartz bulb containing a 0.6 mil tungsten filament produces a lowering of the resistance of the filament if it is originally at 400°C. This is the same effect which Kenty and Turner (Phys. Rev., 32, 799 (1928)) found to be produced by active nitrogen and is presumably attributable to atomic nitrogen. Apparently the excited mercury atoms activate the nitrogen in some way. The effect is obtained only with the water-cooled arc, showing that the absorption of the 2537 line is involved. The effect is not obtained in similar helium-mercury mixtures. Rough preliminary measurements indicate that the magnitude of the effect is proportional to the first power of the intensity of the light.

27. The dissociation of excited iodine molecules by collision with argon atoms. LOUIS A. TURNER AND E. W. SAMSON, *Princeton University*.—By means of the absorption of the resonance line of the iodine atom ($\lambda = 1830\text{Å}$.) it has been shown that iodine atoms are produced upon illumination of an iodine-argon mixture (0.3 mm I_2 , 5 cm A) with continuous light of wave-length greater than 5100Å., from a carbon arc. Absorption of such light should produce excited iodine molecules and not lead to direct optical dissociation. Apparently the excited molecules dissociate upon collision with argon atoms, as we might infer from the quenching of the iodine fluorescence by argon, as observed by Franck and Wood.

28. On the excitation of continuous spectra by bombardment of gases and vapors with cathode-rays. WILLI M. COHN, *University of Berlin*. (Introduced by Otto Glasser.)—It has been observed that gases or vapors which are bombarded by cathode rays, will emit under certain conditions a blue light the spectrum of which is continuous and has a maximum of intensity (photographically determined) at 4500Å. The spectrum has been observed from 6200 to 3000Å. The spectra received are not dependent on the kind of the ions generated. The light emitted is not polarized, but x-rays are generated. A working hypothesis is given in which is shown that the emission of the continuous spectrum may be produced by a mechanism similar to that of the continuous x-ray "Bremsstrahlung."

29. Continuous spectrum from tungsten bombarded by 800 volt electrons. LAURISTON S. TAYLOR, *Bureau of Standards*. (Introduced by F. L. Mohler.)—Foote, Meggers and Chenault have

reported a continuous spectrum from metals bombarded by 1000 volt electrons (J. O. S. A. 9, 541, 1924). Preliminary measurements have been made of the intensity distribution of this radiation in the ultraviolet, from tungsten at voltages from 500 to 1200. At 800 volts the intensity $J(\lambda)$ increases regularly with decreasing wave-length, being about 3 times greater at 2800Å than at 3700Å. Between 500 and 1200 volts, the intensity distribution remains much the same and the intensity increases 2-fold. These results may be subject to an uncertain correction for electrons striking the stem instead of the target face.

30. Radiation from metals bombarded by low speed electrons. F. L. MOHLER AND C. BOECKNER, *Bureau of Standards*.—A paper presented at the New York meeting (No. 28) describes continuous spectra emitted by metals bombarded by large electron currents at low voltage, using the metal in the form of a small probe surface in a caesium or helium discharge. Measurements have been made with Be, Al, Cu, Ag, W, Pt, and Th in caesium discharges. Above 5 volts all except Ag and Cu give a spectrum of nearly equal energy per unit wave-length range. Ag is abnormally bright for wave-lengths longer than 3300Å and Cu has a minimum in the green and yellow. Absolute intensities remain of the same magnitude with the same exceptions. The curves of isochromatic intensity versus voltage are very different. For Ag the intensity increases almost linearly from the threshold to 10 volts and more slowly beyond; for W it increases at an accelerated rate to 7 volts, is nearly constant to 12 and increases beyond. The Al curve has a high maximum at 12 volts and increases again above 16 volts. These variations (notably the Al maximum) are more pronounced at shorter wave-lengths. The intensity differences between Ag and W remain qualitatively similar in Cs and He discharges.

31. The blue-green fluorescence of mercury vapor. PAUL D. FOOTE, ARTHUR E. RUARK AND R. L. CHENAULT, *Gulf Research Laboratory and University of Pittsburgh*.—Visual photometric measurements were made on the blue-green fluorescence of Hg vapor excited only by the core of 2537. At the temperatures employed (21 and 33°C) the green glow cannot be seen in the absence of foreign gas. On adding a few millimeters of nitrogen to bring 3P_1 atoms down to 3P_0 , it is bright. The intensity of the fluorescence increases to a maximum at 13 millimeters of nitrogen and then slowly fades as the pressure is increased. Using calibrated wire gauze screens to vary the intensity I of the exciting light, it was found that the fluorescent intensity J is definitely not a linear function of I . It obeys the equation $j + aj^{1/2} = bi$, where $j = J/J_0$ and $i = I/I_0$; J_0 and I_0 are the values obtained without screens; and a and b are constants for a given temperature and nitrogen pressure. Whatever be the molecule involved in the emission of the 4850 band, these experiments indicate that a 3P_0 atom is essential to its formation. The observed dependence of j on i can apparently be explained by assuming the active molecule contains two metastable atoms.

32. Direct measurement of τ . H. D. KOENIG AND A. ELLETT, *State University of Iowa*.—Ever since the well known experiments of Dunoyer (Le Radium 10, 400, 1913) there has existed the interesting possibility of measuring the time between absorption and subsequent remission of radiation by an atom by observing the displacement taking place in this period because of thermal agitation. And it is equally well known that for such thermal velocities as are available in the laboratory the displacement in 10^{-8} secs. (the order of magnitude of the time usually involved) is too small to be measured. The depolarization of cadmium resonance radiation by very weak magnetic fields shows that τ for the 2^3P_1 state of Cd is unusually large. A beam of cadmium atoms was shot through a narrow perpendicular beam of $\lambda 3261$ radiation. The illuminated part of the beam was screened from the camera. Atoms excited in the light beam and radiating after they had passed beyond the screen produced a blackening on the film densest just beyond the screen and perceptible for a distance of four millimeters. No blackening appeared below the screen showing that the spread above it was not due to secondary resonance. Photometer curves of the blackening are not yet available, but it is evident that τ is of the order of magnitude of 10^{-6} secs.

33. The average life for the line 2733Å of ionized helium. LOUIS R. MAXWELL, *Bartol Research Foundation, Swarthmore, Pa.*—The line 2733Å. (6→3) of ionized helium is made up of five lines (neglecting spin) whose average lives have been calculated according to the method of

Sugiura. The results obtained using Kupper's (amplitudes)² are: $6_1 \rightarrow 3_0$ (2.59×10^{-9} sec.), $6_1 \rightarrow 3_2$ (2.59×10^{-9} sec.), $6_0 \rightarrow 3_1$ (9.06×10^{-9} sec.), $6_3 \rightarrow 3_2$ (1.52×10^{-8} sec.) and $6_2 \rightarrow 3_1$ (7.44×10^{-9} sec.). The experimental method used by the writer for determining the average life of excited ions has been applied to this line (2733A) and it is found to exhibit a displacement under the action of the transverse electric field which is slightly greater than would be calculated on the basis of the above values for the mean lives of the fine structure lines. This difference is probably caused by transitions into the sixth quantum state from higher excited states which would produce an apparent longer mean life and hence give too great an experimental displacement. However the experimental results obtained agree approximately with the above calculated values for the average life.

34. Mean life of the mercury line $\lambda 2537$. PAUL H. GARRETT AND HAROLD W. WEBB, *Columbia University*.—The mean life of the mercury line $\lambda 2537$ was measured by the alternating voltage method previously described (Phys. Rev. **24**, 113, (1924)). The radiation was excited in a quartz tube by impact with electrons from a hot cathode. The photoelectric system was contained in a separate tube also of quartz. The surface was zinc evaporated on a nickel plate. Measurements of the apparent life were made with diminishing mercury vapor pressures until further reduction of pressure produced no change in the measured rate of decay of the radiation. At these low pressures (below 3×10^{-4} mm for the geometry used) the absorption and re-emission of the radiation was negligible and the true life of a single excitation process was measured. This was found to be 1.08×10^{-7} sec. with an estimated precision of one percent.

35. Life of the nitrogen molecule in its first excited vibrational state. M. L. POOL, *Ohio State University*.—Curves showing the rate of decay of the metastable 2^3P_0 state of the mercury atom in a quartz resonance cell, containing carefully purified nitrogen at room temperature, are not accurately exponential. The rate of decay in the neighborhood of 10^{-4} sec. after terminating the optical excitation is more rapid than later. A high concentration of nitrogen molecules excited to the first vibrational state of the zero electronic state might be expected, due to collisions of the second kind with the 2^3P_1 state in mercury. It is assumed that in addition to usual diffusion and dissipative impacts with unexcited nitrogen, the decay of the number of metastable mercury atoms may be influenced by dissipative impacts with these excited nitrogen molecules whose number decreases with time by diffusion and by dissipative impacts. An equation for the number of metastable atoms is then obtained of the form $\exp [\alpha t + A(\exp \beta t - 1)]$. Evaluation of the constants from experimental data gives the following: Life of N_2 in first excited vibrational state, 1.2 to 1.9×10^{-4} sec. depending upon pressure; probability of dissipative impact, 1.5×10^{-4} ; maximum life of 2^3P_0 state of Hg, 30×10^{-4} sec; probability of dissipative impact, 3.5×10^{-6} .

36. High dispersion in the near infrared. J. D. HARDY, *National Research Fellow, University of Michigan*.—Using a Pfund type of spectrometer, with a five inch 1500 line grating and especially long focus mirrors, it has been possible to obtain an experimental resolving power of 20,000 in the region between one and two μ . Using the grating in the first order, the 10830A helium line was resolved into two distinct components, of separation 1.1A. The effective slit-width in the 1.5μ region could be made as small as 0.2A and due to the excellence of the optical system the grating remained completely filled with light. Several other helium doublets have been resolved and the relative intensity of the two components compared. While testing out sources for hollow-cathode-excitation several lines in the neon spectrum were discovered. For the most part they have been classified as belonging to already established series.

37. Polarized fluorescence studied by means of a nicol, photocell and amplifier. D. R. MOREY, *Cornell University*. (Introduced by C. C. Murdock).—It becomes a difficult matter to measure the percent of plane polarized light in weak radiations by means of visual devices. This is a serious disadvantage in the study of fluorescence, for polarization measurements yield valuable information on the fluorescent process. A high quality nicol, with ends perpendicular to the length, rigidly fastened to a photoelectric cell may be made to analyze radiations too weak for visual instruments. The types of cell and amplifier to be used are somewhat dependent on the

nature and intensity of the source. Using such an instrument, the effect of inhibitors (KI, KCN, NaBr, etc.) on the polarization of fluorescent bands has been studied. The results strengthen the present view on the nature of fluorescence.

38. Total emissivities at low temperatures and departures from Lambert's cosine law. E. R. BINKLEY, *Lehigh University*. (Introduced by C. C. Bidwell.)—Emissivity of oxidized copper, nichrome, brass, cold rolled steel, and of aluminum were measured with a special form of total radiation pyrometer which had a slit opening and linear thermopile, permitting observations at nearly grazing angle. Observations were made at temperatures 100°C, 200°C, 300°C, 400°C, 500°C, on each surface and at each temperature at angles ranging from 0° to 85°. The instrument was calibrated on a camphor blacked surface assumed at 98% black body. Lambert's cosine law is found to hold at angles of observation above 60° but an increasing deviation is found for all surfaces when the angle is reduced below 60°, the deviation at 85° becoming as much as 30% for copper, 39% for rolled steel, 56% for nichrome. The value of normal emissivities for the various surfaces at 500° were as follows: copper 0.74; nichrome 0.95; brass 0.68; cold rolled steel 0.93; aluminum 0.29. There was found to be a rise in emissivity with temperature.

39. Absorption and temperature emission of neodymium in various solvents. R. W. WOOD, *Johns Hopkins University*.—A solid solution of neodymium oxide in fused quartz was drawn out into fibres about 0.3 mm in diameter, and a fiber mounted vertically in a bunsen flame. It glowed brilliantly and when viewed through a direct vision prism exhibited a spectrum consisting of a green, yellow and red band with perfectly dark regions between them. (Experiment shown.) This is undoubtedly the best example of a highly selective temperature radiator ever observed. Seven bands have been photographed between the blue and 0.9 μ . An interesting study has been made of solutions of various colored salts in liquid anhydrous ammonia. The rather wide band in the yellow of neodymium ammonium nitrate splits up into five narrow bands. These have been compared with the bands shown by the crystals at liquid air temperature and in solid ammonia. Some results of interest in connection with ray filters have been secured with the ammonia solutions and it seems possible that a suitable filter for giving a comparison spectrum in stellar spectra made with the objective prism may be constructed along these lines. Exhibition of stereoscopic photographs illustrating the orbital motion of the electron in the Stark effect.

40. Paschen-Back effect and hyperfine structure of Bi II. J. B. GREEN, *Ohio State University*. (John Simon Guggenheim Memorial Fellow, Univ. of Tübingen.)—The Zeeman effect in Bi II has been studied in a field of 34,000 gauss. The hyperfine structure of Bi II shows some very large separations and the Zeeman patterns yield very interesting results, since the field strengths available give separations that are about midway between "weak" fields and "strong" fields. In particular, $\lambda 5719$, a $1 \rightarrow 0$ jump in j , gives a completely resolved pattern in the perpendicular polarization, consisting of twenty components, twelve for $m_j = 1$ and eight for $m_j = -1$, thus verifying the nuclear moment of $i = 4 \frac{1}{2}$ for Bi. Fisher and Goudsmit's results for the hyperfine structure in Bi II were used.

41. Effect of combined electric and magnetic fields on the helium spectrum II. J. S. FOSTER, *McGill University*.—In electric and magnetic fields crossed at right angles, the diffuse and fundamental series of helium show a fine structure which is sensitive to changes in the electric field. Effects are similar for members of a single series and differ little from the normal Zeeman effect in the sharp and principal series. The splitting has been found to be less than normal in the $p-p$ combination series. A full account of this research will soon appear.

42. The Stark-effect in xenon. H. W. HARKNESS AND J. F. HEARD, *McGill University*. (Introduced by J. S. Foster.)—Earlier results with complex spectra have been interpreted to show that displacements of spectral terms by electric fields are inversely proportional to the corresponding hydrogen difference provided the latter are not too small. This view altogether fails to account for the present observation. Instead, a qualitative explanation of most displacements is afforded through the separations of the xenon term from its neighbor in the manner indicated in the approximation made by Pauli. Some of the red lines show more complex patterns than have been found in the other rare gases. In contrast with helium and neon these pat-

terns indicate that the m values are determined as components of the j , which is retained as a unit. For example, the line $2p_3-6d_4^1$ ($j:4\rightarrow3$) shows four π components and five σ components, i.e. all that could be observed if the separations in the $2p_3$ state are small.

43. **Asymmetry observed in the Stark-components of $H\alpha$.** D. R. McRAE, *McGill University*. (Introduced by J. S. Foster.)—A special grating, with a dispersion of $3.8\text{\AA}/\text{mm}$., having a very intense first order spectrum on one side, has been used to resolve the Stark components of $H\alpha$ as seen from a Lo Surdo source. An asymmetry is observed in the displacements of the components, which is in general qualitative agreement with the calculations of Schlapp. There are certain discrepancies, however, which have not been explained. An asymmetry in the relative intensities of the components has also been observed. This asymmetry decreases with lower gas pressures, or with increasing proportions of helium, neon, or xenon in the discharge tube, until there is agreement with theory when traces of hydrogen are present in these gases. It may be shown that altering the number of atoms in the initial states does not explain completely the observed asymmetry. Since the probabilities of transition agree with experiment in the cases mentioned it seems that the presence of neighboring hydrogen atoms or molecules may in some way alter the intensities by an action such as collisions of the second kind; but it is difficult to see how this could be carried out in the selective manner required to explain the observations.

44. **The electric field, atmosphere and effective temperature of the sun.** ROSS GUNN, *Naval Research Laboratory, Washington, D.C.*—The study of important electromagnetic effects in the solar atmosphere undertaken in previous papers is continued. It is shown that the large observed spread of effective temperatures of the sun's radiation can be accounted for by the presence of electric and magnetic fields in the solar atmosphere. The magnitude of the electric field at a level where the magnetic field is 25 gauss, calculated from the observed spread of temperatures, is found to be 0.015 volts/cm and agrees well with 0.013 volts/cm calculated earlier from the observed anomalous motions of the solar atmosphere. Gravitational equilibrium is found to be unnecessary in all regions of the atmosphere and it is shown that the "support" and stability of the chromosphere and its anomalous eastward motion are evidences of precisely the same electromagnetic mechanism. An electric field of the value given above is shown to account qualitatively for certain bright line spectra of the sun. The strange observed relation between bright line spectra and rapid axial rotation of stars, just announced by Dr. Struve of the Yerkes Observatory, confirms in a striking manner some of the conclusions of this and earlier papers.

45. **Some new relations in the photographic effects of alpha-rays.** T. R. WILKINS AND R. WOLFE. *Institute of Applied Optics, University of Rochester*.—Jacobsen has recently shown that the number of grains made developable in a photographic plate is proportional to the density provided this number does not exceed 200,000 per sq. mm. The number of developable grains was assumed equal to the number of alpha-particles. In the present work alpha-rays of various speeds have been used with Eastman Slow Lantern plates. For a given exposure time the density is found to be proportional to the number of alpha-rays at least up to 1.5×10^6 per sq. mm determined by a direct scintillation count (density 1.39). It would seem that the lack of linearity in previous work has been due to a variable exposure time. The slopes corresponding to increased exposures are a linear function of the exposure time up to 40 hrs. Thus there is a very marked reciprocity defect in the density amounting to approximately 50% for a 60 hr. exposure. Equations connecting the number of grains per cc of the emulsion with the number of alpha-particles have been obtained. Provided that the reciprocity correction for a given emulsion has been determined, the photographic plate offers a splendid quantitative means for alpha-ray counting.

46. **Continuous ultra- γ spectrum explaining cosmic-ray ionization-depth curve data.** CHARLES M. OLMSTED, *Buffalo, N.Y.*—It is shown that the ultra- γ cosmic-radiation data published by Millikan and Cameron, (Phys. Rev. 37, 235 (1931)) may be completely explained by a continuous spectrum of energy falling off suddenly on the short wave side of 0.000013\AA (as determined by the Klein-Nishina formula; $\mu=0.03$) and extending on the long wave-length side with evenly varying intensity to beyond 0.0008\AA . Tables of values of intensity of ionization

for different values of μ and λ are given. Tables comparing the computed values of ionization at various depths with the values observed by Millikan and Cameron are given. It is shown that the absorption curve computed from the continuous spectrum coincides with the observed curve as closely as does the curve computed by Millikan and Cameron from a group of four bands having frequencies corresponding to the formation out of hydrogen of helium, oxygen, silicon, and iron. The location of the short wave end of the spectrum at a frequency corresponding to the union of electron and proton, together with the shape of the intensity curve, is discussed from the point of view of astrophysics.

47. Wave packets. D. G. BOURGIN, *University of Illinois*.—(I) The formal character of wave packets follows from the equivalence of harmonic and damped waves in representing disturbances. Real integrals are thus replaced by equivalent complex contour integrals. A true "stationary phase" principle depends on certain "sattel-punkt" contours and is described physically as the resultant of a group of damped harmonic waves of varying amplitudes but identical phases. The "Kelvin stationary phase" principle is misnamed since there, amplitudes, not phases, are constant. Huyghen's principle for odd, non-isotropic negligibly absorptive spaces may be generalized by correlating "paths," extensions of rays, with classes of spatially damped waves. (II) Flamm, *Phys. Zeits.* Dec. 1928 and others attempt to construct permanent atom packets of the form

$$\psi(x, t) = \sum_{\nu_0}^{\infty} \left(\int_0^{1/\nu_0} \psi(0, T) e^{2\pi i \nu_0 T} dT \right) e^{2\pi i [x/\lambda_n - \nu_0 t]} \quad (1)$$

with independent λ 's (considered atomic characteristic values). This procedure is incorrect for not only is $\int_0^{\infty} \int_0^{\infty} \psi \bar{\psi}$ infinite but, under some convergence restrictions (1) in its space dependence is an "almost periodic function" i.e. each set of regional values is almost reproduced an infinite number of times contrary to the assumption "nür in einem beschränkten Bereich . . . merklich von Null verschieden."

48. Wave mechanics of electrons in uniform crossed fields. MILTON S. PLESSET, *Yale University*.—We consider the motion of electrons in a uniform magnetic field H in the z -direction and a uniform electric field E in the y -direction. We take for the vector potential $A = -iHy$ and for the scalar potential $V = -Ey$. With these potentials the wave equation does not contain x explicitly, and the solution may be written as $\psi = e^{2\pi i ax/\hbar} \Phi_n(u)$ where $\Phi_n(u)$ is the n^{th} orthogonal function of Hermite (the characteristic function for the simple harmonic oscillator);

$$u = (2k)^{1/2} [y - \pi/k^2 \hbar^2 (\pi m e E - a k \hbar)]; \quad k = \pi e H / \hbar c.$$

The energy is related not only to the values of the fields E and H and to the integral values n , but to the arbitrary constant a as well. The component of the current density in the y -direction vanishes identically; and for the component of the current density in the x -direction we have a function of y alone which is

$$j_x = e^2 H / mc [\Phi_n(u)]^2 (y + \pi a / k \hbar).$$

Thus j_x vanishes at the n roots of Φ_n and at $y = -\pi a / k \hbar$; for this latter value the current reverses its direction.

49. Oscillations due to corona discharges on wires. R. E. TARPLEY, J. T. TYKOCINER AND E. B. PAINE, *University of Illinois*.—An experimental arrangement was used in which the electric constants of the circuit containing a corona tube corresponded to much higher frequencies than could be recorded by a reflecting mirror oscillograph. By amplifying the corona currents 300 to 3000 times it was found with this oscillograph, which was insensitive to circuit oscillations, that corona discharges produce a new type of oscillations whose chief characteristics are as follows: The frequency (2000–10,000 cycles) is independent of circuit constants. The amplitude decreases with increasing applied potentials. The wave has a complex form of distinct ripples superimposed upon the charging a.c. or upon the steady part of applied d.c. The wave form depends on the pressure and nature of the gas and on the polarity of the wire. The wave form varies for different gases but the character of the oscillations remains the same for air, CO_2 and N_2 . The wave form becomes simpler with decreasing gas pressures especially with

CO₂. At high pressures the oscillations appear superimposed on the corona humps of the charging current at moments when the wire is the cathode, but at lower pressures oscillations appear only when the wire is the anode. No oscillations are obtained with oxidized or corroded wires. Details of the investigation will be published in a bulletin of the Eng. Exp. Station, University of Illinois.

50. Detection and comparative measurement of ionization in dielectrics by means of oscillations. J. T. TYKOCINER AND E. B. PAINE, *University of Illinois*.—In the study of dielectrics subjected to high potentials, minute voids and adsorbed gas bubbles give rise to ionization. The latter causes a redistribution of the electric field with the result that impulses of varying intensity are produced in the adjacent circuit. These impulses are made use of in a method for determining the potential at which ionization sets in and for comparing its intensity at varying applied voltages. If the circuit which contains the dielectric is aperiodic and is coupled to an amplifier supplied with a detector and current indicator, the impulses may be separated from the charging a.c. A more sensitive arrangement is obtained by tuning the circuit to a convenient frequency. Impulses in form of damped oscillations are then produced which are entirely free from the a.c. component of the charging source. With four stages of amplification, a thermionic detector and a thermionic voltmeter early stages of ionization in various dielectrics and the dependence of the ionization in various dielectrics on the applied voltage was studied. It was found that oscillations of any chosen frequency (100 to 30,000 k.c.) can be produced in a circuit by corona discharges in condensers, paper cables and rubber insulated conductors and their intensity measured by this method. The complete investigation will be published in a bulletin of the Eng. Exp. Station of the Univ. of Illinois.

51. Some properties of foreign and domestic micas. A. B. LEWIS, E. L. HALL AND F. R. CALDWELL, *Bureau of Standards, Washington, D.C.*—A number of samples of mica, fairly representative of the major sources of the world's supply of mica, have been tested for their dielectric constant, power factor, dielectric strength, and ability to withstand elevated temperatures. Average values are given for the dielectric constant and power factor at radio frequencies, and for the dielectric strength at 60 cycles. The data indicate the deviations from these average values which must be expected in commercial lots of mica. It is shown that stains and inclusions seriously affect the power factor of a sample, but have much less effect on the dielectric strength. Most of the samples were unaffected by exposure to temperatures up to 600°C, but above that temperature only the phlogopites can be said to have successfully withstood the elevated temperatures. On the basis of these data it was not possible to distinguish between micas of like commercial grades obtained from different geographical localities.

52. Cathode sputtering in a commercial application. H. F. FRUTH, *Western Electric Company, Hawthorne Station*. (Introduced by O. S. Duffendock.)—Three sputtering units, each one having six cathodes were designed and operated by one man. These units are used to produce the gold contact surfaces on broadcasting microphone diaphragms. In order to get good continuity, adherence, and uniformity a special method of preparing and cleaning the surface was developed. To produce a uniform quality surface and sputtering rate a bleeder valve to control the vacuum to ± 0.05 mm was developed. Sputtered gold surfaces on duralumin microphone diaphragms proved to be more free from pinholes, blisters and corrosion and gave better service than those made by electrolytic plating. On account of a lighter coat possible the diaphragms can be stretched to a higher natural frequency and show less fatigue.

53. Wave form of pulsating D.C. currents produced by FG-67 thyratrons. WAYNE B. NOTTINGHAM, *Bartol Research Foundation*.—A cathode ray oscillograph has been used to study the wave form in different parts of an "inverter" circuit using two General Electric FG-67 Thyratrons. (For the simple inverter circuit see Fig. 41, Hull, Gen. Elec. Rev. 32, 398, 1929). With the cathodes heated by independent 60 cycles, A. C. windings an "output" can be taken from the lead between the cathode and the negative terminal of the D. C. plate supply. The current flowing in this lead can be made of the "square-top" type up to a frequency of about 6000 cycles per second. The circuit conditions including the plate potential are critical at the highest frequencies while at 500 to 1000 cycles, it is easy to obtain the desired wave form with a wide range

of current and potential conditions. Under the best conditions the time required for the current to rise from zero to its full value was probably not more than 30 microseconds and a slightly shorter time was required for the current to fall from full value to zero. The exact wave form depends on the inductance, capacity and resistance of the D. C. supply. This system has been developed to heat a filament for the investigation of thermionic emission with low accelerations and retarding fields, but undoubtedly has other possible applications.

54. The starting-time of thyratrons. A. W. HULL AND L. B. SNODDY, *General Electric Company*.—Starting-time is defined as the time between the application of grid or plate voltage, and the attainment of full arc current. This time has been studied by means of high frequency alternating voltage, condenser discharge, and cathode ray oscillograms. The observed times depend upon vapor pressure, and upon anode and grid voltages, and lie between one-tenth (0.1) microsecond and 4 microseconds under practical conditions for all commercial thyratrons. Times of the order of one thousandths (0.001) second, as reported by Nottingham, (*Journal Franklin Institute* 211, 271, March 1931) have not been observed.

55. Magnetic induction in a projectile shot into a steady field. L. THOMPSON AND N. RIFFOLT, *Naval Proving Ground, Dahlgren, Va.*—For the solution of the equation of interior ballistics it is essential to define the powder burning and bore dissipation functions appropriate to the system. These can be identified by experimental firing which obtains pressure and displacement of projectile as time distributions. The present experiment measures projectile displacement by use of gun coils, mounted at intervals along the bore. A steady current is established in the coils before the round is fired. As the base of the projectile passes from a coil the transient electromotive forces develop a small change in the primary current, the oscillographic record of the secondary impulse having a form facilitating accurate time evaluation. Absolute position at the instant of current maximum, can be checked for new conditioning by means of external screens times of contact being superposed on the record. The coils are the basis, also, for an empirical method of measuring ejection velocities at high angles of projection, and aboard ship. Magnetic lag measurement for this cycle of short duration, .001 second or less, may be practicable with a coil set external to the gun, utilizing difference between flux values for projectile at rest and in motion and with compensation for eddy current.

56. A method for precise speed control developed in connection with an absolute measurement of resistance. FRANK WENNER AND CHESTER PETERSON, *Bureau of Standards, Washington, D.C.*—Any absolute measurement of resistance inherently involves a measurement of length and of time. In one of the methods on which we are working in the Bureau of Standards time enters as the speed of rotation of a direct-current motor. It is not necessary that the speed over very short periods of time be highly constant, but over periods of about 10 seconds and longer the average speed should be constant and known to within one part in 200,000. On the shaft of the motor there is a 1000-cycle generator whose electromotive force is synchronized with a 1000-cycle electromotive force obtained from a piezoelectric oscillator. Synchronization is secured by rectifying and amplifying the instantaneous sum of the two electromotive forces. The amplifier output current has an average value depending upon the phase angle between the two electrical systems. This current actuates a relay controlling power applied across a heavy inductance in one of the armature leads. As a consequence, the average speed of the motor is constant to the same precision as the oscillator frequency, which is stable to within a few parts in ten million. The method of control requires an oscillation of the speed about the average. This oscillation is of short period and small amplitude.

57. Resistance-temperature law for oxides. J. A. OSTEEN, *Lehigh University*. (*Introduced by C. C. Bidwell*).—Bidwell showed that the resistance temperature law for certain variable conductors (oxides, etc.) was of the form $\rho = Ae^{Q/RT + aT}$. Plotted in the form $(-1/\rho)(d\rho/dT) = [Q/(RT^2)] - a$ he obtained for Fe_2O_3 straight lines with a break near the recalescence point, the two lines having the same y intercept but different slopes. This law was also followed by metallic germanium. The present paper extends this work to zinc oxide and beryllium oxide. Beryllium oxide yields two straight lines showing a transition at 750°C. Zinc oxide yields two straight lines with a transition in the interval 250°C–500°C. The two zinc oxide lines have different

slopes but the same y intercepts. With successive heatings to 1050°C there occurs continued decreases in the slope of the line for the 500°C – 1000°C range but no change in the y intercept. The line for the range 0°C – 250°C changes on successive heatings to 1050°C and finally stabilizes to a value of slope and intercept which repeats on succeeding runs. On the suggestion that the indicated transformation was due to impurity, new material of special purity prepared by the New Jersey Zinc Company was studied. The behavior of this material was found to agree closely with that of the earlier specimen but gave a more clean cut transformation.

58. High resistances made from metallic oxides. E. R. MANN AND D. R. MOREY, *Cornell Univ.* (Introduced by C. C. Murdock.)—The object has been to find a simple and rapid means of making high resistors (10^8 to 10^{12} ohms) of good quality. Resistors are made by mixing metallic oxides in suitable binders of an insulating nature. In all specimens, an ageing process occurs. In certain cases, most of the ageing occurs within a few hours and the resistors show but small and slow changes thereafter. In this there is the advantage of the use of the resistor within a short time after it has been made. A further advantage lies in the extreme ease of making. In the matter of size and ultimate constancy these resistors are not superior to some other types made by more painstaking and laborious methods, yet they will serve excellently for many purposes. A large change with temperature is present in most specimens. They have been tested for deviations from Ohm's law and for small fluctuations under working conditions.

59. A new theorem concerning temperature-compensated millivoltmeters used with shunts for the measurement of current. H. B. BROOKS, *Bureau of Standards, Washington, D. C.*—Millivoltmeters are essentially permanent-magnet moving-coil galvanometers for laboratory or switchboard use. The moving coil is of copper or aluminum wire of high temperature coefficient, hence for a given applied voltage the resulting current and deflection will vary greatly with changing temperature. Millivoltmeters are partly or wholly compensated for temperature by connecting a manganin coil in series with the moving coil. To obtain complete compensation in this way requires, on the average, about 200 millivolts at the millivoltmeter terminals for full-scale deflection. This is undesirably high, and the Swinburne method is therefore used to get complete compensation with about 50 millivolts for full-scale deflection. Either kind of compensated millivoltmeter, used with a shunt for current measurements, is compensated (as an ammeter) only when the resistance of the shunt is small relatively to the resistance of the manganin coil in the millivoltmeter. One maker of high-grade compensated millivoltmeters does not care to supply shunts with a rating of less than 30 times the full-scale current of the millivoltmeter. A simple theorem has been found which applies to either type of compensated millivoltmeter and removes the limitation against low-range shunts.

60. An experimental study of the natural widths of the x-ray lines in the L-series spectrum of uranium. JOHN H. WILLIAMS, *University of California*.—The rocking curves of $UL\alpha_1$ in three different anti-parallel positions of the double x-ray spectrometer give a natural width which is practically independent of the dispersion. The natural widths of $UL\alpha_1$ and $UL\beta_1$ have been observed as a function of voltage and no significant dependence was noted. The half widths at half maximum of twelve lines in the uranium L-series spectrum were studied and the results are:

Line	α_1	α_2	β_1	β_2	β_3	β_4	β_5	β_6	γ_1	γ_2	γ_3	γ_6
$\Delta\lambda$ in X.U.	0.439	0.494	0.299	0.369	0.382	0.726	0.252	0.487	0.242	0.57	0.47	0.233
ΔV in volts	6.56	7.20	7.17	8.04	9.40	16.1	5.94	9.71	7.96	19.7	16.2	8.18

Possible correlations with the electron transitions are suggested and the predominance of nuclear effects are evident from the greater widths of lines involving the elliptical orbit L_I . The large natural widths of the lines excludes the possibility of observing the effects of nuclear spin suggested by Breit. The actual shape of the line $UL\alpha_1$ has been investigated and found to approximate that predicted by the classical theory.

61. The width of soft x-ray lines. WILLIAM V. HOUSTON, *California Institute of Technology*.—The most direct experimental evidence as to the distribution of energy levels in a solid crystal comes from the observations on soft x-ray lines. The work of Söderman and others in

the extreme ultraviolet shows that while spark excitation gives sharp lines, excitation of a solid target by electron bombardment gives very broad lines. The shape of these lines, when proper account is taken of the transition probabilities, gives the distribution of the upper, occupied energy levels of the solid. Although it is difficult to infer the energy level distribution from the observations, because of the unknown transition probabilities, it is easy to determine the line shape to be expected from various models. The simple Pauli-Sommerfeld model of perfectly free electrons, gives the correct order of magnitude for the width of the lines, but does not give a very good approximation to the observed shape. If Bloch's method of starting with the functions of the individual atoms is used, the agreement in both shape and width is rather good. The lines of those elements whose outer shells are incomplete, show the sharp falling off on the short wavelength side which is characteristic of the Fermi statistics.

62. Crystal structure of lithium iodate. F. A. BARTA AND W. H. ZACHARIASEN, *University of Chicago*.—The structure of lithium iodate was determined by using the oscillation and powder methods. Lithium iodate is hexagonal with 2 molecules per unit cell of $a=5.469\text{\AA} \pm 0.003\text{\AA}$, $c=5.155\text{\AA} \pm 0.005\text{\AA}$. The space group assigned is D_6^0 and the atom positions are: 2Li in $(00\frac{1}{2})$ $(00\frac{3}{2})$, 2I in $(\frac{1}{2}\frac{2}{3}\frac{1}{3})$ $(\frac{2}{3}\frac{1}{3}\frac{1}{3})$ and 6O in $(uu0)$ $(0\bar{u}0)$ $(\bar{u}00)$ $(\bar{u}\bar{u}\frac{1}{2})$ $(0u\frac{1}{2})$ $(u0\frac{1}{2})$ with $u=\frac{1}{3}$. The structure is based on hexagonal closest packing, with the lithium and iodine atoms both lying within oxygen octahedra. The atomic distances are Li—O and I—O = 2.23\text{\AA} with lithium octahedra sharing faces with each other, one lithium and one iodine octahedra sharing only edges and two iodine octahedra only corners.

63. The refractive indices of potassium chlorate crystals, and the structure of the ClO_3 group. W. H. ZACHARIASEN, *University of Chicago*.—The method developed by W. L. Bragg (Proc. Roy. Soc. London 105, 370 and 106, 346 (1924)) has been used in order to calculate the refractive indices of KClO_3 crystals from the atomic arrangement. The Cl^{+5} dipole of the ClO_3 group was given one degree of freedom, along the trigonal axis of the radical. The calculations give agreement with the observed birefringence if the height of the Cl^{+5} dipole above the plane of the oxygens is .99\text{\AA}. X-ray determination gives a displacement of .49\text{\AA}. The scattering power for x-rays depends almost entirely upon the K and L electrons. The x-ray method therefore gives us the position of the Cl^{+7} core, whereas the optical calculations fix the position of the dipole. We must suppose the dipole to be formed by a displacement of the core and the two outer electrons. The observations thus indicate that the two valence electrons of Cl^{+5} are displaced with respect to the core, in a direction away from the oxygen plane. This result is in agreement with the picture of the ClO_3 group given by the author in different publications. The calculated and observed birefringence and refractive indices are:

	Observed	Calculated
α	1.410.....	1.420
β	1.517.....	1.535
γ	1.524.....	1.535
$[(\beta+\gamma)/2]-\alpha$	0.111.....	0.115

64. The structure of the NO_2 group. G. E. ZIEGLER, *University of Chicago*.—The structure of NaNO_2 was determined in order to test W. H. Zachariasen's prediction (in press, Jour. Am. Chem. Soc.) that the NO_2 group would be angular with 120° between the N—O bonds. Powder crystal, rotating crystal, and Laue data were used. The lattice is body-centered, orthorhombic, space-group $\text{C}2v-20$, with a unit cell $a=3.55\text{\AA}$, $b=5.56$, $c=5.37$ containing 2 molecules. From visually estimated intensities the positions of the atoms are:

Na	0, u , 0;	$\frac{1}{2}$, $u+\frac{1}{2}$, $\frac{1}{2}$	$u_{\text{Na}}=210^\circ$
N	0, u , 0;	$\frac{1}{2}$, $u+\frac{1}{2}$, $\frac{1}{2}$	$u_{\text{N}}=30^\circ$
O	0, 0, u ;	0, 0, $-u$;	$\frac{1}{2}$, $\frac{1}{2}$, $u+\frac{1}{2}$; $\frac{1}{2}$, $\frac{1}{2}$, $\frac{1}{2}-u$ $u_0=70^\circ$

($360^\circ=a$, b , or c respectively)

Distances between atoms: N—O = 1.13\text{\AA}, O—O same group = 2.09, O—O different groups > 3.3, Na—O two O's = 2.53, Na—O four O's = 2.46. h = displacement of N from O—O line = 0.46 \text{\AA}. The angle between the N—O bonds = 130° . The observed data definitely disagree with a co-linear NO_2 group.

65. Precision wave-length measurement with the double crystal x-ray spectrometer. ARTHUR H. COMPTON, *University of Chicago*.—An x-ray spectrometer was designed with the first crystal mounted on an auxiliary table supported by the frame of the spectrometer, and with the second crystal mounted on the central table of the instrument, whose position is read from a precision circle. The ionization chamber (of 25 cc capacity, filled with krypton) is on an arm whose position is read by a second precision circle. The instrument was built by the Societe Genevoise de Physique. The first crystal was adjusted to throw the $K\alpha_1$ line of molybdenum over the main axis of the spectrometer, and measurements were made with the second crystal in the (1, -1), (1, +1), (1, -4) and (1, +4) positions (Allison's notation). The reflection maxima from calcite (corrected to 18°C) occur at $\theta_1 = 6^\circ 42' 35.5''$ and $\theta_2 = 27^\circ 51' 32.9''$ with a probable error of 0.25" due chiefly to errors in reading the circle. Using an apparent grating space for the first order of 3.02904 Å at 18°C, we get $\lambda = 707.832 \pm 0.002$ mÅ. Larsson obtained 707.831 ± 0.003 mÅ using Siegbahn's photographic method. Comparison of θ_1 and θ_2 gives for the index of refraction in calcite, $1 - \mu = (2.10 \pm 0.15) \times 10^{-6}$, in good accord with Hatley's more direct measurement of 2.04×10^{-6} .

66. Absolute wave-lengths of the copper and chromium K series. J. A. BEARDEN, *Johns Hopkins University*.—A consideration of the objections to the measurement of x-ray wave-lengths by ruled gratings shows that the method should be reliable if the apparatus is in precise adjustment and the gratings of good quality. In the present experiments 5 gratings were used which were ruled on two ruling engines. The method of the experiment was similar to that given by the writer in the Proc. of the Nat. Acad. of Sci. 15, 528, (1929). The results from different gratings on the same wave-length agree very satisfactorily. The final results of 172 plates are given in the following table.

Spectral Line	Crystal λ	Grating λ	Limiting Error	Grating λ - Crystal λ
Cu K_β	1.38914 Å	1.39225 Å	± 0.00014 Å	+0.224%
Cu K_α	1.53838	1.54172	$\pm .00015$	+ .217
Cr K_β	2.08017	2.08478	$\pm .00021$	$\pm .222$
Cr K_α	2.28590	2.29097	$\pm .00023$	+ .222

From these results, the grating constant of calcite is $d = 3.0359 \pm 0.0003$ Å, and Planck's constant h as determined by Duane, Palmer and Yeh is $h = 6.573 \pm 0.007 \times 10^{-27}$ erg sec. The mean value of the dispersion of x-rays as determined by Stauss (Phys. Rev. 36, 1101, (1930)) and Larsson (Inaugural Dissertation, Uppsala, 1929) gives $e/m = 1.769 \times 10^7$ e.m.u. g^{-1} . The values of these constants are independent of any imperfection in the crystal grating. If the crystal lattice is assumed "perfect" then we have, Avogadro's number $N = 6.019 \times 10^{23}$ mol. per mol. the charge on the electron $e = 4.806 \times 10^{-13}$ e.s.u. and $h = 6.623 \times 10^{-27}$ erg. sec.

67. Absolute measurement of the Cu L_α line. CARL E. HOWE AND MILDRED ALLEN, *Oberlin College*.—Two photographic plates at different distances from a plane glass grating of 600 lines/mm are exposed simultaneously to the radiation from a copper target. Wave-lengths are computed from the plates and the constants of the apparatus. Over sixty determinations indicate for the wave-length of the L_α line of copper a value close to $13.326 \text{ Å} \pm 0.01$ (mean deviation) ± 0.001 (probable error). This differs by 0.15% from 13.306 Å as obtained by Larsson from crystal measurements.

68. Theory of the diffuse scattering of x-rays by solids. G. E. M. JAUNCEY, *Washington University, St. Louis*.—The classical theory of x-ray scattering has been applied to the scattering of x-rays by the electrons in the atoms of a solid. The case in which the solid consists of atoms of one kind has been considered. The interaction of the waves scattered by each electron with these scattered by every other electron in the solid has been considered. The analysis is simplified by the fact that the orbital periods of the electrons in the atoms are very much shorter than the vibrational periods of the atoms, due to thermal agitation. The final formula obtained is $S = 1 + (Z-1)(f^2/Z^2) + (F^2/ZN)X$ where S is the scattered intensity per electron relative to the scattered intensity from a single isolated electron, Z is the atomic number, F the atomic struc-

ture factor including the effect of thermal agitation f' is related to f the true atomic structure factor (without thermal agitation), N is the total number of atoms, and X is a certain double summation. The value of X has not been obtained for an amorphous substance, but it has been evaluated for the case of a simple cubic crystal by Jauncey and Harvey in another paper (No. 153).

69. Hyperfine structure and width of x-ray spectral lines. F. K. RICHTMYER AND S. W. BARNES, *Cornell University*.—In a recent letter to the *Physical Review* (Sept., 1930) we reported measurements which seemed to indicate that the $K\alpha_1$ line of W(79) has a hyperfine structure of the type predicted by Breit. The measurements were made with a two-crystal spectrometer of special design. It now appears, after further critical and extensive study, that the apparent separation must have been due to some (as yet) unknown instrumental peculiarity. The numerous measurements made in connection with this study permit a determination of the width of $WK\alpha_1$. The average of several measurements in second, third and fourth order, after applying corrections for rocking curves of the crystals in the parallel position, gives a half width of 0.154 X.U.

70. Survey of the satellites of the $K\alpha_{1,2}$ doublet, the $K\beta_1$ and $K\beta_2$ lines. O. REX FORD, *West Virginia University*. (Introduced by R. C. Colwell).—In a paper on the satellite structure of the x-ray diagram lines $L\alpha_1$, $L\beta_1$ and $L\beta_2$ for the elements Rb (37) to Sn (50) Richtmyer and Richtmyer, by a careful timing of exposures, were able to show that the number of satellites were more numerous than previously reported. These results called for a survey of the satellite structure of the K-diagram lines. Such a survey extended the range of the elements over which the satellites $K\alpha_3$, $K\alpha_4$ and $K\alpha'$ could be measured. An entirely new satellite of the diagram line $K\beta_1$, designated by $K\beta^0$, was found for the elements Ca(20) to Cr(24). The satellite $K\alpha_3$ was found to consist of two components over the range of elements Al(13) to Cl(17) instead of a singlet as previously supposed. Microphotometer records of the spectrograms show a very significant reversal in the relative intensities of the $K\alpha_3$ and $K\alpha_4$ satellites at the element P(15). That the square root of the difference in frequency between a satellite and its parent line is a linear function of the atomic number is shown to be approximately true for satellites of the $K\alpha_{1,2}$ doublet. This relation is not valid for satellites of $K\beta_1$ and $K\beta_2$.

71. Effect of piezoelectric oscillations on the Laue patterns of quartz. G. W. FOX AND P. H. CARR, *Iowa State College*.—In an attempt to determine the amplitude of vibration of the atoms in a quartz lattice brought about by piezoelectric oscillations, a series of Laue photographs have been made of both Curie and thirty-degree cut plates, using the white radiation from a standard Coolidge tube. This tube had a tungsten anode and carried a current of four milliamperes at 95 kilovolts. Eastman standard x-ray film was used with no sensitizing screens. On examination, the patterns produced by each plate, oscillating and non-oscillating, appear identical except in one respect: the pattern of the oscillating plate is several times as intense as that of the non-oscillating. A four-hour exposure of a non-oscillating plate to radiation of the above mentioned type, produces but the rudiments of a pattern, whereas, the same plate oscillating produces a very beautiful intense pattern for the same time of exposure. The effect is quite independent of the piezoelectric frequency and does not depend on whether the plate vibrates according to the shear mode or the transverse mode. It is hoped that the work in progress will establish the cause of this peculiar intensity difference.

72. Calculation of the resolving power attainable in x-ray spectroscopy by photographic methods. SAMUEL K. ALLISON, *University of Chicago*.—If w_c , the (half) range of glancing angle over which a crystal will reflect monochromatic x-rays has been determined by the double spectrometer method, it is possible to calculate what resolving power is attainable from this crystal by photographic methods. Equations are set up giving the resolving power in terms of a , the slit width, and R , the distance from slit to photographic plate. Some results are: (1) No appreciable increase in resolving power is obtained by making $a/2R < \frac{1}{2}w_c$. (2) If $a/2R > 2.5w_c$ the resolving power does not involve w_c . (3) The resolving power attainable in the first order by photographic methods is $1/2^{1/2}$ of that attained in a double spectrometer in the (1, 1) position with crystals of equal perfection, as stated by Valasek (*Phys. Rev.* 36, 1523 (1930)). (4) The

resolving power of the instrument used by Valasek in his experiments on the molybdenum K spectrum in the first order was about 5350, whereas that of a double spectrometer in the (1, 1) position with crystals of the perfection of those used by Allison and Williams (Phys. Rev. 35, 1476 (1930)) is about 8100. The calculations are extended to include measurements of widths of spectrum lines by photographic methods.

73. Indices of refraction and absorption in the case of soft x-rays. ELMER DERSHEM, *University of Chicago*.—Measurements of the absorption of the $K\alpha$ line of carbon in carbon, nitrogen, oxygen and neon indicate that for elements such that $\lambda_K < 44.6\text{\AA} < \lambda_{L_I}$ the atomic absorption coefficient is given by the following equation: $\mu_a = 1.65Z^{4.4} \times 10^{-23}$. The linear absorption coefficient of fused quartz may be calculated from its density and the absorption coefficients of its constituents and is found to be 47,200. The index of absorption κ , is found from the equation $\kappa = \mu\lambda/4\pi = 1.68 \times 10^{-3}$. The Drude-Lorentz dispersion formula yields the value, $\delta = 1 - n = 4.8 \times 10^{-3}$. Reflected intensities computed from these values are somewhat higher than those found experimentally. Good agreement is secured if κ is assumed to be 2.5×10^{-3} . The results indicate that the value of δ computed from the Drude-Lorentz formula is the correct one but that surface films or imperfections reduce the reflected intensity in much the same manner as an increase of absorption. Other measured values of atomic absorption coefficients for the $K\alpha$ line of carbon are as follows: A, 30.1×10^{-19} ; Kr, 43.4×10^{-19} ; Xe, 14.5×10^{-19} ; Au, 40.7×10^{-19} . The bearing of these results upon x-ray absorption formulas is discussed.

74. Change in x-ray wave-lengths by partial absorption. J. M. CORK, *University of Michigan*.—Experiments have been carried out to duplicate those of Dr. B. B. Ray, in which a beam of x-rays traversing an absorbing medium gave in the direction of transmission a modified line of longer wave-length. The shift in wave-length corresponded to the x-ray photon elevating an electron to an outer atomic level and passing on unchanged in direction with diminished energy and hence a longer wave-length. Using the $K\alpha$ lines of copper and the $L\alpha$ line of tungsten with absorbing screens of beryllium, boron, carbon, oxygen and nitrogen under a variety of conditions, it has been impossible to show the existence, in any case, of a modified line.

75. X-ray absorption measurements in mercury vapor. FRED M. UBER, *University of California*. (Introduced by Robert B. Brode.)—The mass absorption coefficients, μ/ρ , of mercury in the wave-length region 0.74 to 1.4A were determined by an ionization method. The absorber was in the form of superheated vapor, whose density was calculated on the assumption of perfect gas behavior. The absorption chamber was entirely of pyrex glass, and was combined with the x-ray tube into a single unit. Electrometer deflections of several millimeters per second were obtained with the tube currents ranging from 6.5 to 17.5 m.a. and with the voltage low enough to prevent excitation of wave-lengths corresponding to the second order reflection. Readings were taken for several positions of the crystal before removing the absorbing vapor from the path of the beam. The magnitudes, δ , of the three L absorption discontinuities, where δ is defined as the ratio of μ/ρ on the short and long wave-length sides of the limit, are $\delta L_I = 1.18$, $\delta L_{II} = 1.39$, $\delta L_{III} = 2.45$. The mass absorption coefficient can be expressed by the relation $\mu/\rho = A\lambda^c$. The constant A assumes a different value for each branch of the curve, but the value of c does not vary from 2.6 by more than 0.1 for all four branches. The value of μ/ρ at 1.4A is in accord with what one would expect from Allen's values for gold and lead, which indicates that no appreciable error is introduced by using the perfect gas equation for superheated mercury vapor.

76. Lattice parameter of copper by a precision instrument. C. S. BARRETT AND H. F. KAISER, *Naval Research Laboratory, Washington, D. C.*—A precision x-ray camera for large angle diffraction, a modification of the instrument of Sachs (Phys. Zeit. 60, 481, 1930), has been constructed. A photographic plate is used, avoiding film shrinkage. A specimen is used whose surface is plane, parallel to the photographic plate, and perpendicular to the x-ray beam. The distance from specimen to plate is measured by a micrometer. The instrument is applicable to specimens prepared for metallographic examination, and is convenient for high temperature studies. The parameter of copper was determined for material from Adam Hilger Ltd. analyzing

Oxygen 0.040%, Nickel 0.002%, Iron 0.003%, Arsenic 0.004%, Lead 0.001%, Calcium 0.001%, with spectroscopic analysis indicating in addition only slight traces of magnesium, caesium, and sodium. The specimen was prepared with a polished surface, annealed two hours in vacuum, and etched lightly. Copper and brass anticathodes were used. Wave-lengths assumed were Cu $K\alpha_1=1.53739\text{\AA}$, Cu $K\alpha_2=1.54126\text{\AA}$, Zn $K\alpha_1=1.43206\text{\AA}$, Zn $K\alpha_2=1.43587\text{\AA}$. The mean value of 18 observations of a_0 for copper at 20°C was 3.6078 ± 0.0001 . This value agrees closely with that of Ageew, Hansen, and Sachs, (Phys. Zeit. 66, 350, 1930), 3.6081\AA and yields a calculated density of 8.93 in accord with measured densities, 8.94 ± 0.01 (I.C.T. Vol. II, p. 456).

77 Lattice parameters of solid solutions of silicon in copper. H. F. KAISER AND C. S. BARRETT, *Naval Research Laboratory, Washington, D. C.*—Measurements of a_0 for α -Cu-Si alloys containing less than 0.06% total impurities were made on the precision instrument described above. The alloys were homogenized by a 48 hour anneal at 750°C in vacuum, terminated by a quench in water. After a polish, they were given a 3 hour anneal at 725°C in purified hydrogen and again quenched in water. Subsequent polishing and etching was done with great care to provide a surface free from cold work, and exposures were made within 24 hours; these precautions were taken to avoid decomposition of the solid solutions. Alloys containing 5.91% and 6.36% Si, however, showed by their diffraction patterns and by their a_0 values that there was precipitate present. The parameters found were as follows in A.U. at 20°C : 1.09% Si = 3.6103; 3.01% Si = 3.6128; 5.02% Si = 3.6150; 5.91% Si = 3.6151; 6.36% Si = 3.6157. Densities calculated from these parameters and compared with densities as measured by Norbury (Trans. Farad Soc. 19, 586, 1923–24) indicate that the solid solution is of the simple substitutional type, and agree well with Norbury's densities when calculated on this theory. That the silicon atom expands the copper lattice in spite of its smaller radius is not regarded as an anomaly, since the elements differ in crystal structure. Studies of orientation of the precipitate are being conducted.

78. The x-ray analysis of vesuvianite. B. E. WARREN, *Massachusetts Institute of Technology*.—Vesuvianite $\text{H}_2\text{Ca}_{10}\text{Al}_6\text{Si}_9\text{O}_{38}$ is a complex, tetragonal silicate with $a=15.60\text{\AA}$ $c=11.83\text{\AA}$ space group D_{4h}^4 and four molecules in the unit cell. The cell contains 260 atoms and involves 44 parameters. The analysis is of particular interest as an extreme case of a complex structure, and illustrates the extent to which our present knowledge of the physical chemistry of the silicates has progressed. The structure is determined by means of a close relationship which is discovered between vesuvianite and the cubic crystal garnet $\text{Ca}_3\text{Al}_2\text{Si}_3\text{O}_{12}$. Two quadrants in the vesuvianite unit cell are identical in structure to the corresponding two quadrants in garnet except that they are rotated 45° about c . Quantitative measurements of the integrated reflexion with a Bragg ionization spectrometer for 40 planes give structure amplitudes in good agreement with those calculated from the structure. The structure contains SiO_4 and Si_2O_7 groups, and the coordination numbers are Si-4, Al-6, Ca-8.

79. Atomic scattering power of copper and oxygen in cuprous oxide. G. A. MORTON, *Massachusetts Institute of Technology, Rockefeller Institute for Medical Research*. (Introduced by B. E. Warren.)—The atomic F -curves for copper and oxygen for the $K\alpha$ radiation of copper have been determined from cuprous oxide, and are compared with the F_{Cu} -curve from metallic copper and F_{O} -curve from NiO. Measurements were made on samples of finely powdered Cu_2O pressed into suitable briquets, using an x-ray powder spectrometer to measure reflected intensity. The structure factor F for the reflecting planes is calculated from the power of reflexion. The atomic scattering factors as a function of $\sin \theta/\lambda$ are found from these F values. The F_{Cu} -curve and F_{O} -curve as obtained from Cu_2O and those from metallic copper and oxygen in NiO are found to be the same over the overlapping portions of the curves.

80. An x-ray determination of crystal orientation in nickel, copper and aluminum, produced by cold rolling. C. B. HOLLABAUGH AND W. P. DAVEY, *The Pennsylvania State College*.—High purity nickel, copper and aluminum, free from all preferred orientation, were cold rolled in such a way as to produce no appreciable temperature rise and the orientations were determined after each pass using the method of Davey, Nitchie and Fuller (Mines and Met.

Tech. Pub., 243, E88). Nickel and copper showed identical orientations both as to limits of ranges of preferred orientations and mean positions. The number of passes through the rolls determines the probability that a crystal fragment will be within the preferred range, but does not affect the limits of the preferred range. Aluminum shows a related preferred orientation, but with widely different angular limits which depend on the number of passes through the rolls. This work, with similar work on silver previously reported, shows, contrary to the accepted belief, that except for copper and nickel, the common face-centered cubic metals show differences in preferred orientation both with respect to the limits of preferred range and with respect to the mean position of orientation. The preferred positions are similar only in that they all show one face diagonal of the cube always in a plane parallel to the direction of rolling and perpendicular to the rolling surface.

81. X-ray evidence as to the size of a gene. OSWALD BLACKWOOD, *University of Pittsburgh*.—To explain certain facts of heredity, geneticists postulate the existence of bodies called genes in the chromosomes of living cells. The diameter of these bodies in the cells of the fruit fly (*Drosophila*) is roughly estimated to be 600A. The writer has computed the approximate number of ions produced in such a gene when exposed to x-rays of known intensity for a known time. Using Patterson's experimental value for the percentage of exposed flies showing a certain mutation about one per cent of the atoms in a gene are found to be "sensitive," (i.e. their ionization is assumed to be accompanied by mutation). If the sensitive material were concentrated in a spherical nucleus, its diameter would be about one-fifth that of the gene. The hypothesis that natural mutations are caused by cosmic or natural gamma-rays seems improbable since the ionization produced in this manner is about three billion times smaller than that due to the x-rays as used by Patterson. The period for one per cent mutation would therefore be about one million years instead of a few weeks.

82. Parallax stereoscopic x-ray pictures. KENNETH S. COLE, *Columbia University*.—Shadow parallax "stereograms" and "panoramagrams" can be made with visible light or x-rays by several types of relative motion of a point source of radiation, the object, a suitable grating, and the photographic plate. Viewed with a similar grating, either a stereoscopic or pseudoscopic effect may be obtained, also, small movements of the object can be followed in the "panoramagram." Stereoscopic x-ray "vision" can be obtained with a fluorescent screen and two gratings.

83. The lethal effect of intense x-rays on the organism *colpidium colpoda*. HARRY CLARK, MORDEN BROWN, AND JOHN THOMAS, *Stanford University*.—Several single-cell organisms have been studied by various investigators. The curves showing the relation between the number of survivors of a group and the time of radiation have been fitted usually by the use of Poisson's exponential series, the number of terms required lying between 1 and 8 with one exception. The results are generally interpreted as statistical evidence of a definite lethal number of quantum-hits, which must fall inside a small "sensitive volume" within the cell, although normal biological variation is sometimes considered. Although Crowther, working with *colpidium colpoda*, used 49 terms for immediate death, the range of individual lethal doses was still very wide. Using silver radiation at 50 kv, several times more intense than Crowther's and well controlled, we have found evidence of an approach to a critical lethal dose, the same for all individuals, which would exclude normal biological variation. To reconcile this result with Crowther's, we suggest that the processes to recuperation, which are known to be very rapid, are less rapid in the sensitive volume than elsewhere. Less intense radiation produces death by injury to the sensitive volume; more intense rays operate predominantly on other parts of the cell.

84. The extension of Clapeyron-Clausius equation to dissociation within the gaseous phase. J. L. FINCK, *Washington, D. C.*.—This paper is a study of the thermodynamic analogies between the liquid-vapor state and the gaseous state in which dissociation occurs. It is noted that the associated gaseous component corresponds to the saturated liquid and that the dissociated gaseous component is the analogue to the saturated vapor. By means of a hypothetical

mechanism, consisting of a piston and cylinder, which contains the gas, and two semi-permeable membranes, it is possible to separate the gas into two phases, one containing the associated component and the second the dissociated component. This permits dissociation to take place by an isothermal-isopiestic process, analogous to the evaporation of a liquid. By means of this hypothetical process it is shown that Clapeyron-Clausius equation must take the form $\Lambda = \theta(v_2 - v_1) (\delta p / \delta \theta)_x$, where Λ is the heat of dissociation, v_1 and v_2 the specific volumes of the associated and dissociated components, each taken at p , θ , and x is the degree of dissociation. Calculations based on experimental data for NH_3 , H_2O , and CO_2 gases check the experimentally determined values for Λ to 1 percent and less. Some remarks are made with regard to superheated and supercooled states.

85. The mechanics of effervescence. C. J. CRAVEN AND OTTO STUHLMAN, JR., *University of North Carolina*.—Small bubbles of gas rising through a liquid originating at various depths, great compared to their dimensions, arrive along a spiral path, at the surface with the same terminal velocity. They roll under the surface film, come to rest and burst, projecting fragments of liquid into the air. These fragments rise to different heights. For a given radius of bubble, temperature remaining constant, the separate fragments follow a near Maxwellian distribution when distribution in height is examined as a function of diameter of bubble. After the maximum height is passed the above distribution becomes less regular, probably due to distortion in shape of the larger bubbles. Bubbles rising through water at 21°C , having diameters up to 0.16 cm burst into three fragments, from 0.16 to 0.20 cm they burst into two fragments. Bubbles larger than this burst irregularly.

86. The absorption of audible vibrations in the air. VERN O. KNUDSEN AND L. P. DELSASSO, *University of California at Los Angeles*.—Recent measurements on the absorption of high pitched sound in air show (1) that the absorption is several times greater than that accounted for by viscosity, heat conduction and radiation losses, and (2) that the absorption decreases as the amount of water vapor in the air increases. By making reverberation measurements in two rooms which have the same boundary material (painted concrete) but different "mean free paths," it is possible to eliminate the surface absorption, and thus determine the absorption in the air only. Measurements obtained to date, both in the two room experiments and in the free atmosphere, indicate that at a frequency of 4096 cycles, for example, the attenuation constant at 21°C and 20% relative humidity is about 0.00009 and at 70% relative humidity is about 0.00005 C.G.S. units. In a mixture of air and CO_2 (4% by volume) there was evidence of a slight increase in absorption owing to the presence of CO_2 . The data have a bearing upon problems in sound signaling and in architectural acoustics, and may have a bearing upon the absorption of energy within the molecule.

87. The flow of gases through porous materials. H. G. BOTSET AND M. MUSKAT, *Gulf Research Laboratory, Pittsburgh, Pa.*—An experimental study has been made to establish quantitatively the characteristics of and laws governing the flow of gases through consolidated and unconsolidated porous materials of fine texture. Experiments were performed with columns of glass beads, homogeneous and heterogeneous unconsolidated sands, as well as with samples of actual sandstones. With the sandstones linear flows were made both perpendicular and parallel to the bedding plane. Radial flows through annular sections of the sandstone were also made. In all cases it was found that the gradient of the squares of the pressures is proportional to a power of the mass velocity. In the various cases the exponent was found to lie between the limits 1 and 2 corresponding respectively to completely viscous and completely turbulent flow in straight cylindrical tubes. For a given sand however it remains fairly constant over a considerable range in the mass velocity. On the basis of these results a theory was developed for the production from and pressure decline in a closed sand reservoir of uniform thickness producing into a well under conditions of radial two-dimensional flow. The theoretical predictions check qualitatively with the limited field data that are available.

88. Molecular flow and the formation of beams. A. ELLETT, *State University of Iowa*.—The streaming of air at low pressure through short circular tubes is shown to give rise to an angular distribution of the molecules emerging from the tube in fair agreement with the cal-

culations of P. Clausing (*Zeits. f. Physik* **66**, 471, 1930). Measurements were made by means of a Pirani gauge.

89. The Brownian motion of strings and elastic rods. G. A. VAN LEAR, JR., AND G. E. UHLENBECK, *University of Michigan*.—The method introduced by Ornstein is applied to calculate the Brownian-motion mean-square deviation for strings and for elastic rods, the surrounding medium being a gas. For the string, a varying tension and elastic binding at the ends are supposed, and a formula is obtained for the mean-square deviation of any point at time t , having started with a given deviation of that point; the result contains infinite series. This result is specialized to: (1) the string with fixed ends and constant tension, and (2) the string hanging under gravity. In case (1), for the mid-point, and for a limited time interval, the series are summed; for $t \rightarrow \infty$, the result is given for all points, agreeing with that given by Ornstein for the mid-point. Elastic rods are treated similarly, and similar results are obtained. The effect of gravity, when the rod is vertical, is introduced by a simple and consequent perturbation method, and a formula is obtained for the mean-square deviation of the lower end; this agrees closely with Houdijk's experimental results. The time dependence given by the complete formula cannot yet be tested, for Houdijk gives only limiting values in his publication.

90. Pirani gauge applied to the measurement of small pressure changes. R. M. ZABEL AND A. ELLETT, *State University of Iowa*.—The application of the Pirani gauge to the measurement of small pressure changes is discussed. Both nickel and tungsten wires are used as filaments in the gauge. Nickel wire not only has the greater sensitivity but possesses several other advantages. The theory of the gauge is developed so that it is possible to predict the affect of change in length or diameter of the gauge wire upon the sensitivity of the gauge. To obtain maximum sensitivity the wire should be made as long as convenient and its diameter adjusted so that its resistance is approximately equal to the resistance of the galvanometer. Both theory and experiment indicate that the sensitivity of the gauge is increased by increasing the area of the wire or by decreasing the temperature of the walls of the gauge. The theory also predicts that there is an optimum temperature to which the wire should be heated for maximum sensitivity of the gauge. The observed and computed values of the optimum temperature are compared. The maximum sensitivity attained is a galvanometer deflection of 1 mm for a pressure change of air equivalent to $5 \pm 1 \times 10^{-9}$ mm of mercury.

91. Application of transient network theory to gas flow in vacuum systems. DONALD S. BOND, *University of Chicago*. (Introduced by Harvey B. Lemon.)—With complex vacuum systems employing connecting tubing of only moderate diameter, the instantaneous pressure at any point may be calculated with considerable simplicity by employing the electrical analogy. Resistance is defined (by Knudsen's equation) in terms of tube dimensions; capacity (both lumped and distributed), in terms of volume. The network which simulates the most general type of closed vacuum system consists of n T-mesh circuits with resistance and capacity only. The solution of the n mesh equations gives the potential drop (or pressure) across each capacity of the form $e_j = \sum a_{jk} \exp(-b_k t)$. The solution can be carried out numerically for any number of meshes. Using curves of this form, which check with experiment at low pressures, it has been possible to correct McLeod and ionization manometer readings to give true pressures at any part of the system. These have been used in the evaluation of true pump speeds. The agreement has given a check on the region over which Knudsen's low-pressure equation is valid.

92. Time-pressure characteristics of some diffusion and molecular pumps. PETER J. MILLS, *University of Chicago*. (Introduced by Harvey B. Lemon.)—Observations on various pumps were made of the time rate of change of pressure during the evacuation of a 4 liter volume and of the equilibrium pressure reached when this same 4 liter volume was leaking at a measured rate. The high vacuum pumps included single and multistage, air and water cooled, glass and steel diffusion pumps; and molecular pumps. Most of the diffusion pumps were mercury filled but several were tested with a filling of oils of low vapor pressure. Various backing pressures were obtained from several types of force pumps. Pressures, read on a pair of McLeod gauges and on an ionization manometer, gave apparent speeds from which true pump speeds were calculated by the method outlined in the preceding abstract.

93. The theoretical pressure distribution on wing sections. THEODORE THEODORSEN, *National Advisory Committee for Aeronautics, Langley Field, Virginia.* (Introduced by J. S. Ames.)—This paper presents a simple and exact method of calculating the lift distribution on thin wing sections. The angle at which the flow enters the leading edge smoothly is shown to play an important rôle in the theory, and is termed the ideal angle of attack. The lift distribution at this particular angle, termed the "basic distribution," is shown to be a characteristic property of the section. It is shown that the lift of a wing section may be considered to consist of (a) the basic distribution and (b) the additional distribution, the latter being identical for all sections. It is further shown that the additional lift intensity in potential flow of a non-compressible liquid is infinite at the leading edge, and the conclusion is made that the present theory of thin wing sections is applicable only at the ideal angle of attack. The theory is adapted to describe some of the properties of the actual or thick wing sections, and it is established that the essential parameter occurring in this analysis is the radius of curvature at the leading edge. The approximate magnitude and location of the maximum lift intensity is determined.

94. The effect of the presence of a grid upon certain characteristics of the airflow at the surface of an airfoil. MERIT SCOTT, *Cornell University.*—In a previous paper it was reported that the heat dissipation per unit area from the surface of an airfoil, as measured by resistance strips mounted parallel to the span and flush with the surface, is a characteristic of the airflow. An integral relation was set up from which it was shown that the coefficient of heat dissipation is proportional to the velocity gradient at the surface of the airfoil and hence to the viscous resistance. The effect of the presence of a grid, whose position with respect to the airfoil is varied, upon the above mentioned characteristics, has now been observed. It is found that systematic changes in these quantities may be followed as various parameters in the problem are altered. Mathematical treatment appears to be too involved for the present; but qualitative explanation is being attempted in terms of types of flow, the Prantl boundary layer, the Rayleigh surface of separation, etc.

95. Some examples of dimensional analysis. JAKOB KUNZ, *University of Illinois.*—The dimensional analysis has been applied to the following cases. (1) A solid body moves in a viscous medium, so that the motion is essentially determined by the viscosity, a characteristic length of the body, and the velocity, but independent of inertia, i.e., the density. The analysis leads to the formula $F = K\mu v C$. Stokes analysis gives $C = 6\pi$. For higher velocity we assume that the viscosity has very little influence and that on the contrary the forces are determined by vortices and waves mixed up, or on the density ρ . The analysis leads to $F = v^2 \rho l^3 C$, Jonkowski-Cutta found $F = v^2 \rho A \sin \alpha \cdot k$ for the lift of an airplane. (2) When the velocity of a projectile approaches that of sound, then the force depends probably on the compressibility of the medium. The force of resistance appears in the form $F = \rho l^2 (v/c)^n C_1$, where c is the velocity of sound. (3) In an analogous way we proceed to study the motion of a fluid in a tube under a pressure gradient P . For a slow laminar motion under the influence of viscosity μ we obtain $P = (v/r^2)\mu C$, which is Poiseuille's law. In the case of turbulent motion we obtain $P = v^2 r^{-1} \rho C$, where C is a dimensionless constant. Finally if the velocity is very large, approaching that of sound, P appears in the form: $P = \rho/r (v/c)^n C$.

96. The Auger effect in atomic spectra. A. G. SHENSTONE, *Princeton University.*—In most complex spectra there are two distinct series limits, the corresponding ions being of different structure. A term built on the ion of higher energy may be above the lower of the two limits. It is then possible for the atom to dissociate spontaneously into an ion plus an electron if there is a correct relationship between the quantum numbers of the term and those of the ion and electron. The transition probabilities may be expected to be governed by rules similar to those which are applicable in predissociation of molecules. The effect is shown in the terms from the structure d^9s, s in CuI. The terms are 4D , 2D , 2D and the lines due to all the components with $J = 1\frac{1}{2}$ or $2\frac{1}{2}$ are absent or extremely weak in low-pressure sources, and very diffuse under high pressure. The ionization transition must be to the ion d^{10} plus a d -electron. The fact that the coupling is not completely Russell-Saunders accounts for the presence of the effect in 4D . The structure d^9s , d also shows the same type of effect, but the observations are as yet incomplete. In BeI, the lines due to the negative term $3s2p^3P$ are absent in the spectrum

from the Schuler tube but present in high-pressure sources. The negative terms of CaI should show the effect but there are no observations in proper sources.

97. Intensity relations in complex spectra. GEORGE R. HARRISON AND M. H. JOHNSON, JR., *Massachusetts Institute of Technology, and Harvard University*.—A correlation is found between anomalous intensities in multiplets and the presence of neighboring states having the same J values as the perturbed terms. This indicates that the extension of the sum rules ordinarily assumed, in which all lines arising from a given state are summed, is incorrect, and that all similar terms having identical J values and lying near one another must be summed together. A general quantum-mechanical proof has been found that the following rule holds: The relative total intensity of all lines arising from transitions between all states J_1 and J_2 in two configurations is constant for any coupling. Where several configurations overlap the rule must be extended to include the new terms of similar J . Where relatively small departures from LS coupling exist only close-lying terms of similar J need be grouped together. Experimental verification is difficult as generally a large number of lines must be summed, but fragments often serve to test the rule. Confirmatory intensity measurements are presented which prove the interdependence of neighboring terms of common J , and it is shown that intensity anomalies are more sensitive indicators of departures from LS coupling than are the other anomalies associated with it.

98. Electrostatic interactions in (jj) coupling. D. R. INGLIS, *University of Michigan*.—A method is developed for calculating the energy of electrostatic electronic interaction for the various states of an atom in (jj) coupling. The largest perturbation of spin-orbit interaction is first taken into account by using single-electron wave functions stabilized for this interaction. Antisymmetric combinations of products of these form the fundamental wave functions in the perturbation calculation of the electrostatic interaction. The energy is expressed in terms of the same integrals that Slater (*Phys. Rev.* **34**, (1293)) met in the case of (LS) coupling, and one new integral. Of this latter, the angular integrations are carried out and are presented in tabular form. Its radial integrals are the same as those of Slater. In addition to giving interval relations in (jj) coupling, the results help to solve the problem of determining the levels of a configuration for general coupling.

99. Many electron transitions. S. GOUDSMIT AND L. GROPPER, *University of Michigan*.—First and higher order perturbation terms of the spin-orbit and electrostatic interaction in the eigenfunctions of many-electron configurations explain the occurrence of many-electron transitions. By considering which terms can occur in first order perturbation the following selection rules were obtained. No more than three electrons can jump at a time. (a) When three electrons jump all can change their n by an arbitrary amount, one changes its l by ± 1 , the others by δ and ϵ , $\delta + \epsilon$ being even. (b) When two electrons jump both can change their n arbitrarily, one changes its l by $\delta \pm 1$, the other one by ϵ . Breaking off the series expansion for $1/r_{ij}$ in the electrostatic interaction after the second term gives for δ and ϵ only the values 0, ± 1 . The Heisenberg two-electron selection rule is therefore to be considered as a special case of (b). Qualitative rules have been derived to tell when many-electron transitions may be strong. Special selection rules were found for (j, j) coupling. The first order terms also cause anomalies in the intensities of one-electron transitions.

100. The arc spectrum of rhenium. WILLIAM F. MEGGERS, *Bureau of Standards*.—The arc spectrum of rhenium has been photographed from 2100A in the ultraviolet to 8800A in the infra-red; it has more than 3,000 lines in this interval. About 25% of the lines show hyperfine structure of 2 to 6, or more, components. The centers of gravity of complex lines have been determined and are assumed to represent the effective wave-lengths for purposes of analysing the gross structure of the ReI spectrum. About 500 lines, including nearly all of the stronger ones, have been classified as combinations of terms belonging to quartet, sextet and octet systems. The normal state of the neutral Re atom is represented by $(5d^6s^2)a^6S_{21}$. Series-forming terms have been identified which indicate that the ionization potential is approximately 7.8 volts.

101. Evidence regarding the structure of the arc and spark lines of nitrogen. P. G. KRUGER

AND R. C. GIBBS, *Cornell University*.—Nitrogen arc (NI) lines (λ 's 6484, 4151, 4109, and 4099A) have been excited in a liquid air cooled condenser type discharge. These lines were photographically examined with the aid of a Fabry-Perot interferometer whose resolving power, depending on the spacing of the mirror surfaces, was 10^6 or better. With the resolution and dispersion thus obtained, the above lines were found to be sharp and lacking in any evidence of structure. The total line widths have been found to be 0.015, 0.011, 0.010 and 0.010A respectively. Nitrogen spark (N II) lines (λ 's 3995, 4601, 4607, 4614, 4621, 4630, 4643, 5666, 5675, 5679, 5686 and 5710A) have been excited in a liquid air cooled electrodeless ring discharge. The microphotometer curves of the interference patterns from these lines show evidence of structure, although the components are so near together that they have not been clearly separated. The total line widths of these lines are three or four times as large as the widths of the arc lines. This gives added support to the conclusion that the spark lines are definitely complex.

102. The spectrum of Li III. H. G. GALE AND J. B. HOAG, *University of Chicago*.—In accordance with the simple Bohr theory, the spectrum of Li III should show lines analogous to the Lyman series at 135.0, 113.9, 108.0, 105.5, 104.2 etc., and lines analogous to the Balmer series at 729.1, 540.0 Angstroms, etc. We have succeeded in photographing and measuring on several plates five lines of the first of these series and the first line of the second. The line at 135A has been measured in three orders. The first two lines of the first series were previously measured by Edlén and Ericson. The third, fourth and fifth lines of the first series and the first line of the second series have not been previously reported. The $K\alpha$ line of lithium (199.26A) is very strong on many of the plates and has been measured in four orders. The vacuum spectrograph is the same as that first used by Hoag. (Astro. Jr. LXVI, 225, 1927). An electric furnace was used at first to produce lithium vapor between metallic poles. Better success has been obtained recently by using poles of lithium stanide and also metallic lithium in nickel holders.

103. Hyperfine structures in the first spectra of krypton and xenon. C. J. HUMPHREYS, *Bureau of Standards, Washington, D. C.*—The stronger arc lines of krypton and xenon have been examined for hyperfine structures. Methods of observation include the use of a Hilger Fabry-Perot interferometer having quartz plates of 6 cm aperture, a number of fixed étalons, and two quartz Lummer-Gehrke plates. The results obtained by different methods show very satisfactory agreement. Structures of the following lines have been measured: Krypton, 5570.2890, 7685.2472, 8059.5053, 8104.3660, 8281.11, and 8508.8736A; Xenon, 4193.5296, 4500.9772, 4734.1524, 8231.6348, 8409.190, and 8819.412A. No definite numerical regularities in the spacing of components, such as have been reported in the case of neon, have been observed, although with one exception the xenon lines showing structures are due to combinations with the low 3P_2 level and the pattern consists of four components. The satellites of neon lines are supposed to be due to Ne isotope, 22. Krypton and xenon are reported to have 6 and 9 isotopes respectively and the fine structure might be expected to be more complicated. The existence of a reported satellite of the krypton line, λ 5570.2890A, has been confirmed. It is hoped that, by use of some cooling agent such as dry ice, additional structures may be resolved.

104. On the spectra of singly ionized rubidium and caesium. OTTO LAPORTE AND GEORGE R. MILLER, *University of Michigan*.—The spectra of Rb II and Cs II were investigated by means of a hollow cathode tube and a hot spark in the visible and ultra-violet regions. The data obtained were compared with the analyses of Reinheimer (Ann. d. Physik 71, 162, 1923) and Sommer (Ann. d. Physik 75, 163, 1924) respectively. The classifications of these authors were found to be essentially correct though lacking greatly in completeness. The present analysis established the configurations $4p^6$, $4p^55s$, $4p^54d$, $4p^55p$, $4p^56s$ and $4p^55d$ in Rb II and of the corresponding configurations in Cs II. Spectrograms of the hollow cathode discharge of Rb II in the visible region are of special interest because the limit of excitation furnished by metastable helium falls exactly between the various levels caused by $4p^55p$, thus providing a check on the interpretation of the classification. The energy diagram of Cs II shows as a characteristic feature the decomposition of the levels of the above mentioned configurations into two distinct groups due to the large separation of $5p^{5/2}P$ of Cs III. The value of the ionizing potential of Rb II is 27.3 volts and that of Cs II 23.4 volts. Both values are about two volts larger than those given by Mohler (Phys. Rev. 28, 46, (1926)).

105. Term values in the arc spectrum of selenium, Se I. R. C. GIBBS AND J. E. RUEDY, *Cornell University*.—A partial analysis of the arc spectrum of selenium has been given by Runge and Paschen (*Astrophys. Jour.* 8, 70, 1898) in the region 4700–7100 λ , and by McLennan, McLay, and McLeod (*Phil. Mag.* 4, 486, 1927) in the region 1400–2300 λ . The present work is an extension of the data throughout the region 1300–9100 λ , with the classification of a number of new lines. It has been found possible to determine the term values of certain levels built on the lowest level of Se II, $4p^3^4S_{3/2}$, and to relate them to this limit. The ionizing potential between the lowest level of Se I, $4p^4^2P_{3/2}$, and this limit has been computed as 9.70 volts.

106. Series in the spectrum of Germanium II. C. W. GARTLEIN, *Cornell University*.—High excitation of the first spark spectrum of germanium, Ge II, has been obtained in a Schuler lamp with circulating helium gas and a quantity of metallic germanium of high purity in a carbon cathode. The spectrum was photographed in the region 500A to 2500A with a vacuum spectrograph, from 2500A to 4000A with a 75 cm focus quartz spectrograph, and from 4000A to 9000A with a Zeiss 3 prism glass spectrograph. The series $4s^24p^2P_{1,1}^0 - 4s^2nd^2D_{1,2,3}$ has been obtained for values of n from 4 to 11, and five members of the series $4s4p^2D_{1,2,3} - 4s^2nf^2F_{2,3,4}$ have also been obtained. From these data the series limit has been calculated to be $128,535 \pm 50 \text{ cm}^{-1}$ above $4s^24p^2P_{1,1}^0$ and gives about 15.86 volts as the second ionization potential of germanium. Many new intercombination lines have been obtained. This work confirms the assignment of the low terms made by R. J. Lang (*Phys. Rev.* 34, 696, (1929)) and shows the ionization potential to be slightly lower than the estimates of Lang and of Rao and Narayan (*Proc. Roy. Soc. A*119, 607, 1928).

107. A study of the vanadium I iso-electronic sequence. HELEN T. GILROY, *Cornell University*.—A study has been made of most of the spectra in the vanadium I iso-electronic sequence due to the possible electronic changes between the following configurations, $-3d^4s$, $3d^4p$, $3d^5$, $3d^4d$, $3d^34s^2$, $3d^34sp$. Application of the regular and irregular doublet laws to this sequence indicates that a five-electron system, giving quartets and sextets may be added to the systems studied by Bowen and Millikan and Gibbs and White, all of which obey these laws. To illustrate the regular doublet law one $\Delta\nu$ between sextet or quartet levels has been selected from each electronic configuration and $(\Delta\nu/K)^{1/4}$ calculated. The increase in $(\Delta\nu/K)^{1/4}$ is nearly linear with increase in atomic number. Screening constants obtained from these same 'doublets' vary from 16.18 to 15.05 through the sequence from vanadium to cobalt. Moseley diagrams have been drawn for sextets and quartets from each configuration. Utilizing the values of the vanadium I and chromium II limits as estimated by Russell, square roots of term values $(\nu)^{1/2}$ were computed and plotted against atomic number for sextets and quartets. Wherever the electron change did not involve a change in total quantum number $\Delta(\nu)^{1/2}$ was found constant through the sequence to Ni VI.

108. Possible direct reading methods for measuring the current in the electrodeless discharge. CHAS. T. KNIPP, *University of Illinois*.—An inductive method is described for measuring the magnetic component of the electrodeless discharge. In this the gaseous electric current circulating through a reentrant discharge tube was piped, so to speak, aside where it made a loop of one turn and then returned. A low resistance coil of one turn of heavy braid copper wire was placed in the maximum inductive position about this loop. Its terminals were connected to a radio ammeter. With this arrangement the ammeter, on excitation of the electrodeless discharge, read 3 amperes. Further, replacing the ammeter by a 5 cm bridge of No. 38 Ni wire, the wire instantly was fused; and, finally, an aluminum disc suspended within the loop, by a thread attached to its edge, and with its plane parallel to the gaseous current set itself briskly at right angles to same. The magnitude of these effects came as a surprise. The energy was supplied by a 25 kv., 800 kc motor-generator set, which gave highly damped waves.

109. Electrodeless discharge characteristics of hydrogen and nitrogen. OTTO STUHLMAN, JR. AND HENRY ZURBURG, *University of North Carolina*.—Electrodeless arc discharges were obtained by means of a predominant electrostatic field in a spherical bulb placed in a long solenoid excited by undamped high frequency oscillations. Critical minimum potentials to strike the arc were obtained as a function of gas pressure for frequencies between 1.5 and 4.5 million cycles.

The characteristics conformed closely to Pashan's law. The critical points defined by the minimum values of X_m and P_m for a given frequency of excitation showed that the $\text{Log } (X/p)_m$ was a linear function of the frequency f , between discontinuities, interpreted as critical points of ionization. These critical ionization points were found to be interpretable as arising through successive impacts. The results show that here as in Townsend's work at higher pressures X/p increases with decreases in p . X_m was found to decrease with increase in f except where the relation passed periodically through sharp maxima, indicating by their shapes differences in elasticity of impact between the two gases, nitrogen behaving like an inelastic gas and hydrogen like an elastic gas. Pressure-frequency relations indicated the existence of the same ionization discontinuities.

110. The ionization by electron impact and extra ionization potentials of nitrogen and carbon monoxide. JOHN T. TATE AND P. T. SMITH, *University of Minnesota*.—The total positive ion current in nitrogen and carbon monoxide has been measured as a function of the energy of the impacting electrons out to 750 volts. The number of positive charges per electron per cm path at 1 mm pressure of Hg and 0°C was calculated. The efficiency curves for the two gases are almost the same and are very similar to those obtained for the inert gases (Phys. Rev. **36**, 1293 (1930)) and Hg vapor (Phys. Rev. **37**, 808 (1931)). Nitrogen has a maximum efficiency of 10.25 ions at about 100 volts and carbon monoxide a maximum of 10.87 at 105 volts. Extra ionization potentials in nitrogen were found at 15.80 (first ionization potential), 16.01, 16.30, 16.45, 16.55, 16.68, 16.79, 16.88, 16.96, 17.08, 17.20 and 17.44 volts. In carbon monoxide they were found at 14.20 (first ionization potential), 14.36, 14.49, 14.61, 14.71, 14.82, 14.91, 15.36, and 16.38 volts.

111. Mobilities of Na^+ ions in H_2 as a function of time. LEONARD B. LOEB, *University of California*.—The mobilities observed for Na^+ ions from a Kunsman source in H_2 (Phys. Rev. **36**, 152 (1930)) lead to a study of the square wave-form oscillations used. These were shown to be unreliable above 5000 cycles. The previous observations were substantially confirmed with the square waveform tube oscillator and by commutator at low frequencies and by sinusoidal oscillations from two different sources and with two different approaches from 2000 to 40000 cycles. For times of ion transit greater than 5×10^{-4} seconds the mobility uncorrected for temperature was 16 cm/sec per volt/cm. From 10^{-4} to 10^{-5} seconds mobilities of 21 were observed. Between these times intermediate values were found depending somewhat on the purity of the gas. The density correction for gas temperature in the path is slightly uncertain. The average temperature lay between 115°C and 60°C, the best value being 80°C. The mobility constants for the values above are therefore 13.5 and 17.5 respectively. The normal values observed in H_2 from ionization processes are 8.4 cm/sec. The latter value has no significance as the nature of the positively charged molecular nucleus of the ion is not known. The 17.5 value possibly corresponds to the Na^+ ion, while the 13.5 cm/sec value corresponds to a Na^+ ion with an attached molecule.

112. Evidence of energy exchanges accompanying scattering of atoms by crystals. H. A' ZAHL AND A. ELLETT, *State University of Iowa*.—The distribution of mercury atoms scattered from NaCl, KCl, KBr, KI has been studied by means of an ionization gauge as a function of angle of incidence and temperatures of scatterer and incident beam. The direction of maximum intensity makes an angle with the crystal normal not equal to the angle of incidence but always slightly less. The distribution can be well represented by $A \cos \theta + B \cos m(\alpha - \theta)$ ($B=0$ when $|m(\alpha - \theta)| > \pi/4$). The departure from specular reflection $\gamma = (\text{angle of incidence} - \alpha)$ is greatest for high incidence, being 16° to 4° at an angle of incidence of 70° and about 5° at 45° . The values of A/B , m and γ depend on temperatures of crystal and beam. For rock salt at least, γ is less (more nearly specular) the colder the crystal and hotter the beam. Since any incident beam gives rise to diffuse scattering ($A \cos \theta$) plus directed scattering $\{B \cos m(\alpha - \theta)\}$ centered about a line making a greater angle with the crystal surface than does the incident beam it follows that the scattering is accompanied by an energy exchange.

113. The dependence of reaction velocity on temperature. R. M. LANGER AND B. G. CALVERT, *Massachusetts Institute of Technology*.—In a reaction which goes according to the law

$N_E(t) = N_E(0)e^{-\lambda(E)t}$ where $\lambda(E)$ is an increasing function of the energy E , and $N_E(0)$ is the number of systems in state E given by Boltzmann's Law, there are three characteristic types of temperature dependence. (1) For low temperatures there is a range in which the temperature coefficient defined by Tolman's formula $(\bar{E} - \bar{E})/kT^2$ is constant and exceedingly small. Then comes a region (2) where the temperature coefficient rapidly increases with temperature. For higher temperatures (3) the curve again flattens out and the reaction rate K which is an average of $\lambda(E)$ can be expressed in the form $K = (1/\tau)e^{-A/kT}$ where τ is of the order of the period of oscillation of the system. Enough is known about the function $\lambda(E)$ to show for example that in the case of ordinary chemical reactions the region of (3) has already set in far below room temperature and that τ is of the order of 10^{-14} sec. For the typical radioactive processes on the other hand the region of (1) extends above 10^6 degrees. The temperature coefficient at ordinary temperatures is about 10^9 times smaller than in the chemical case so that regardless of the closeness of energy levels in the nucleus and even if the nucleus were in thermal equilibrium which is not the case until very much higher temperatures) the difference in radioactive decay rate between 0° absolute and ten thousand degrees would be inappreciable ($\Delta K/K < 10^{-4}$) even if there were no experimental difficulties in its determination.

114. Improved apparatus for temperature control. E. J. WORKMAN, *National Research Fellow, Bartol Research Foundation of the Franklin Institute*.—Temperature regulators involving the use of a grid controlled arc (thyatron) with a photoelectric cell and galvanometer light spot usually suffer from the effect of "hunting." This effect is inherent in the thermal capacity of the heated unit and is not reduced by increasing the galvanometer sensitivity. Such effects may be eliminated by placing in front of the photoelectric cell a rotating diaphragm having the form of an Archimedes spiral [$r(\text{inches}) = 1 + 0.08\theta$]. The rotating spiral is placed in such a position that the light from the galvanometer mirror falls intermittently on the photoelectric cell, and its duration of transmission is proportional to the galvanometer deflection. With the light beam intercepted in this way, the photoelectric cell causes a thyatron to give pulses of current of duration appropriate to the conditions of balance in the galvanometer circuit. This apparatus reduces the temperature fluctuations by a factor of from 10 to 50 times in comparison to the fluctuations obtained when the stationary diaphragm is used. Applications other than temperature control are discussed.

115. The isotopes of lithium, sodium and potassium. K. T. BAINBRIDGE, *National Research Fellow, Bartol Research Foundation, Swarthmore, Pa.*—Magnetic analysis of the positive rays of lithium from a spodumene source shows no change in the relative abundance of Li^7 and Li^6 with temperature. This is in agreement with Aston and Morand but at variance with the results of Dempster, Thompson, and the similar work of Hundley. A possible explanation of Hundley's results appears when the effects of space charge and the geometry of the tube are considered. In the present work, the ion currents were not limited by space charge, the ions when brought successively to the receiving slit described exactly the same path throughout, and the resolution was great enough to secure complete separation of the ion beams with freedom from background and strays. If Na^{21} or Na^{26} exist at all they are present to less than $1/3000$ of Na^{23} . No evidence is secured of K^{40} or K^{43} to $1/300$ to $1/1500$ respectively of K^{39} . The presence of these isotopes has been predicted or suggested by Beck, Fournier, Kossel and others from nuclear regularities among the elements or to account for the radio-activity of potassium. The complete paper will appear in the Journal of the Franklin Institute.

116. The absorption coefficient for electrons in phosphorus and arsenic vapors. ROBERT B. BRODE AND METTA CLARE GREEN, *University of California*.—The absorption of electrons from a beam sent through the vapor has been observed for a range of electron velocities from 1 to 100 volts in phosphorus and from 4 to 200 volts in arsenic. In the phosphorus curve α has a minimum of about $345 \text{ cm}^2/\text{cm}^3$ at 2 volts, a maximum of about 380 at 4 volts, shows a definite decrease of slope around 16 volts and becomes about 150 at 100 volts. The actual magnitudes are not definite, due to uncertainties in vapor pressure data, to thermal effusion, and to transitions between yellow and red phosphorus during the measurements. No maxima or minima were observed in the arsenic curve. The values of α ranged from about $800 \text{ cm}^2/\text{cm}^3$ at 4 volts to about

250 at 200 volts. These values were taken using pressures from 1 to 3×10^{-3} mm of Hg. because outside these limits there were consistent departures from a linear relationship between $\log I/I_0$ and pressure. At the temperatures and pressures used the molecular formulas are indicated by available data to be P_4 and As_4 .

117. Neutralization and ionization of high velocity helium particles. PHILIP RUDNICK, *University of Chicago.* (Introduced by A. J. Dempster.)—A low voltage hot cathode arc and an accelerating potential were employed to produce high speed helium particles of homogeneous velocity corresponding to 7 to 22 kilovolts, which were then allowed to pass through helium gas. The equilibrium proportion of positive to neutral particles was found to increase with voltage in this range from 0.08 to 0.23. The mean free path for ionization of the high velocity neutral helium atom was found to vary approximately inversely as the square of the velocity from 19×10^{-4} cms to 6.5×10^{-4} compared with the kinetic theory mean free path of 17×10^{-6} cm. This is in agreement with R  chhardt's hydrogen canal-ray measurements but differs from the behaviour of α particles where free path for change from single to double charge increases with the velocity. The mean free path for neutralization of the positive ions was computed to be 1.4×10^{-4} , practically independent of the velocity. The probability of capture of electrons by α rays has been found to depend very strongly on the velocity, in contrast to the approximate independence shown by these slower helium ions. These measurements were made by the method of Wien, with transverse electrostatic fields, using a thermocouple to detect the rays.

118. A method for producing high speed hydrogen ions without the use of high voltages. ERNEST O. LAWRENCE AND M. STANLEY LIVINGSTON, *University of California.*—A method for producing high speed hydrogen ions without the use of high voltages was described at the September meeting of the National Academy of Sciences. (*Science* **72**, 376 (1930).) The hydrogen ions are set in resonance with a high frequency oscillating voltage between two hollow semicircular plates in a vacuum, and are made to spiral around in semicircular paths inside these plates by a magnetic field. Each time the ions pass from the interior of one plate to that of the other they gain energy corresponding to the voltage across the plates. This method has now been tried out with the following results: Using a magnet with pole faces 10 cm in diameter and giving a field of 12,700 gauss, 80,000 volt hydrogen molecule ions have been produced using 2000 volt high frequency oscillations on the plates. A voltage amplification (the ratio of the equivalent voltage of the ions produced to the high frequency voltage applied to the plates) of 82 has been obtained. These preliminary experiments indicate clearly that there are no difficulties in the way of producing one million volt ions in this manner. A larger magnet is under construction for this purpose.

119. Photoelectric fatigue in cobalt. GEORGE B. WELCH, *Marshall College.*—The rate of photoelectric fatigue in cobalt, as a function of the incident radiation, is greater when a quartz-to-Pyrex graded seal is used on the apparatus than it is when the quartz window is attached with de Khotinsky cement. Sealing a side tube containing de Khotinsky cement into the apparatus causes the rate of fatigue to decrease. With nitrogen in the cell, the customary fatigue effects were observed. These experiments were made with pressures ranging from 10^{-7} to 10^{-6} mm of mercury, using the method described by the writer (*Phys. Rev.* **32**, 657 (1928)). Within these limits, an increase in pressure increases the rate of fatigue, an observation which receives some confirmation in experiments performed with electrolytically deposited sodium cells. An explanation is made on the basis of the "patch" theory. (Acknowledgment is made to the National Research Council and to Cornell University for material assistance in this work.)

120. Photoelectric effect of caesium vapour. F. W. COOKE, *University of Illinois.*—The measurements reported by Mr. E. M. Little, (*Physical Review* **30**, 109, (1927)), have been continued with a view to explaining the difference between the results of Little and F. L. Mohler. No effect has been found on the long wave-length side of the critical wave-length 318.4μ . The effect is a maximum at this convergency frequency, decreases with increasing frequency, reaches a minimum and begins to increase again. The order of magnitude of the effect is the same as that of Mohler. Several disturbing effects had to be eliminated and the final effect was only obtained as a difference between a dark current and the current due to light.

121. **Intensity of infrared absorption bands.** LORNE A. MATHESON, *University of Michigan*.—The intensity of absorption bands of gases in the near infrared has been determined by a new method. A beam of radiation of known spectral intensity is passed through the absorbing gas and the absorbed energy found by its resulting heat production causing a measurable expansion of the gas. Readings for various concentrations of absorbing gas are extrapolated to zero concentration. From the results one may calculate the matrix component of the electric moment corresponding to the vibration transition causing the band and the line width of the individual lines. Preliminary results have been obtained with CO.
122. **Infrared absorption bands in formaldehyde vapor.** HAROLD H. NIELSEN AND JOHN R. PATTY, *Ohio State University*.—Two of the principal regions of absorption in Formaldehyde vapor reported earlier at 3.5μ and 4.7μ have been further investigated with an echellette grating with a spacing of 3600 lines to the inch. The region at 3.5μ , earlier thought to be a band consisting of *P*, *Q* and *R* branches has been found under higher dispersion to consist of three overlapping bands with centers at 3.61μ , 3.52μ and 3.37μ . Two of these (3.61μ and 3.37μ) show *P*, *Q* and *R* branches. The average spacing between lines in these bands is about 3.5 cm^{-1} . The third band (3.52μ) has only one branch which consists of groups of closely spaced lines. The spacings between these groups is about 14.0 cm^{-1} or about four times that of the other bands. The region at 4.7μ is similar to those at 3.6μ and 3.37μ in spacing and structure. Due to better resolution in this region, what at 3.37μ appeared as a single line here appears as a group of very closely spaced lines incompletely resolved. Calculations on molecular models of slight asymmetry show very good agreement between theory and experiment for the case where the principal moments of inertia have the values: $A_x = 2.7 \times 10^{-40}$, $A_y = 18.0 \times 10^{-40}$, $A_z = 21.0 \times 10^{-40}\text{ gm-cm}^2$.
123. **The visible and ultraviolet absorption spectra of certain amino acids and their significance.** GLADYS A. ANSLOW AND MARY LOUISE FOSTER, *Smith College*.—The absorption spectra of the acid solutions of alanine, cysteine, aspartic acid, glutaminic acid, and cystine have been studied from 650 to $200\text{ m}\mu$ with a rotating sector photometer. Aspartic and glutaminic acids, whose molecules are nearly symmetrical about the bond between the α and β carbons, gave broad, structureless bands in the visible region with maxima at 526 and $495\text{ m}\mu$, respectively, probably caused by vibration in this bond. Cystine showed a narrower band with maximum at $251\text{ m}\mu$, which is ascribed to vibration in the *S-S* bond, about which it is symmetrical. Continuous absorption started in all the acids between 225 and $200\text{ m}\mu$, due to dissociation in a common group, the least energy being required to dissociate the heaviest molecule. The energy of dissociation in volts is 5.46 , 5.52 , 5.62 , 5.75 , and 6.07 for cystine, glutaminic acid, aspartic acid, cysteine, and alanine, respectively. This dissociation probably occurs in the carboxyl group, for similar compounds, lacking the amino group, give continuous spectra in the same region, as was also found by Ley and Hünecke (*Ber. Deut. Chem. Gesel.* **59**, 510, 1926). Since the water solutions give like spectra except for a slight shift to shorter wave-lengths, the carboxyl group must be present in the same form in acid and water solutions, contrary to the zwitterion theory.
124. **The fundamental vibration bands of CO₂.** P. E. MARTIN AND E. F. BARKER, *University of Michigan*.—The absorption bands of CO₂ at 4.3μ and 14.9μ have been examined with a grating spectrometer of resolving power sufficient to separate the rotation lines. The 4.3μ band consists of positive and negative branches only, with rotation lines about 1.5 cm^{-1} apart, and shows considerable convergence. The spacing is the same as in the long wave band, and is about twice the value obtained when estimated in the usual way from the doublet separation. This indicates that the molecule is linear, with the carbon atom midway between the two oxygen atoms. In the low frequency band a strong zero branch appears at 14.9μ , with twenty or more rotation lines on either side, about equally spaced. The motion associated with this band is one in which the carbon atom vibrates in a plane normal to the line adjoining the two oxygen atoms. A second harmonic band appears at 4.8μ , but there is no first harmonic. Superposed upon the fundamental are three other bands, considerably less intense, of which two correspond to absorption by molecules already excited to the first vibration state by thermal impacts, while the third is a difference band involving the inactive symmetrical vibration. The energy values for three of the vibration states associated with the lower frequency may thus be determined, and

these yield precisely the Raman frequencies observed by Dickinson, Dillon and Rasetti, interpreted as transitions of two in the vibrational quantum number which are required by the selection rules for this isotropic vibration.

125. The vibration spectrum of the N_2O molecule. E. K. PLYLER AND E. F. BARKER, *University of Michigan*. Three very intense infrared bands which apparently correspond to the fundamental vibrations of the N_2O molecule have been observed at wave lengths of 16.9μ , 7.7μ and 4.5μ . All three have been resolved under high dispersion, the rotation lines in each case being spaced about 0.8 cm^{-1} apart. The band at 16.9μ has a strong zero branch, while the other two are of the doublet type. The three first harmonics have also been found, and the one at 8.6μ resolved. This latter is a doublet type band although its fundamental has a zero branch. In addition to these, five combination bands have been studied, all but one being of the doublet type. Several of the bands are complicated by the superposition of absorption due to molecules already excited to the first or second vibration state for the lowest frequency.

126. The band spectrum of germanium sulfide. C. V. SHAPIRO, R. C. GIBBS AND J. R. JOHNSON, *Cornell University*.—A band spectrum of germanous sulfide (GeS) has been observed in absorption at temperatures between 450 and 550°C , in the region $\lambda 3300$ to $\lambda 2400$. Two electronic transitions have been observed, originating from the same normal state of the molecule. The equations for the band heads are:

$$\begin{aligned} \text{I. } \nu &= \nu_e(\text{I}) + 378.2(v' + 1/2) - 1.55(v' + 1/2)^2 - 580.2(v'' + 1/2) + 3.2(v'' + 1/2)^2 \\ \text{II. } \nu &= \nu_e(\text{II}) + 309.6(v' + 1/2) - 1.3(v' + 1/2)^2 - 580.2(v'' + 1/2) + 3.2(v'' + 1/2)^2 \end{aligned}$$

v' progressions of 13 and 9 members respectively have been followed in these systems, while v'' takes on values from 0 to 4. The intensity distribution is normal. There are indications of an isotope effect, as most of the heads are accompanied by two satellites, whose intensity is comparable to that of the main head, corresponding to the fact that germanium consists chiefly of three isotopes. These satellites are being investigated further. Extrapolation of the vibrational series of the two upper levels indicates that the products of dissociation are the same for the two. Assuming that normal atoms are produced by dissociation from the normal state, 3.7 volts are obtained as the upper limit for the energy of one or both of the atoms resulting from dissociation from the excited state of the molecule. This value is of the order of magnitude to be expected for the (still unknown) 1S_0 level of the basic configuration, $3s^23p^4$, of sulfur.

127. Zeeman effect in the $^2\Sigma - ^2\Sigma$ cyanogen bands. E. L. HILL, *University of Minnesota*.—Interpreting the doublet separations in the lower state of these bands as due to a molecular magnetization by rotation, as suggested by Kemble, preliminary calculations have been made of the expected widths and intensity distributions of the Zeeman patterns of some of the doublets for various strengths of the magnetic field. The results indicate that for fields of about 8500 gauss a representative doublet such as $\lambda 3796.104 - 0.184$ should be unobservable as two lines, which seems at variance with the experiments of A. Bachem (*Zeits. f. Physik* 3, 372 (1920)). For somewhat lower fields there may be complete or partial separation of the doublets. Further experiments are being conducted by Dr. Crawford at Harvard to determine with greater accuracy the form of the components of the doublets in the field. Assuming a suitable doublet separation in the upper $^2\Sigma$ state it seems possible that the rapid convergence of the predicted patterns might be checked, but there is at present no estimate of the magnitude of the no-field doubling for this state. If the experimental data seem to justify the effort, a more complete study of the Zeeman effect for Σ states will be undertaken.

128. Interpretation of the spectrum of BaF . A. HARVEY (*Commonwealth Fund Fellow*) AND F. A. JENKINS, *University of California*.—Observed in the first order of the 21-foot grating, the absorption spectrum of BaF presents some 200 bands heads in the region 3600–9000 Å. These represent all of the band systems previously known in emission, and two additional ones. The electronic levels, and the vibration frequencies, $\omega_{1/2}$, (in parentheses) are as follows: X, 0 (465.4); A, 11,630 (434.2); B, 12,260 (433.8); C, 14,040 (420.7); D, 19,990 (452.5); E, 20,190 (454.5); F, 24,170 (504.6); G, 26,240 (501.8). The systems $A \leftarrow X$ and $B \leftarrow X$, discovered in emission by Querbach, are evidently the components of the $^2\Pi \leftarrow ^2\Sigma$ system analogous to that in

SrF and CaF, while the $C \leftarrow X$ system represents the ${}^2\Sigma \leftarrow {}^2\Sigma$ system also found for these molecules. $D \leftarrow X$ and $E \leftarrow X$ probably form a doublet system, which, by analogy with the Cs atom, would involve a more excited ${}^2\Pi$ level. The new systems $F \leftarrow X$ and $G \leftarrow X$ each consist of single-headed bands. New sequences in the $D \leftarrow X$ and $E \leftarrow X$ systems confirm Johnson's vibrational analysis, but Querbach's assignments in the infra-red system are corrected in important respects. All the bands resemble closely those of the isoelectronic molecule LaO, and here also the normal state must be the common lower level of all the known systems.

129. Boron hydride bands. R. F. PATON AND G. M. ALMY, *University of Illinois*.—Two bands due to boron hydride have been photographed in the spectrum of a 110-volt d.c. arc in hydrogen with amorphous boron contained in a nickel or copper cup as one of the electrodes. The bands obtained are those recently reported by W. Lochte-Holtgreven and E. S. van der Vleugel (*Nature*, Feb. 14, 1931) as the (0, 0) and (1, 1) bands of a ${}^1\Pi \rightarrow {}^1\Sigma$ transition in BH. They consist of P , Q , and R branches degraded to the red. The conspicuous Q heads are at $\lambda 4331$ (0, 0) and $\lambda 4367$ (1, 1). From the P and R branches the molecular constants obtained are $B_0' = 11.920$, $B_0'' = 11.808$, $B_1' = 11.21$, $B_1'' = 11.44$, $D_0' = -0.00143$, $D_0'' = -0.00118$, $D_1' = -0.0017$, $D_1'' = -0.00145$. These values indicate that the (0, 1) band should degrade rapidly to the violet. A careful search on our heaviest exposures failed to give definite evidence of such a band. The isotope band due to $B_{10}H$ was observed through the greater part of the P and R branches of the (0, 0) band and establishes the identity of the carrier. Microphotometer comparisons on three plates of the intensities of the 7 best lines in the R branch gave the abundance ratio of B_{11} to B_{10} as $4.86 \pm .15$, indicating an atomic weight of $10.841 \pm .005$, in good agreement with the chemical determination.

130. A further study of the emission spectrum of CO_2 . H. D. SMYTH AND T. C. CHOW, *Princeton University*.—The analysis of the CO_2 bands reported at the New York meeting has been considerably extended. We have now found combinations between the set of vibration terms previously reported ($\nu = \nu_0 + 1101.7\nu + 1.7\nu^2$) and eight or more levels of a different electronic state. This second set of levels seems to be made up of a double vibration set and seven of them can be fitted by a simple quadratic formula of the type

$$\nu = \nu_0 + a_1\nu_1 + b_1\nu_1^2 + a_2\nu_2 + b_2\nu_2^2 + b_{12}\nu_1\nu_2$$

where the constants a_1 and a_2 are of the same order of magnitude as the Raman frequencies of CO_2 . Though nearly a hundred bands have now been fitted into the scheme there remain numerous anomalies which we hope may be removed by further adjustment of the numerical constants. We are also endeavoring to get in emission the bands observed by Leifson in absorption and for this purpose are setting up a small fluorite vacuum spectrograph separated by a fluorite window from the excitation chamber previously described.

131. Band spectrum of bismuth chloride. PAUL G. SAPER, *University of Chicago*. (*Introduced by Robert S. Mulliken*.)—A band system of $BiCl$ in the region from about 4300 to 5500 Å was excited by introducing vapor from heated $BiCl_3$ into active nitrogen. The bands are degraded toward longer wave-lengths. No other bands were found besides this system. The vibrational isotope effect showed that $BiCl$ was the emitter. The isotope effect also served as a valuable aid in locating the origin of the system. The heads were measured and a vibrational analysis made. From the analysis an equation was obtained for the wave numbers of the $BiCl^{35}$ heads. Coefficients for an equation for the $BiCl^{37}$ heads were computed from theory from those of the $BiCl^{35}$ equation. These equations are given below.

$$BiCl^{35}: \nu = 21802.1 + [221.2(\nu' + \frac{1}{2}) - 308.6(\nu'' + \frac{1}{2})] - [2.65(\nu' + \frac{1}{2})^2 - 0.95(\nu'' + \frac{1}{2})^2]$$

$$BiCl^{37}: \nu = 21802.1 + [216.0(\nu' + \frac{1}{2}) - 301.4(\nu'' + \frac{1}{2})] - [2.53(\nu' + \frac{1}{2})^2 - 0.91(\nu'' + \frac{1}{2})^2]$$

The average difference between calculated and observed frequencies was $\pm 1.7 \text{ cm}^{-1}$. The isotopic displacement was calculated for the heads in the cases where the effect was evident, and a close agreement was found with corresponding observed values of the displacement.

132. Perturbations in the helium band spectrum. G. H. DIEKE, *The Johns Hopkins University*.—A large number of electronic terms of the He_2 molecule is known, and therefore

its spectrum is especially suited to test the theory of perturbations developed mainly by Kronig. Two levels which lie close together perturb each other if they have: 1. The same J , 2. The same inversion symmetry, 3. The same exchange symmetry, 4. Δ different by at most ± 1 , 5. The same multiplicity, 6. Approximately the same internuclear distance. The $ns\Sigma$ and $nd\Sigma$ levels of the He_2 molecule satisfy conditions 1. to 6. Rotational levels having the same J lie close together for $J=17$ if $n=4$, for $J=9$ if $n=5$, for $J=5$ if $n=6$. [n , total quantum number.] All these levels show marked perturbations which show in the spectrum by a displacement of the lines in question and sometimes by abnormal intensities. The two levels involved are shifted in opposite directions as required by the theory. There are numerous cases in which levels of the He_2 molecule come close together which do not satisfy the above conditions. Then there is no trace of any perturbation.

133. The effect of temperature upon the ultraviolet band spectrum of ozone and the structure of this spectrum. OLIVER R. WULF AND EUGENE H. MELVIN, *Bureau of Chemistry and Soils, Washington, D. C.*—The ultraviolet absorption of ozone in the region 3400–2300 Å consists of a large number of bands appearing against a background of continuous absorption. The effect of temperature upon this spectrum has been studied over the range -78° to 250°C . A definite though small effect has been observed. Grossly it manifests itself as an increase in contrast with decreasing temperature. Photometric results show this to be chiefly a decrease in absorption between the band edges, all of the bands appearing to come from normal vibrational levels of very low if not the lowest energy. Though somewhat diffuse, the bands tend to degrade to the red. The observed influence of temperature can be explained as the decrease of intensity in the higher rotational absorption of the bands, and possibly also in the continuous background, with decreasing temperature. Discontinuities in the intensity relations and the regular spacing of certain of the bands have led to a partial vibrational analysis indicating two active vibrational degrees of freedom in the excited electronic state. The observed change in the absorption with temperature may affect somewhat the estimates which have been made of the amount of ozone existing in the upper atmosphere.

134. Rotational analysis of the first negative group of oxygen (O_2^+) bands. DANIEL S. STEVENS, *University of Chicago*. (Introduced by R. S. Mulliken.)—The bands were produced by a hollow cathode discharge and photographed in the second order of 21-foot Rowland grating. The following bands were used in the analysis: 1–6; 0–6; 1–7; 0–7. As was expected these bands correspond to ${}^2\Pi \rightarrow {}^2\Pi$ transition like the double headed β bands of NO, the two molecules being alike in their electron configurations. The lower ${}^2\Pi$ is case a as in NO. Unlike the case of NO, however, the upper ${}^2\Pi$ is case b . The lower ${}^2\Pi$ is regular, with a doublet separation (corrected to zero rotation) of 195 cm^{-1} . Each band consists of eight branches (four P and four R) together with some indications of four weak Q branches. This is in agreement with theory. Alternate levels in each Λ -type rotational doublet are missing in both the upper and lower ${}^2\Pi$ states. This is as predicted by the quantum theory of homopolar molecules, since it is known that the nuclear spin of the oxygen atom is zero. The constants of the molecule in the two electronic states are given by: $B' = 1.043 - 0.027v'$ cm^{-1} , $B'' = 1.583 - 0.009v''$ cm^{-1} , $r_e' = 1.41 \times 10^{-8}\text{ cm}$, $r_e'' = 1.15 \times 10^{-8}\text{ cm}$.

135. Electronic energy levels of neutral and ionized oxygen. ROBERT S. MULLIKEN, *University of Chicago*.—The normal state of O_2 is known to be a ${}^3\Sigma_g^-$, probably corresponding to an electron configuration $\cdots 3d\sigma^2 2p\pi^4 3d\pi^2$ hereafter called A . The upper state of the Schumann-Runge bands is a ${}^3\Sigma_u^-$ probably derived (Herzberg) from $\cdots 3d\sigma^2 2p\pi^3 3d\pi^3$, hereafter called B . Configuration A should also give two metastable levels ${}^1\Delta_g$ and ${}^1\Sigma_g^+$, and B a set of metastable levels ${}^3\Delta_u$, ${}^1\Delta_u$, ${}^3\Sigma_u^+$, ${}^1\Sigma_u^+$, and one non-metastable level ${}^1\Sigma_u^-$. The upper level of the atmospheric bands, previously identified as the metastable ${}^1\Sigma_g^+$, is more probably the ${}^1\Sigma_u^-$. If it were ${}^1\Sigma_g^+$, the bands would be an intersystem quadrupole transition and probably much weaker than they are. (That ${}^1\Sigma_u^-$ of B should be below ${}^3\Sigma_u^-$, as here assumed, is indicated by consideration of the wave-functions.) The numerous bands observed by McLennan and others in liquid oxygen probably represent transitions to various metastable levels mentioned above. Or possibly some of these and the ${}^1\Sigma_u^-$ may belong to some other configuration, e.g. $3d\sigma^2 2p\pi^4 3d\pi 3p\pi$.

The normal and excited ^2H states of O_2^+ (cf. preceding abstract) probably result from the respective removal of a $3d\pi$ or a $2p\pi$ electron from A . Existing data on O_2 and O_2^+ bands indicate 11.7 volts as the most probable value of the minimum ionizing potential of O_2 .

136. Magnetic rotation spectrum and heat of dissociation of Li_2 . F. W. LOOMIS AND R. E. NUSBAUM, *University of Illinois*.—The green magnetic rotation spectrum has been obtained from lithium contained in a nickel tube which was heated to about 1200°C by a low voltage stepped-down current. The tube was mounted in a solenoid which produced a field of 1300 gauss. The phenomenon can be seen in greater detail than in the previously studied spectra of Na_2 and K_2 . In addition to the strong line at the head of each band caused by the piling up of the R branch lines, one can see the first few lines of the P branches of the strongest bands. Bands due to the lighter isotope are also visible. The spectrum extends to much higher values of v' and v'' than Wurm or Harvey and Jenkins report in absorption. It has consequently been possible to deduce a much improved value for the heat of dissociation. The frequencies of the magnetic rotation lines are represented by the following formula:

$$= 20398.4 + (266.90v' - 2.840v'^2 - 0.0637v'^3) \\ - (349.00v'' - 2.605v''^2 - 0.0097v''^3).$$

The heat of dissociation deduced by extrapolation of the upper set of levels with a slight correction, due to the deviation of the highest observed levels from the formula, is 1.14 volts. Since the upper levels have been followed to within 0.1 volt of convergence this figure can hardly be in error by more than about 0.03 volt.

137. Valence forces in lithium and beryllium. J. H. BARTLETT, JR., AND W. H. FURRY, *University of Illinois*.—By methods similar to those used by Heitler and London, an investigation has been made of the interaction of two normal lithium atoms, and also of the interaction of two normal beryllium atoms. In the first case, two states, one attractive and the other repulsive, are possible for the molecule. The influence of the K shells has been neglected, and a nodeless wave function such as used by Guillemin and Zener (*Zeits. f. Physik* 61, 199 (1930)) has been employed. The heat of dissociation of Li_2 is calculated to be 1.12 volts and the equilibrium internuclear distance to be 2.4Å as against the experimental values of 1.14 volts (Loomis and Nusbaum, unpublished) and 2.67Å, respectively (Harvey and Jenkins, *Phys. Rev.* 35, 789 (1930)). No stable state is possible when two normal beryllium atoms interact with each other. A study is being made to ascertain under what conditions stable beryllium molecules will be formed.

138. Evidence against the existence of a chlorine isotope of mass 39. MURIEL ASHLEY AND F. A. JENKINS, *University of California*.—From results on the infrared spectrum of HCl , Becker (*Zeits. f. Physik* 59, 601 (1930)) concluded that Cl^{39} exists in small amounts, in addition to Cl^{35} and Cl^{37} . A favorable opportunity for confirming this result is found in the ultraviolet absorption bands of AgCl analysed by Brice. The region adjacent to the AgCl^{37} head of the 0.1 band is exceptionally free from structure, and the AgCl^{39} head should appear at high vapor densities, if this isotope exists. The bands have been photographed with the 21-foot grating, using various vapor densities, from that at which the first appreciable absorption of the AgCl^{37} head begins (550°C), to that for practically continuous absorption (850°). No trace of the predicted band was found. Using the vapor pressure data of Vartenberg and Bosse, the densities at the above temperatures are in the ratio 1/1000, and hence Cl^{39} cannot be present to a greater extent than 1/1000 of Cl^{37} , or 1/4200 of the whole. Similar investigations of the AgBr and AgI bands show that none of the elements involved possess heavier isotopes in quantities detectable by this method. For AgBr , the vapor pressure data of Jellinek and Rudat yield 1/2500 as the upper limit for a Br isotope of mass greater than 81.

139. The $\lambda 3360$ band of NH . R. W. B. PEARSE, *Commonwealth Research Fellow, University of California*.—The band at $\lambda 3360$ emitted by the molecule NH (so-called "ammonia" band) has been photographed in the second order of the twenty-one foot concave grating for the purpose of remeasurement. The source used was a water-cooled discharge tube of large current carrying capacity containing a mixture of hydrogen and nitrogen. With the dispersion of

1.3 Å/mm which was obtained the closely crowded line structure of the central maximum of intensity could be to a large extent analysed into the three components of a triple Q -branch. The band shows the three P , three Q and three R branches appropriate to a $^3\Pi \rightarrow ^3\Sigma$ transition where the $^3\Pi$ state is near Hund's case b . The rotational term differences are obtained from these branches and used to evaluate the molecular constants. The improved wave-length data giving rise to improved values of these constants.

140. On the resolving power of the concave grating. J. E. MACK AND J. R. STEHN, *University of Wisconsin*.—An expression for the resolving power of the concave grating has been obtained, taking into account the fourth order effect upon the phase, of the departure of the grating from the plane. The result is expressed in terms of the "effective width" of the grating; i.e., the width of plane grating which gives the same resolving power as the concave one under consideration. This effective width is equal to the actual width, for narrow gratings. It increases to a maximum as the width of the grating is increased, then it decreases again and oscillates about a constant value, so that there is an optimum width, depending on the radius of the grating ρ , the angle of incidence ϕ , the wave-length λ , and the order of the spectrum. Of special interest is the case of grazing incidence (which has recently become important in extreme ultraviolet spectroscopy), where the effective width can never be greater than $2.3[\rho^3 \lambda \cos \phi]^{1/4}$, and approaches a value 20 per cent less, as the width of the grating is increased. In actual cases the optimum width may be as small as 1 cm.

141. Reflecting power and grating efficiency in the extreme ultraviolet. H. M. O'BRYAN, *The Johns Hopkins University*.—By using a lightly ruled concave glass grating with a water-cooled vacuum spark between tungsten electrodes, enough intensity has been obtained to make quantitative measurements of grating efficiencies and reflection coefficients for various angles of incidence between 1000 Å and 280 Å in a vacuum spectrograph. To obtain the reflection coefficients, a mirror of the substance to be examined was rotated about the axis of a cylindrical oil-coated film on which the reflected spectra was photographed. Small gratings were inserted in place of the mirror with their rulings perpendicular to those of the concave grating and the spectra of the crossed gratings examined. Lightly ruled glass gratings, which were good at normal incidence, gave only extremely faint spectra near grazing incidence. Glass gratings etched with hydrofluoric acid were of little value at normal incidence but surprisingly efficient near grazing incidence. A grating of the echelette type, with the angle between the incident light and reflecting face of the groove made small enough to utilize the increased reflecting power at small angles will be the most efficient grating for the extreme ultraviolet and soft x-ray regions. The etched glass gratings approximate an echelette with a wide V-shaped groove.

142. Three methods of studying capillary structure as applied to wood. ALFRED J. STAMM, *Chemist Forest Products Laboratory, U. S. Department of Agriculture*.—Three different physical methods for studying the capillary structure of porous materials are developed and applied to the study of the fine effective continuous capillary structure of wood. The three characteristic capillary properties measured are, (1) the ratio of effective capillary cross-section to the effective length, (2) the average effective capillary radius, and (3) the maximum effective capillary radius. Some of the important characteristics of the porous structure of wood are briefly presented in order to show that the major part of the void structure, the fiber cavities, have very little to do with the permeability of wood. The pores in the pit membranes which connect the adjacent fiber cavities are shown to be the structure effective in controlling permeability of wood. These pores in the pit membranes in general, are below microscopic visibility, thus necessitating other means of study.

The ratio of the effective capillary cross-section to the effective capillary length is determined from electrical resistance measurements of strong salt solutions filling the void structure and from the specific resistance of the salt solutions in bulk. Strong salt solutions are used in order to make the surface conductivity negligible as well as the conductivity of the swollen cell wall. The average effective capillary radius is determined by combining the results of the preceding measurements with results obtained from hydrostatic flow studies of a continuous water phase extending through the section. Poiseuille's law is used for the calculations. A

differential pressure drop apparatus was devised for these measurements in which the flow of liquid through a standard capillary tube and the test specimen connected in series is determined by measuring the pressure drop through each. The maximum effective capillary radius is determined by measuring the gas pressure required to overcome the effect of the surface tension of water in the capillary systems. The data show the large differences between the fine capillary structure of heartwood and of sapwood.

143. The electric conductivity and dielectric constant of disperse systems. HUGO FRICKE, *The Biological Laboratory, Cold Spring Harbor, Long Island*.—This report refers in particular to suspensions of biological cells. The interior of a biological cell is a well conducting salt solution, but at its surface polarization or the presence of a non-conducting membrane obstructs the passage of an electric current with a resulting low conductivity and high dielectric constant of the suspension. The theory for the passage of an alternating current through a suspension of this type is dealt with and experimental work with various kinds of suspensions such as cream, wet sand, blood, and animal tissues, is described to show the applicability of the theory. The determination of the volume concentration of suspensions, of the form factor of the suspended particles, of the thickness of surface membranes, and of the interior conductivity of living cells are instances of practical applications.

144. Three component emulsions. P. G. NUTTING, *U. S. Geological Survey*.—A quartz sand grain, wet with water, tends to cling to oil but tends to remain on the water side of an interface. A glass plate, such as a microscope cover glass, may readily be floated on water if the water is first covered with gasoline. Muddy water, shaken with gasoline, is cleared, the particles of silt collecting in a tough skin at the interface. Muddy gasoline shaken with clear water gives the same result. Emulsions form whenever a dielectric fluid (air or an insulating oil), solid particles and a second fluid containing OH (water, alcohol, glycerine, linseed oil) are thoroughly mixed and allowed to stand. Two components give solutions and suspensions but never emulsions. The solid particles are supposed to adsorb OH ions on one side thereby acquiring an induced charge on the other which clings to the dielectric.

145. The electric mobility of proteins. HAROLD A. ABRAMSON, *Harvard University*.—
I. The electric mobility of microscopic quartz particles covered with egg and serum albumins (crystallized $3\times$) is, between $pH=3.5$ to 5.5 (1) equal to the mobility of the dissolved protein molecules, and (2) proportional to the combining power of the proteins for acids and bases. This indicates that the amino and carboxyl groups of the adsorbed protein molecules are practically all oriented toward the aqueous phase. The method of mobilities, therefore, is a valuable means of studying the orientation of polar molecules at solid-liquid and liquid-liquid phase boundaries. This is further demonstrated by the behavior of crystals of tyrosine, cystine and aspartic acid. The electric mobilities of these particles indicate that the ampholytic nature of these substances is not simply responsible for the values of mobility. All these crystals are negatively charged at the isoelectric point calculated from the dissociation constants. All three have an isoelectric point at about $pH=2.4$, with reversal of sign in more acid solutions. The mobilities of the amino-acid crystals are, therefore, somewhat like those of inert surfaces, differing however in important respects. It seems likely that the amino and carboxyl groups at the surface of the crystal are not oriented toward the liquid.

II. The change in electric mobility of egg albumin with pH is proportional to the change in specific rotation. A method is available, therefore, for the comparison of change in potential with change in the rotation of the plane of polarized light.

146. The application of the ultracentrifuge to some colloid physical problems. J. B. NICHOLS, *E. I. duPont de Nemours & Company*.—Until recently there existed no very reliable method for determining particle-size distribution curves of colloidal material, especially lyophilic colloids. Accordingly a study was undertaken of the conditions required for undisturbed centrifugal sedimentation of fine-grained colloids and for the accurate determination of the sedimentation-velocity and diffusion relations. The present ultracentrifuge, as developed in Svedberg's laboratory, enables us to exert a centrifugal force 100,000 times that of gravity on a solution and thus to determine the particle size of a great variety of colloidal material and even

molecular weights of complex dyes or proteins. Valuable information can be obtained on phenomena such as the interaction of particles in solution, the effect of the environment on the state of aggregation, and Donnan potential effects.

147. The limitations and adaptability of ultramicroscopes to the study of colloid systems.

L. V. FOSTER, *Bausch and Lomb Optical Co.*—Ultramicroscopes are of two distinctly different types. The best known is the cardioid ultramicroscope in which the illuminating portion produces a hollow cone of large angular aperture with its apex at the object. The observing system is a microscope consisting of a high aperture objective of angular aperture slightly less than that of the hollow cone and a high power eyepiece. The other is the slit ultramicroscope. The illumination system in the slit ultramicroscope is perpendicular to the observing system. Both systems are of high numerical aperture, but no direct light can enter the observation system. Details of construction of both types of ultramicroscopes and their sensitiveness of adjustment will be discussed. Expressions for their limitations in colloid microscopy will be given.

148. Physics in the study of pigment dispersions. F. A. STEELE, *The New Jersey Zinc Co., Palmerton, Pennsylvania.*

—The study of colloids has reached the point where many important contributions are coming from physicists. Even more attention from physicists will be required if this science is to progress as it should. A suitable dispersion of zinc oxide in kerosene has a high yield value and marked plastic properties. A few drops of a dispersing agent added to this mixture largely destroys its plastic properties and greatly increases its fluidity. It is well established that the dispersing agent accomplishes this result by decreasing the interfacial tension and thereby destroying the flocculation of the pigment. In certain cases in paints, however, there is reason to believe an entirely different phenomenon is responsible for yield value and plasticity. Much work with the tools of the physicist is indicated in the solution of this problem. There is much to be done in the study of solid-liquid interfacial tension, adsorption layers, interfacial potentials, and the di-electric properties of colloids before these problems are to be solved. The behavior of pigments in rubber is also discussed.

149. Some theoretical aspects of the biological applications of physics of disperse systems.

N. RASHEVSKY, *Westinghouse Research Laboratories, East Pittsburgh.*—A review of the author's recent theoretical work on the properties of small liquid drops and more generally of systems with very large specific surface, is given. When such a system interacts chemically with the surrounding, in such a way, that the mass of the substances, of which the system is constituted, slowly increases, the system will possess, under very general conditions, properties remarkably similar to those found in living organisms. Thus it is found that such a system may possess a positive rate of growth, when its size exceeds a certain critical one. Below this critical size the rate of growth is negative. Such a system therefore can never be formed spontaneously, although all substances necessary for its formation may be present. Under certain very general conditions such a system will, under the influence of osmotic and other forces, divide into two halves, when reaching a certain size, each half again growing and dividing, and so forth. In many cases the system will possess a very definite geometrical form, which will tend to be restored, when the system is deformed by some external disturbance.

150. Some colloidal properties of bentonite suspensions. H. A. AMBROSE AND A. G. LOOMIS, *Mellon Institute of Industrial Research and Gulf Research Laboratory, Pittsburgh, Pa.*

—A study of the swelling and gelling properties of bentonite dispersions has been made in connection with the increasing use of this mineral for drilling oil wells. It is shown that the emulsoid type of colloids present responds to changes in the pH of the dispersion medium with respect to rate of settling, viscosity and swelling, thus behaving as a typical hydrophilic colloid. The curve for per cent of solid matter settled in a definite time as ordinate against the pH shows a maximum at the isoelectric point, with minima on each side of this point, corresponding to the points of maximum adsorption. As the pH is further increased or decreased flocculation begins with increased rate of settling. The viscosity curve is closely related to the rate of settling curve,

showing maxima and minima corresponding to the electro-viscous effect. Maximum swelling occurs at approximately the point of maximum viscosity. Methods are given for controlling the swelling of bentonites. Relaxation curves are given for bentonite suspensions and utilized to explain the suspension qualities of these sols for heavy mineral dispersions, such as barite or amorphous silica. A few applications of bentonite sols to the drilling of oil wells are given.

151. The theory of electrophoretic mobility. M. MOONEY, *United States Rubber Co., Passaic, New Jersey*.—The Helmholtz theory of electrophoresis is modified, in the case of a spherical particle, to take account of ionic diffusion, ionic mobility and the motion of the water. The effect of these factors on the charge distribution in the double-layer and on the electrophoretic mobility is calculated. The principal term in the resulting mobility formula applies to a sphere whose radius is infinitely greater than the mean thickness of the electric double-layer. It agrees with the Helmholtz mobility formula. A second term gives the first order correction for the curvature of the spherical surface. The Debye-Hückel theory of electrophoresis, the Helmholtz theory and the modified Helmholtz theory are compared; and it is shown that the different value for the numerical factor in the Debye-Hückel mobility formula results from a different assumption concerning the electric field in the immediate neighborhood of the particle when subjected to an external field. It is also argued, as a further consequence of this assumption, that the use of the Debye-Hückel formula is justified only at the other extreme in particle size, that is, for particles whose radii are small in comparison with the mean thickness of the double-layer. The experimental results of several investigators are considered in their connection with these theoretical deductions.

152. Wave motion and the equation of continuity. R. B. LINDSAY, *Brown University*.—The motion of a compressible fluid medium slightly disturbed from equilibrium is described by means of the two fundamental relations between ϕ , the velocity potential, and s , the condensation, viz., (A), the equation of motion: $\dot{\phi} = -c^2 s$, and (B), the equation of continuity: $\nabla^2 \phi = -\dot{s}$. The elimination of either ϕ or s between (A) and (B) leads to the usual wave equation for propagation with velocity c . Now it is interesting that (A) focusses attention on the motion of a part of the medium which is considered to move as a whole (i.e., as a single particle), while (B) is the expression of the fact that a continuous medium is involved. Both ideas are thus implied in wave motion. The present paper studies several other cases where the combination of equations of type (A) and (B) leads to the wave equation. Such are, for example: (a) longitudinal waves in solid rods, (b) transverse waves along a flexible string (wherein, as in (a), the equation of continuity appears in the guise of Hooke's law), and (c), electromagnetic waves. As an allied matter of interest it is shown that equations of type (A) and (B) for a one dimensional continuum may be expressed in the form of generalized Hamiltonian canonical equations of motion where the Hamiltonian is replaced by a functional of ϕ representing the total energy in the medium. This further emphasizes the fundamental nature of equations of type (A) and (B).

153. Diffuse scattering of x-rays by simple cubic crystals. G. E. M. JAUNCEY AND G. G. HARVEY, *Washington University, St. Louis, Mo.*—The value of X in a previous paper by Jauncey (No. 68) has been determined for the case of a simple cubic crystal consisting of atoms of one kind and the formula obtained by Jauncey reduces to: $S = 1 + (Z-1)(f'^2/Z^2) - (F^2/Z)$. There are no experimental results for a crystal consisting of atoms of one kind, but Jauncey and May (Phys. Rev. 23, 128 (1929)) have obtained values for the diffuse scattering of x-rays from a crystal of rocksalt. Assuming rocksalt to consist of atoms of atomic number $(11+17)/2$ or 14, we have calculated values of f' using values of F given by James and Firth (Proc. Roy. Soc. A117, 62 (1928)). These calculated values of f' are found to be only slightly greater than the values of F at absolute zero. Also Jauncey (Phys. Rev. 20, 421 (1922)) has measured the effect of temperature on the diffuse scattering from crystals. From the above formula calculations of the ratio of the scattering at temperatures of 568° and 290°K have been made, using F values given by James and Firth. The theoretical and experimental values of this ratio in

one case are 1.29 and 1.33 respectively, and in another case are 1.13 and 1.18, thus showing good agreement between theory and experiment.

154. An experimental test of the ionization chamber method of measuring relative intensities of x-ray spectrum lines. SAMUEL K. ALLISON AND VICTOR J. ANDREW, *University of Chicago*.—A two-compartment ionization chamber has been constructed with the following properties (1) The fraction of the x-ray energy in the direct beam absorbed in the front compartment could be directly measured, (2) The volume of gas from which the ionic saturation current was drawn was sharply defined, (3) Fluorescent radiation or photoelectrons produced in the chamber could not reach the walls (4) The direct beam entered and left the chamber through thin windows and encountered no other parts of the chamber. The relative ionization currents produced in methyl iodide, methyl bromide, argon, sulphur dioxide, and air by the α_1 , β_1 , γ_1 lines of the tungsten *L*-series were measured and the ratios obtained after correction for fraction absorbed were found to vary not more than 1 per cent in the first four gases. In air a correction (Compton, *Phil. Mag.* **8**, 961 (1929)) must be made for scattering; if this is done, ratios agreeing with the first four gases were obtained. The results give strong support to the following hypothesis: The saturation current obtained from a given volume of any gas is proportional to the power of the fraction of the x-ray beam transformed into β -rays within it, providing the β -rays come to the end of their ionising range within the volume. Similar experiments on the uranium *L*-series are being completed.

155. Effects of ground faults and ground connections of the Wheatstone bridge. FRANK WENNER, *Bureau of Standards, Washington, D. C.*—The insulation outside the bridge proper may not be perfect, and with an alternating test current there may also be displacement currents between the source and detector leads. Either results in ground faults and requires that a correction be applied to the usual bridge equation or that certain auxiliary adjustments be made, and usually these adjustments involve some type of ground connection. Ground faults in each of the source and each of the detector leads increase the number of arms of the bridge from 4 to 8. While the equation for the 8-arm bridge is easily determined, usually a part of the data required for its use are lacking. It is shown, however, that the correction to the usual bridge equation necessary to take account of the effect of these ground faults can in most cases be determined from two additional balances of the bridge. One of these is made with one terminal and the other with the opposite terminal of the bridge grounded. Effects of other types of ground faults, and the effectiveness of various adjustments and ground connections in reducing the magnitude of the error resulting from ground faults in case a correction is not applied, are considered.

156. A new principle of sound frequency analysis. THEODORE THEODORSEN, *National Advisory Committee for Aeronautics, Langley Field, Virginia. (Introduced by J. S. Ames)*.—A new method of sound frequency analysis has been developed by the National Advisory Committee for Aeronautics in connection with a study of aircraft noises. The method is based on the well known fact that the ohmic loss in an electrical resistance is equal to the sum of the losses of the harmonic components of a complex wave, except for the case in which any two components approach or attain vectorial identity, in which case the ohmic loss is increased by a definite amount, even though the total current remains the same. This fact has been utilized for the purpose of frequency analysis by applying the unknown complex voltage and a known voltage of pure sine form to a common resistance. By varying the frequency of the latter throughout the range in question, the individual components of the former will manifest themselves, both with respect to intensity as well as frequency, by changes in the temperature of the resistance. No difficulties exist as to distortions of any kind. The fidelity of operation depends solely on the quality of the associated vacuum-tube equipment. An automatic recording instrument embodying this principle is described in detail.

157. The blackening of photographic plates by positive ions of the alkali metals. K. T. BAINBRIDGE, *National Research Fellow, Bartol Research Foundation, Swarthmore, Pa.*—The

blackening of Eastman x-ray plates has been measured as a function of the energy of the ions of Li, Na, K, Rb and Cs. The current density in the ion beam in the mass spectrograph was maintained at 1.32×10^{-8} amp/cm² for the most abundant isotope of each element. With exposures of one minute and for a density $D=0.3$ the energy of the ions ranged from 1440 electron-volts for Cs to 850 electron volts for Li⁷. For a threshold density, $D=0.04$, the energy ranged from approximately 750 to 450 electron-volts for Cs and Li⁷ respectively. A discussion is included of the probable mechanism of rendering a silver bromide grain developable, results with Schumann and Process plates, and blackening as a function of time and the intensity of the ion beams. The ion sources used, which are unsurpassed for steadiness, purity, and ease of manipulation, are described. The complete paper will appear in the Journal of the Franklin Institute.

158. The angular distribution of photoelectrons ejected by polarized ultraviolet light in potassium vapor. ERNEST O. LAWRENCE AND MILTON A. CHAFFEE, *University of California*.—Light of wave-lengths in the region of 2400Å selected by a monochromator and polarized by a pile of quartz plates illuminated a jet of potassium vapor. The lateral directions of emission of the photoelectrons relative to the electric vector were studied. Though the electrons were ejected with less than one equivalent volt velocity, the experiments were definite in establishing that the most probable direction of ejection is that of the electric vector and moreover that the angular distribution varies as the square of the cosine of the angle between the electric vector and the direction in question. This result is in accord with predictions of the wave mechanics for a spherically symmetrical atom and incidentally therefore constitutes additional evidence that molecules do not play an appreciable part in the observed photoionization of potassium vapor.

159. A-type doubling and electron configurations in diatomic molecules. ROBERT S. MULLIKEN AND ANDREW CHRISTY, *University of Chicago*.—Van Vleck's equations for the A-type doublet widths in ²II states, for all intermediate coupling cases between cases *a* and *b*, have been found to fit excellently the data on CH, OH, SiH, CaH, ZnH, CdH, HgH, etc. (Incidentally this had made possible a revision of the hitherto doubtful assignment of *J* values for the Q₂ lines in the ²II, ²Σ bands of CaH, and has permitted identification of the ²R branch.) From the constants of these equations and similar constants for ¹II and ²Σ states, determined from empirical data, further confirmation of Van Vleck's theoretical results is obtained, also interesting information concerning electron configurations of molecules. In this way it is found that the *n* and *l* values previously assigned to outer electrons in hydrides have almost the same well-defined significance as they would in an atom formed by uniting the H nucleus with the heavier nucleus. For example, in the normal (²Σ) and first excited (²II) state of CdH, with configurations $\cdots 5s^2 5p\sigma$ and $\cdots 5s^2 5p\pi$, the present evidence shows that the last electron really behaves like a 5*p* atomic electron, even though the normal (²Σ) state is formed with a small energy of formation from a normal Cd atom ($\cdots 5s^2$, ¹S) and a normal H atom (1*s*, ²S).

160. Colloid physics in latex technology. ANDREW SZEGVARI, *American Anode Inc., Akron, Ohio*. Latex, a suspension of rubber hydrocarbon (latex particles) in an aqueous solution, flows from the rubber tree in an extremely unstable state. When stabilized by raising the *pH* with ammonia it may be stored and becomes available for commercial purposes. The concentration may then be increased by centrifuging, creaming, or evaporation until 60 percent or more is rubber. Rubber goods may be made directly from such stabilized latex by electrodeposition, coagulation, ultrafiltration, evaporation, etc. The controlling factors in the deposition processes are the colloid physical conditions of dispersed systems and most eminently, the electrokinetic characteristics. The electrodeposition of latex gives an interesting colloid physical analogy to electrodeposition of ionic dispersed metals. The most striking difference between these systems with particles of such widely varying size, is the rate of deposition. This is considerably larger in colloid dispersed than in ionic dispersed systems. For most technological purposes the liquid latex systems must be compounded with conditioning ingredients. In this compounding the physical properties of suspensoid-dispersed systems are again concerned.

161. Dirac's spinning electron and Barnett's gyromagnetic effect. OTTO HALPERN, *New York University*.—The paper contains a treatment of the influence of a constrained rotation of the Dirac electron which may be free or bound to a nucleus. The proper values in the rotating system are changed as in the old quantum theory, the sum of spin and orbital angular momentum entering instead of the orbital momentum alone. There appear small additional terms of the order of fine structure separation times angular velocity of rotation.

162. On the design of high-tension condenser leads. HARRY CLARK, *Stanford University*.—A condenser was built for use at 50 kv on direct current consisting of several large glass plates coated with tinfoil and stacked together almost in contact in air. The leads were tinfoil strips 1 inch wide. Although each plate withstood a long test at 80 kv, the assembly sparked over at 50 kv. The discharge occurred opposite a lead where the minimum spark-length was 9 inches and was caused by the inductive effect of the lead and proximity of the plates. The defect was remedied without separating the plates by using leads of thick wire so bent as to cross the margin of the plate at a 30-degree angle. This apparently causes the leakage along the glass opposite the lead to proceed as a very long narrow salient with a smaller potential-gradient.

163. Air-cooled electromagnet for Zeeman effect. I. WALTERSTEIN AND A. I. MAY (*D. E. Ross Research Fellow*), *Purdue University*. (Introduced by K. Lark-Horowitz).—An air-cooled electromagnet for work in Zeeman effect has been constructed due to lack of a "soft" water supply for cooling. The pattern of the instrument follows the Boas type, but includes a number of improvements. The yoke is made of a wider cross section, thus eliminating the narrowing of the pole gap upon application of the field. The current is carried by 2000 turns of flat bare copper ribbon wound in 24 pancake coils which are cooled by a forced draft of air circulated between the coils by a fan. Temperature equilibrium is reached throughout the instrument in less than an hour, and in half an hour in the pole-gap where the temperature rise is about 5°C for an inducing current of 20 amps. Using ferro-cobalt pole caps with pole face of 8 mm diameter fields of 39500 gauss and 43500 gauss were obtained respectively for gaps of 4 mm and 2.4 mm with a current of 25 amps. For a gap of 1 mm and a current of 33 amps a field of 48500 gauss was reached. Zeeman patterns were produced corresponding to nearly full strength of the magnetic field with no loss in sharpness, due to thermal fluctuations even during the first hour of application of the field.

ANALYTIC SUBJECT INDEX TO VOLUME 37

References marked (A) are to abstracts of papers presented at meetings of the Physical Society, those marked with (L) refer to Letters to the Editor.

Absorption coefficient (see also **x-ray absorption, collision diameter**)

- Of gases from 20 to 30μ , J. Strong—1003(L)
- Mass absorption coefficient, the K shell, Dirac relativistic electron, L. C. Roess—455(A), 532

Absorption of light (see also **Spectra, absorption**)

- Of light by fog, S. H. Anderson—1012(A)
- Transformation of light into heat in solids, J. Frenkel—17, 459(A), 1276
- Visible light through fog, (theoretical discussion), H. G. Houghton—466(A)

Acoustics

- Absorption in air, V. O. Knudsen, L. P. Delsasso—1699(A)
- Chladni figures, R. C. Colwell—1684(A)
- Effects of intense audio-frequency sound, N. Gaines—109(A)
- Effects of phase and time shifts on binaural sensation, A. W. Nye, A. K. Steunenberg—228(A)
- Kundt's tube dust figures, E. Hutchisson, F. B. Morgan—1155; R. V. Cook—1189(L)
- New principle of frequency analysis, T. Theodorsen—1717(A)
- Sound absorption determined by transmission measurements, F. R. Watson—109(A)
- Supersonic interferometers, E. Klein, W. D. Hershberger—109(A)
- Supersonic satellites, W. H. Pielemeier—1682(A)
- Velocity of sound at ultrasonic frequencies, C. D. Reid—1147
- Velocity of sound in metal rods, L. C. Shugart—1683(A)
- Vibrations of a loaded string, R. B. Lindsay—1682(A)

Activated gases (see also **Afterglow**)

- Adsorbed films on tungsten in presence of active nitrogen, I. Langmuir—1006(L)
- Dissociation of excited iodine molecules, L. A. Turner, E. W. Samson—1684(A)
- New source of active nitrogen, J. Kaplan—1004(L)
- N_2 -Hg mixtures, B. L. Snively, L. A. Turner—1684(A)

Aerodynamics (see also **Hydrodynamics**)

- Automatic generation of airfoils, D. E. Olshevsky—401
- Heat dissipation and airflow, M. Scott—1701(A)
- Pressure distribution on wing sections, T. Theodorsen—1701(A)

- Thermal boundary layer of a miniature airfoil, M. Scott—1016(A)

Afterglow

- In active nitrogen, apparent fatigue and aging phenomena, C. T. Knipp, L. N. Scheuerman—475(A); spectrum, J. Kaplan—226(A); methods of producing and spectrum, J. Kaplan—1004(L); explanation, J. Kaplan—1406
- In Hg vapor, as recombination phenomenon, H. W. Webb, D. Sinclair—182, 469(A)

Alloys

- Impurities in metals, F. Bitter—1527
- Cu-Ni, magnetic properties, E. H. Williams—1681(A)
- Cu-Ni and Fe-Ni, $K\alpha$ doublets, G. R. Fonda, G. B. Collins—328(L)

Alpha-particles (see also **Radioactivity**)

- Bombardment of N_2 , mass of O^{17} , H. C. Urey—923, 1023(A)
- Capture of electrons, B. Davis, A. H. Barnes—1368(L)
- Photographic effects, T. R. Wilkins, R. Wolfe—1688(A)

Arcs (see also **Discharge of electricity in gases, Spark discharge**)

- Accommodation coefficients, of + ions, C. C. Van Voorhis, K. T. Compton—1596
- Cathode fall, R. C. Mason—1679(A)
- Current carried by electrons at the cathode, K. T. Compton—468(A)
- Electronic velocities in the positive column at high frequency, E. Hiedemann—978
- Formation, T. J. Killian—1678(A)
- High frequency behavior of a plasma, L. Tonks—1020(A), 1458
- High frequency, in Hg, He and Ne, C. J. Brasefield—82
- High velocity vapor jets at cathodes, J. Slepian, R. C. Mason—779(L)
- Mercury arc, theory, K. T. Compton—1077
- Momentum transfer to cathode surfaces, E. S. Lamar—842(L)
- Oscillating arc: elements, group VI, E. Z. Stowell—1452
- Potential drop and ionization at mercury arc cathode, E. S. Lamar, K. T. Compton—1069
- Recombination in mercury vapor, H. W. Webb, D. Sinclair—182, 469(A)

Arcs (continued)

- Temperature of cathode, R. Tanberg, W. E. Berkey—1679(A)
 Vapor stream from the cathode, W. E. Berkey, R. C. Mason—1679(A)

Astrophysics

- Axial rotation of the sun, R. Gunn—283
 Axial rotation and spectra of stars, R. Gunn—1573
 Electrical state of the sun, R. Gunn—983, 1672(L)
 Electric field, atmosphere and temperature of sun, R. Gunn—1129, 1688(A)
 Energy distribution in the lunar ultraviolet spectrum, B. O'Brien, E. D. O'Brien—1012(A)
 Entropy of the universe, R. C. Tolman—1639
 Nebular and coronal lines of oxygen, J. J. Hopfield—160
 Position of the moon in the observer's sky, and radio reception, H. T. Stetson—1021(A)
 Solar and lunar spectra taken in Little America, Antarctica, M. P. Hanson, E. O. Hulburt—477
 Zodiacal light and magnetic disturbances, C. Bittinger, E. O. Hulburt—1190(L)

Atomic and molecular beams

- Bismuth, molecular velocities, I. F. Zartman—383
 Diffraction of hydrogen atoms, T. H. Johnson—87(L), 99(A), 847
 Evidence of energy exchanges, H. A. Zahl, A. Ellett—1705(A)
 Formation of beams, A. Ellett—1699(A)
 Measurement of intensity, A. Ellett, R. M. Zabel—99(A), 1112

Atomic and molecular radii (see Collision diameter)**Atmospheric electricity (see also Meteorology)**

- Atmospheric ionization by cosmic radiation, E. O. Hulburt—1

Atomic structure (see also Energy levels, Spectra)

- Building of atoms, nuclear abundance and stability, W. D. Harkins—105(A)
 Electron distribution in argon, A. H. Compton—104(A)
 Factor curves, M. Muskat—656(L)
 Fermi-Thomas model of positive ions, E. Guth, R. Peierls—217(L)
 Models showing the electron's motion in the Stark effect, R. W. Wood—1022(A)

Atomic weights

- Basis of atomic weight system, R. T. Birge, D. H. Menzel—1669(L)

Barkhausen effect (see also Magnetic properties)

- Propagation of large Barkhausen discontinuities, K. J. Sixtus, L. Tonks—930

Biophysics

- Absorption spectrum of blood and its relation to rickets, R. C. Gibbs, J. R. Johnson, C. V. Shapiro—1012(A)

- Biological effects of gamma-rays, W. G. Whitman, M. A. Tuve—330(L)

- Conductivity of suspensions of biological cells, H. Fricke—1714(A)

- Lethal effect of x-rays on the organism colpidium colpoda, H. Clark, M. Brown, J. Thomas—1698(A)

- Mitogenetic radiation, O. Glasser, V. B. Seitz—465(A)

- Parallax stereoscopic x-ray pictures, K. S. Cole—1698(A)

- Physics of disperse systems, N. Rashevsky—1715(A)

- Significance of wave-length in color vision, C. A. Rinde—465(A)

- Size of a gene, O. Blackwood—1698(A)

- Capillary action (see also Surface tension)**

- Rise in sands of uniform spherical grains, W. O. Smith, P. D. Foote, P. F. Busang—1015(A)
- Structure study as applied to wood, A. J. Stamm—1713(A)

Chemical reactions

- Dependence of reaction velocity on temperature, R. M. Langer, B. G. Calvert—1705(A)
- Collision diameter of atoms and molecules.**
- Collision processes involving no radiation of energy, theory, P. M. Morse, E. C. G. Stueckelberg—449(L)
- Of Hg by scattering of electrons, J. M. Pearson, W. N. Arnquist—970
- Interchange of energy in collisions, theory, C. Zener—459(A), 556
- Of P and As for electrons, R. B. Brode, M. C. Green—1706(A)
- Of Hg and He, effect of resolving power on absorption coefficient, R. R. Palmer—70, 101(A)
- Of Tl, for slow electrons R. B. Brode—231(A), 570

Colloids

- Electric mobility of proteins, H. A. Abramson—1714(A)
- Physics in latex technology, Andrew Szegvari—1718(A)
- Physics in the study of pigment dispersions, F. A. Steele—1715(A)
- Physics of disperse systems, biological applications, N. Rashevsky—1715(A)
- Some colloidal properties of bentonite suspensions, H. A. Ambrose, A. G. Loomis—1715(A)
- Structure study as applied to wood, A. J. Stamm—1713(A)
- Study of colloid systems by ultramicroscopes, L. V. Foster—1715(A)
- Three-component emulsions, P. G. Nutting—1714(A)
- Ultracentrifuge; some colloid physical problems, J. B. Nichols—1714(A)
- Compton effect, (see X-rays diffraction, scattering)**
- Conductivity, Electrical, (see Electrical conductivity and resistance)**
- Constants, physical**
- From absolute wave-lengths of x-rays, J. A. Bearden—1210, 1694(A)
- e/m , by deflection, G. E. Uhlenbeck and L. A. Young—99(A)
- Contact potentials**
- Between iron and nickel, G. N. Glasoe—102(A)
- Corona discharge**
- Oscillation on wires, R. E. Tarpley, J. T. Tykociner, E. B. Paine—1689(A)
- Cosmic radiation**
- Atmospheric ionization, E. O. Hulburt—1

Cosmic radiation (continued)

- Continuous ultra- γ spectrum explanation, cosmic-ray ionization, C. M. Olmsted—1688(A)
Energy of the cosmic electrons by magnetic deflection, L. M. Mott-Smith—1001(L)
Ionization-depth curve, and the present evidence for atom-building, R. A. Millikan, G. H. Cameron—235
Least-square adjustment of cosmic-ray observations, L. D. Weld—1368(L)
Residual ionization in air at high pressures, J. W. Broxon—468(A), 1320

Crystals and crystal structure

- Of anhydrous sodium sulphite, W. H. Zachariasen, H. E. Buckley—1295
Black structure and ferromagnetism, F. Bitter—91(L)
Of the ClO_3 group, W. H. Zachariasen—1693(A)
Cold rolling and recrystallization in steel, C. Nussbaum—458(A)
Density and conductivity of Bi single crystals, grown in magnetic fields, A. Goetz, A. B. Focke—1044
Mosaic structure, diffraction of H atoms, T. H. Johnson—87(L), 99(A), 847
Extra lines in x-ray diffraction patterns, R. W. Drier—712
Of stibnite, J. G. Albright—458(A)
Of copper, C. S. Barrett, H. F. Kaiser—1696(A)
Of lithium iodate, W. H. Zachariasen, F. A. Barta—1693(A), 1626
Mosaic structure, J. A. Bearden—1210, 1694(A)
Of the NO_2 group, G. E. Ziegler—1693(A)
Orientation in Ni, Cu and Al, C. B. Hollabaugh, W. P. Davey—1697(A)
Parameters of solid solutions of Si in Cu, H. F. Kaiser, C. S. Barrett—1697(A)
Of potassium permanganate, R. C. L. Mooney—474(A), 1306
Properties of single crystal Mg, P. W. Bridgman—460(A)
Specific resistances of Zn single crystals, E. P. T. Tyndall, A. G. Hoyem—101(A)
Transparency of sodium fluoride and lithium fluoride, E. H. Melvin—1230
Valence pairs and structure of group, W. H. Zachariasen—105(A), 775(L), M. L. Huggins—447(L), 1177(L)
Of vesuvianite, B. E. Warren—1697(A)
Transverse heat effect, H. P. Stabler—461(A)

Cybotactic state

- Molecular association in water, G. W. Stewart—9

Dielectric constants

- Air at high pressure, J. W. Broxon—473(A), 1338

- Castor oil, linseed oil and tung oil, W. N. Stoops—103(A)

- Complex molecules, formic, acetic, and propionic acids, C. T. Zahn—1516

- Amines, electric moment, P. N. Ghosh, T. P. Chatterjee—427

- And intramolecular field, F. G. Keyes, J. G. Kirkwood—202

- And molecular association, J. A. Wehrle—1135

- Organic compounds, W. R. Pyle—463(A)

- Polarization of electrets, M. Ewing—463(A)

- Rubber time lag, A. H. Scott—1186(L)

- Tung oil, A. A. Bless—1149

Dielectrics and dielectric properties

- Dielectric loss, variations with temperature and frequency, H. H. Race—430, 463(A), erratum—1371

- Of foreign and domestic micas, A. B. Lewis, E. L. Hall, F. R. Caldwell—1690(A)

- Ionization in dielectrics, J. T. Tykociner, E. B. Paine—1690(A)

- Orientation of hydrocarbon crystals by an electric field, R. D. Bennett—103(A)

Diffraction of atoms (see Atomic and molecular beams)**Diffraction of elections (see Election, diffraction)****Dimensional analysis**

- Body moving in viscous medium, J. Kunz—1701(A)

Discharge of electricity in gases (see also Arcs, Spark discharge)

- Accommodation coefficients, of $+$ ions, C. C. Van Voorhis, K. T. Compton—1596

- Collisions of the second kind, L. B. Headrick, O. S. Duffendack—736

- Electrodeless, frequency variations resulting from, J. T. Tykociner, J. Kunz—100(A)

- Electronic velocities in the positive column at high frequency, E. Hiedemann—978

- High frequency behavior of a plasma, L. Tonks—1020(A), 1458

- High frequency discharges in Hg, He and Ne, C. J. Brasefield—82

- Negative volt-ampere characteristics of neon positive column, C. G. Found—100(A)

- Mobility of elections in argon, H. B. Wahlin—101(A), 260

- Oscillations in the glow discharge in argon, G. W. Fox—815; T. C. Chow—574, 1020(A)

Discharge of electricity in high vacua (see Thermionic emission, High voltage tubes)**Dissociation**

- Of excited iodine molecules, L. A. Turner, E. W. Samson—1684(A)

- Of water vapor in electrical discharge, E. G. Linder—1677(A)

- Dissociation, heat of** (see also **Spectra, molecular**)
 Of Li₂, F. W. Loomis, R. E. Nusbaum—1712(A);
 J. H. Bartlett, W. H. Furry—1712(A)
 From predissociation spectra, L. A. Turner—
 1014(A)
 Of zinc, cadmium, and mercury molecules, J. G.
 Winans—107(A), 897, 902, erratum, 1371
- Doppler effect**
 In hydrogen canal rays, H. F. Batho, A. J. Demp-
 ster—100(A)
- Dynamics** (see also **Mechanics, quantum**)
 Vibrations of a loaded string, R. B. Lindsay—
 1682(A)
 Wave motion and the equation of continuity, R.
 B. Lindsay—1716(A)
- Efficiency of ionization**
 Mercury vapor, P. T. Smith—808
 N₂ and CO, J. T. Tate, P. T. Smith—1705(A)
- Elasticity**
 Coefficient of restitution, L. J. Briggs—1683(A)
 Columns with variable end restraints, L. B.
 Tuckerman, Wm. R. Osgood—1683(A)
 Determination of principal stresses from crossed
 nicol observations, R. V. Baud—111(A)
 Of rubber, W. W. Stifler, P. C. Mitchell—1683(A)
 X-ray measurements of the elastic deformation,
 W. P. Jesse—1017(A)
- Electrical conductivity and resistance**
 Of Bi in alternating magnetic fields, W. W. Macal-
 pine—624
 Of bismuth single crystals grown in magnetic
 fields, A. Goetz, A. B. Focke—1044
 Changes, due to magnetism and hardness, S. R.
 Williams, R. A. Sanderson—309
 Of contacts, J. Frenkel—102(A)
 Of disperse systems, H. Fricke—1714(A)
 Hall effect and resistance, F. W. Warburton, J. W.
 Todd—775(L)
 High resistances made from metallic oxides, E. R.
 Mann, D. R. Morey—1692(A)
 Of insulating oils, K. F. Herzfeld—287
 Of Ni and Fe wires in magnetic field, O. Stierstadt
 —1356
 Of oxide cathodes, N. H. Williams, W. S. Hux-
 ford—463(A)
 Potential due to a buried sphere, J. H. Webb—292
 Resistance-temperature law for oxides, J. A.
 Osteen—1691(A)
 Specific resistances of Zn single crystals, E. P. T.
 Tyndall, A. G. Hoyem—101(A)
- Electrical circuits**
 Ground faults and ground connections of the
 Wheatstone bridge, F. Wenner—1717(A)
- Group theory, applied to, N. Howitt—1015(A),
 1583
 Linear time scale for voltage, C. K. Stedman—
 474(A)
 Mutual impedance of grounded wires, J. Riorden,
 E. D. Sunde—1369(L)
 Non-linear circuits, C. G. Suits—462(A)
 Wave form of pulsating D.C., W. B. Notting-
 ham—1690(A)
- Electrical oscillations and waves**
 Effect of meteors on Heaviside layer A. M. Skellett
 —1668(L)
 Frequency and damping of resonating circuits, J.
 T. Tykociner—461(A)
 Position of the moon in the observer's sky and
 radio reception, H. T. Stetson—1021(A)
 Travelling striations in an argon discharge tube,
 T. C. Chow—574, 1020(A) G. W. Fox, 815.
- Electrical moment**, (see **Dielectric constant**)
- Electrodeless discharge**
 Current in, C. T. Knipp—1704(A)
 Decomposition of organic vapors, D. M. Gans,
 W. D. Harkins—107(A)
 Frequency variations, J. T. Tykociner, J. Kunz
 —100(A)
 In H₂ and N₂, O. Stuhlman, Jr., H. ZurBurg—
 1704(A)
 In mercury vapor, H. Smith, W. A. Lynch, N.
 Hilberry—1091
 Relative intensities of the magnetic and electro-
 static illumination components, C. T. Knipp—
 756, 1020(A)
- Electrolytic cells**
 Electro-motive force of paraffin membranes, K.
 Lark-Horovitz, J. E. Ferguson—101(A)
 Photovoltaic effects in Grignard solutions, R. T.
 Dufford—102(A)
- Electrons**
 Capture by alpha-particles, B. Davis, A. H.
 Barnes—1368(L)
 Charge, from wave-lengths of x-rays, J. A. Bear-
 den—1210, 1694(A)
 e/m by deflection experiments, G. E. Uhlenbeck,
 L. A. Young—99(A)
 Pictorial representations of the electron cloud for
 hydrogen-like atoms, H. E. White—1416
- Electron diffraction**
 By a silver crystal, H. E. Farnsworth—1017(A)
 By a single layer of atoms, M. v. Laue—53, 99(A)
- Electrons, photoelectric** (see **Photoelectric effect**)
- Electrons, scattering**
 Resolving power, effect on measurements of ab-
 sorption coefficient, R. R. Palmer—70, 101(A)
 Nuclear scattering, H. V. Neher—229(A)

Electrons, scattering (continued)

- Reflection from solid surfaces, H. V. Neher—655(L)
- of high velocity electrons in hydrogen, H. C. Wolfe—231(A), 591
- In mercury vapor, J. M. Pearson, W. N. Arnquist—970
- Of slow electrons in thallium vapor, R. B. Brode—231(A) 570

Electrons, secondary

- From molybdenum, L. J. Haworth—93(L)

Electrons, thermionic

- Adsorbed films on tungsten in active nitrogen, I. Langmuir—1006(L)
- Barium films on W, H. Nelson—1018(A)
- Dual work function, A. H. Warner—233(A)
- Fermi-Dirac statistics, space charge, R. S. Bartlett—959
- Origin of, from oxide-coated filaments, R. W. Sears, J. A. Becker—1681(A)
- Patch sizes, on a thoriated tungsten filament, L. B. Linford—1018(A)
- Photoelectric and thermionic properties of Rh, E. H. Dixon—60
- Temperature dependence of the work function, J. A. Becker, W. H. Brattain—462(A)
- Thermal fluctuations of surface of cathode, K. H. Kingdon—89(L)
- Theoretical interpretation, W. H. Brattain, J. A. Becker—1681(A)
- Time changes, E. F. Lowry, W. T. Millis—1019(A)

Electro-optical effects

- Deviations from Kerr's law, J. W. Beams—781(L)
- Electro-optical shutter, F. G. Dunnington—1677(A)
- Kerr effect in gases, E. C. Stevenson, J. W. Beams—1021(A)
- Kerr effect in the infrared spectrum, L. R. Ingersoll—1184(L)

Electrophoresis

- Theory of electrophoretic mobility, M. Mooney—1716(A)

Electrostatics

- Potential due to a buried sphere, J. H. Webb—292

e/m

- From absolute wave-lengths of x-rays, J. A. Bearden—1210, 1694(A)
- Of Fe and Cu ions, L. L. Barnes—218(L)
- Value by deflection experiments, G. E. Uhlenbeck, L. A. Young—99(A)
- From the Zeeman effect, J. S. Campbell, W. V. Houston—228(A)

Elements

- Detection of element 85, F. Allison, E. J. Murphy,

E. R. Bishop, A. L. Sommer—1178(L)

Neutron, R. M. Langer, N. Rosen—1579

Energy states of atoms (see *Spectra, atomic*)

Entropy

- Energy and entropy, T. C. Huang—1171
- Of hydrogen, W. H. Rodebush—221(L)
- Of universe, Richard C. Tolman—1639

Errata

- Book review—1675
- Dielectric loss in a viscous, mineral, insulating oil, H. H. Race—1371
- Electrical state of the sun, Ross Gunn—1672(L)
- Energy of dissociation of Hg molecules, J. G. Winans—1371
- Hyperfine structure in ionized Bi, R. A. Fisher and S. Goudsmit—1674
- Magnetic susceptibility of gases. Part I, pressure dependence, F. Bitter—222
- Radiation of multipoles, K. F. Herzfeld—1673
- Field currents**, (see *Thermionic emission, High voltage tubes*)

Fine structure (see also *Spectra, hyperfine structure and x-rays*)

Ferromagnetism, (see *Magnetic properties*)

Fluorescence

- Blue-green, of Hg vapor, P. D. Foote, A. E. Ruark, R. L. Chenault—1685(A)
- Studied by means of a nicol, photocell, D. R. Morey—1686(A)

Galvanoluminescence

- Further study, R. R. Sullivan, R. T. Dufford—1019(A)

Gamma-rays (see also *Radioactivity*)

- Absorption coefficient of, C. S. Barrett, R. A. Gezelius—105(A)
- Biological effects, W. G. Whitman, M. A. Tuve—330(L)
- Wave-length measurement, resolving power of spectrometer, L. T. Steadman—447(L)

Gases (see also *Kinetic theory*)

- Clapeyron-Clausius equation, Extension of, J. L. Finck—1698(A)
- Deposition of dust on walls, W. J. Hooper—111(A)
- Energy and entropy, T. C. Huang—1171
- Equation of state of He, J. G. Kirkwood, F. G. Keyes—832
- Flow through porous materials, H. G. Botset, M. Muskat—1699(A)
- Intramolecular field and the dielectric constant, F. G. Keyes, J. G. Kirkwood—202
- Persistence of molecular rotation and vibration, O. Oldenberg—194
- Physical properties of compressed N₂, W. E. Deming, L. E. Shupe—110(A), 220(L), 638

Gases (continued)

- van der Waals forces, H. Margenau—1014(A),
1425, J. C. Slater, J. G. Kirkwood—682

Gravitation

- Field produced by light, R. C. Tolman, P. Ehrenfest, B. Podolsky—602

Group theory

- Applied to electrical circuits, N. Howitt—1015(A), 1583

Heat conduction

- Diffusion problem for a solid in contact with a liquid, T. E. W. Schumann—1508

Heat of dissociation, (see Dissociation, heat of)**High voltage tubes (see also Ions, high speed)**

- Cold emission from unconditioned surfaces, W. H. Bennett—582
Experiments with high-voltage tubes, M. A. Tuve, L. R. Hafstad, O. Dahl—469(A)
Problems in the design, W. H. Bennett—469(A)

Hydrodynamics

- Air resistance of high velocity projectiles, P. S. Epstein—233(A)
Dimensional analysis, J. Kunz—1701(A)

Hyperfine structure

- Of Al lines, R. C. Gibbs, P. G. Kruger—656(L), H. E. White—1175(L)
Anomalies, G. Breit—1182(L)
Of Bi II and Bi III, R. A. Fisher, S. Goudsmit—1013(A) 1057; J. B. Green—1013(A), 1674(A).
In Cu spectrum, A. G. Shenstone—1023(A)
Derivation of, formulas for one-electron spectra, G. Breit—51
Interval rule and patterns of Bi II, S. Goudsmit, R. A. Fisher—107(A)
Of Li II, S. Goudsmit, D. R. Inglis—328(L)
Of Kr and Xe spectra, C. J. Humphreys—1703(A)
Hg resonance radiation, A. Ellett 216(L) S. Mrozowski—845(L)
Nuclear spin, J. H. Bartlett, Jr.—327(L)
Test of a linear wave equation, D. R. Inglis—795
Theory of separations, S. Goudsmit—663, 1014(A)
Of x-ray spectral lines, F. K. Richtmyer, S. W. Barnes—1695(A)
Zeeman effect of Tl II and III, R. F. Bacher—226(A)

Instruments (see Methods and instruments)**Insulators**

- Dust figures in liquid insulator, Y. Toriyama—619

Intensities in spectra

- Band spectrum intensities for symmetrical diatomic molecules. II, E. Hutchisson—45
 β and γ band systems of nitric oxide, O. R. Wulf, E. J. Jones—471(A)

- Effect of H₂ on spectra of Zn, Cd and Hg, J. G. Black, W. G. Nash—468(A)

- Of He with voltage, J. Razek—1252

- Intensity data from Laue photographs, M. L. Huggins—456

- Of Hg, M. J. E. Golay—821, E. W. McAlister—1021(A)

- Relations in complex spectra, G. R. Harrison, M. H. Johnson, Jr.—1702(A)

- Of Mn, R. S. Seward—344

Ionization by impact

- A, Ne and He by various alkali ions, R. M. Sutton, J. C. Mouzon—229(A), 379

- Of H₂ by positive ions, M. E. Hufford—468(A)

- Hg vapor, ultra-ionization potentials, W. M. Nielsen—87(L); C. R. Haupt—229(A); P. T. Smith—100(A), 808

- Of N₂ and CO, J. T. Tate, P. T. Smith—1705(A)

- Velocities of ions formed in N₂, W. W. Lozier—101(A)

Ionization potentials (see also Ionization by impact)

- Of Hg vapor, W. M. Nielsen—87(L)

- Of O₂, R. S. Mulliken—1711(A)

- Of Sc I, R. C. Gibbs, J. E. Ruedy—1704(A)

- Ultra-ionization in Hg vapor, C. R. Haupt,—229(A); W. M. Nielsen—87(L) P. T. Smith—100(A), 808

- Of N₂ and CO, J. T. Tate, P. T. Smith—1705(A)

- Of Xe II, C. J. Humphreys, T. L. de Bruin, W. F. Meggers—106(A)

Ions, high speed

- Experiments with high-voltage tubes, M. A. Tuve, L. R. Hafstad, O. Dahl—469(A)

- Ions without the use of high voltages, E. O. Lawrence, M. S. Livingston—1707(A), E. O. Lawrence, D. H. Sloan—231(A)

- Problems in the design of high voltage tubes, W. H. Bennett—469(A)

Ions in gases

- Coefficient of recombination, O. Luhr, N. E. Bradbury—998

- Neutralization and ionization of high velocity helium particles, P. Rudnick—1707(A)

- Residual ionization in air at high pressures, J. W. Broxon—468(A), 1320

Ions, mobility

- Aged ions in air, N. E. Bradbury—230(A), 1311

- Electric mobility of proteins, H. A. Abramson—1714(A)

- Electrons in argon, H. B. Wahlin—101(A), 260

- In insulating oils, K. F. Herzfeld—287

- Of Na⁺ ions in H₂, L. B. Loeb—1705(A)

Isotopes

- Absorption bands of atmospheric oxygen, H. D. Babcock, W. P. Hoge—227(A)

Isotopes (continued)

- Be⁸ from band spectra measurements, W. W. Watson, A. E. Parker—167
Of Cl, mass 39, negative evidence, M. Ashley, F. A. Jenkins—1712(A)
Of Li, Na and K, K. T. Bainbridge—1706(A)
Mass defects, R. T. Birge—841(L)
Masses of O¹⁷, H. C. Urey—923, 1023(A), Wm. D. Harkins; D. M. Gans—1671(L)
Mass ratio of oxygen 18 and 16, H. D. Babcock, R. T. Birge—233(A)
Mass ratios from band spectra, R. T. Birge—227(A)
Neutron, R. M. Langer, N. Rosen—1579
Of O, relative abundance, R. T. Birge, D. H. Menzel—1669(L)
Principle of continuity and regularity of series of atom nuclei, W. D. Harkins—1180(L)

Joule-Thomson effect

- In He, J. R. Roebuck, H. Osterberg—110(A)

Kerr effect (see Electro-optical effects)**Kinetic theory of gases (see also Gases)**

- Characteristics of some diffusion pumps, P. J. Mills—1700(A)
Molecular velocities, direct measurement, I. F. Zartman—383
Gas glow in vacuum systems, D. S. Bond—1700(A)

Life of excited states

- Direct measurement of τ , H. D. Koenig, A. Ellett—1685(A)
For 2733A of ionized He, L. R. Maxwell—1685(A)
Of the Hg line λ 2537, P. H. Garrett, H. W. Webb—1686(A)
Of the N₂ molecule in first state, M. L. Pool—1686(A)

Liquids (see also Hydrodynamics)

- Flow through porous mediums, L. A. Richards—461(A)
Mechanics of effervescence, C. J. Craven, O. Stuhlman, Jr.—1699(A)
Molecular association, nature of, G. W. Stewart—9
Structure factor, by x-rays, G. W. Stewart, R. D. Spangler—472(A)
Water, x-ray diffraction and molecular association, G. W. Stewart—9

Magnetic properties

- Block structure, F. Bitter—91(L), 1176(L), 1679(A)
Crystals at low temperature, C. Li—1680(A)
Cu-Ni alloys, E. H. Williams—1681(A)
Fundamental assumptions, ferromagnetism, F. Bitter—1175(L)
Hall effect and resistance, F. W. Warburton, J. W. Todd—775(L)

Heating and residual magnetism R. L. Sanford—1680(A)

Impurities in metals, F. Bitter—1015(A), 1527

Magnetic lag at low flux densities, L. W. McKeehan—1015(A)

Magnetostriction measurements, A. B. Bryan, C. W. Heaps—466(A)

Magnetic doublet, nature of, G. W. Stewart—455(A)

Propagation of large Barkhausen discontinuities, K. J. Sixtus, L. Tonks—930

Resistance of Bi in alternating magnetic fields, W. W. Macalpine—624

Resistance of Ni and Fe wires in longitudinal magnetic fields, O. Stierstadt—1356

And strain of Ag and Cu, H. E. Banta—634

Susceptibilities and ionic moments in the Pd and Pt groups, A. N. Guthrie, L. T. Bourland—303

Susceptibilities of salts of the Fe group, J. H. Van Vleck—467(A)

Susceptibilities of some binary alloys, F. L. Meara—467(A)

Susceptibility of gases, pressure dependence, erratum, F. Bitter—222

Susceptibility, variation with temperature, A. Frank—467(A)

Mass defects

Atmospheric oxygen, H. D. Babcock, W. P. Hoge—227(A)

From band spectra, R. T. Birge—841(L)

Measurements (See also Methods and instruments)

Knowledge of past and future in quantum mechanics, A. Einstein, R. C. Tolman, B. Podolsky—780(L)

Mechanics (see Dynamics)**Mechanics, quantum-atomic structure and spectra**

Hyperfine structure as a test of a linear wave equation, D. R. Inglis—795

Hyperfine-structure formulas, G. Breit—51

Hyperfine structure separations, S. Goudsmit—663, 1014(A)

Pictorial representations of the electron cloud for hydrogen-like atoms, H. E. White—1416

Wave-functions of the state (1s) (2s)¹S, J. P. Vinti—448(L)

Mechanics, quantum—general

Collision processes involving no radiation of energy, P. M. Morse, E. C. G. Stueckelberg—449(L)

Diffraction of electron waves, M. v. Laue—53

Dirac's equation, tensor form, B. Podolsky—1398

Directed valence in polyatomic molecules, J. C. Slater—459(A), 481, L. Pauling—1185(L)

Mechanics, quantum—general (continued)

- Discrete and continuous theories in physics, A. Ruark—315
- Of electrons in uniform crossed fields, M. S. Plesset—1689(A)
- e/m by deflection experiments G. E. Uhlenbeck, L. A. Young—99(A)
- Interchange of energy in collisions, C. Zener—459(A), 556
- Inverse-cube central force field, G. H. Shortley—1014(A)
- Knowledge of past and future in quantum mechanics, A. Einstein, R. C. Tolman, B. Podolsky—780(L)
- Mass absorption coefficient, the K shell, Dirac relativistic electron, L. C. Roess—455(A), 532
- Mean value theories, G. Breit—90(L)
- Neutron, R. M. Langer, N. Rosen—1579
- Orbital valency, J. H. Bartlett, Jr.—459(A), 507
- Polarizabilities, of hydrogen and helium, J. G. Kirkwood—459(A)
- Quantum postulates, logical relativity, W. Band—1164
- Resonance and exchange of excitation energy, O. K. Rice—1187(L), 1551(L)
- Scattering of alpha-rays, M. Muskat—473(A)
- Scattering of high velocity electrons in hydrogen, H. C. Wolfe—231(A), 591
- Schrödinger ψ -function, conditions imposed on it, R. M. Langer, N. Rosen—658(L)
- Spinning electron and gyromagnetic effect, O. Halpern—1719(A)
- Uncertainty principle, A. W. Stern—1186(L)
- van der Waals forces, H. Margenau—1014(A), 1425, J. C. Slater, J. G. Kirkwood—682
- Wave-mechanical theory of radiation, E. H. Kennard—458(A)
- Wave packets, D. G. Bourgin—1689(A)
- Mechanics, quantum—molecular structure and spectra**

- Statistics of nuclei, P. Ehrenfest, J. R. Oppenheimer—333
- Valence forces in Li and Be, J. H. Bartlett, Jr., W. H. Furry—1712(A)
- Mechanics, quantum—of solid bodies**
- Electrical resistance of contacts, J. Frenkel—102(A)
- Problem of crystals, E. L. Hill—785
- Transformation of light into heat in solids, J. Frenkel—17, 459(A), 1276
- Mechanics, statistical**
- Fermi-Dirac statistics, thermionic emission, R. S. Bartlett—959

Statistics of nuclei, P. Ehrenfest, J. R. Oppenheimer—333, J. R. Oppenheimer—232(A)

Metals

- Distribution of electricity near surface, A. T. Waterman—1018(A)
- Impurities in metals, F. Bitter—1015(A), 1527

Metastable atoms and molecules

- Glow discharge in mixtures of the rare gases, L. B. Headrick, O. S. Duffendack—736
- In N_2 , J. Kaplan—226(A)
- Negative volt ampere characteristics of Ne positive column, C. G. Found—100(A)
- And quenching of Hg resonance radiation, O. S. Duffendack—107(A)

Meteorology

- Annual variations in magnetic storms, H. B. Maris—1680(A)
- Atmospheric ionization by cosmic radiation, E. O. Hulburt—1
- Weather forecasting, R. C. Colwell—464(A)

Methods and instruments

- Absorption of x-rays, E. Dershem, M. Schein—104(A) 1238
- Air-cooled electromagnet, I. Walerstein, A. I. May—1719(A)
- Airfoils, automatic generation of, D. E. Olshevsky—401
- Amplification of small direct currents, L. A. DuBridge—392, 461(A)
- Barkhausen effect, E. J. Sixtus, L. Tonks—930
- Coefficient of restitution, L. J. Briggs—1683(A)
- C_p , Variation with pressure, E. J. Workman 1016(A), 1345
- Current measurement in electrodeless discharge C. T. Knipp—1704(A)
- Diffraction of hydrogen atoms, T. H. Johnson—87(L), 99(A), 847
- Diffusion pumps, Characteristics of, P. J. Mills—1700(A)
- Direct measurement of molecular velocities, I. F. Zartman—383
- Electro-optical shutter, F. G. Dunnington—1677(A)
- Errors in physical measurements, E. Q. Adams—458(A)
- Evaporation of various materials in vacuo, J. Strong, C. H. Cartwright—228(A)
- Flight, maintaining direction of, J. D. Tear—464(A)
- Fluorescence studies by means of a nicol, photocell, D. R. Morey—1686(A)
- Frequency and damping of resonating circuits, J. Tykocinski-Tykociner—461(A)
- Galvanometer or radiometer deflections, masked by Brownian movement, S. Smith—229(A)

Methods and instruments (continued)

Geiger-Müller counter and magnetic analyser, J. A. Van den Akker; E. C. Watson—1631
High dispersion in the near infrared, J. D. Hardy—1686(A)
High resistance made from metallic oxides, E. R. Mann, D. R. Morey—1692(A)
High speed ions without the use of high voltages, E. O. Lawrence, D. H. Sloan—231(A), E. O. Lawrence, M. S. Livingston—1707(A)
High-tension condenser leads, H. Clark—1719(A)
H₂, laboratory source, G. W. Sargent, W. P. Davey—111(A)
Intensity of infrared absorption bands, L. A. Matheson—1708(A)
Intensity variations of the helium lines with voltage, J. Razez—1252
Ionization chamber method of measuring relative intensities of x-ray spectrum lines, S. K. Allison, V. J. Andrew—1717(A)
Ionization in dielectrics, J. T. Tykociner, E. B. Paine—1690(A)
Kundt's tube dust figures, E. Hutchisson, F. B. Morgan—1155
Latent image at low intensities, F. E. Poindexter, L. E. James—106(A)
Lens for use with the concave grating, J. B. Green—473(A)
Linear time scale for voltage, C. K. Stedman—474(A)
Magnetic susceptibilities, companion of, L. G. Hector, A. N. Benson—1679(A)
Molecular beams, measuring the intensity of, A. Ellett, R. M. Zabel—99(A), 1112
Multicrystal x-ray spectrograph, J. W. M. DuMond, H. A. Kirkpatrick—136, 232(A)
Non-linear circuits, C. G. Suits—462(A)
Oscillating arc, E. Z. Stowell—1452
Photoelectric cell in a magneto-optic method of analysis, F. Allison, J. H. Christensen, G. V. Waldo—1003(L)
Photoelectric currents, D. Ramadanoff—464(A), 884
Photoflash lamp, W. E. Forsythe, M. A. Easley—466(A)
Photographic spectro-photometry, B. O'Brien, E. D. O'Brien—471(A)
Photometric study of appearance of spectra lines, H. V. Knorr—1611
Photometry in the Schumann region, G. R. Harrison, P. A. Leighton—470(A)
Pirani gauge, small changes of pressure, A. Ellett, R. M. Zabel—99(A), 1102, 1700(A)
Potential in condensed discharges, Kerr cells, J. C. Street, J. W. Beams—1677(A)

Projectile velocity, L. Thompson, N. Riffolt—1691(A)
Raman effect, improved technique, R. W. Wood—1022(A)
Reciprocity law and alpha-ray blackening, T. R. Wilkins, R. Wolfe—1688(A)
Resolving power, prism spectrometer in infrared, J. Strong—1661
Resonance radiometer, J. D. Hardy, S. Silverman—176
Reststrahlen, region 20 to 40 μ , John Strong—1565
Siegbahn x-ray vacuum spectrograph accessories, F. K. Richtmeyer—472(A)
Simultaneous dispersion and refractive index, C. E. Bennett—263, 474(A)
Source of + ions, blackening of photographic plate, K. T. Bainbridge—1718(A)
Spark breakdown, visual study, F. G. Dunnington—230(A), 1677(A)
Spectrograph slit irradiation, D. C. Stockbarger, L. Burns—920
Speed control, F. Wenner, C. Peterson—1691(A)
Supersonic interferometers, E. Klein, W. D. Hershberger—109(A), 760
Surface tension, M. Kernaghan—990
Temperature control improved apparatus, E. J. Workman—1706(A)
Temperature-compensated millivoltmeters, H. B. Brooks—1692(A)
Time lag in the formation of the latent image, L. I. Zimmerman—106(A)
Velocity of sound in metal rods, L. C. Shugart—1683(A)
X-ray powder diffraction, T. M. Hahn—475(A)
Mobility of ions (see Ions, mobility)
Molecular beams (see Atomic and molecular beams)
Molecular structure and constants (see Spectra, molecular)
Multiplets (see also Spectra, atomic)
Separations and Zeeman effects, Sn, Pb and Sb, J. B. Green—469(A)
Nucleus
Mass of O¹⁷, H. C. Urey—923, 1023(A)
Nuclear abundance and stability, W. D. Harkins—105(A)
Nuclear spin, J. H. Bartlett, Jr.—327(L)
Spin in Al, R. C. Gibbs, P. G. Kruger—656(L), H. E. White—1175(L)
Statistics of nuclei, P. Ehrenfest, J. R. Oppenheimer—333, 232(A)
Optical constants and properties
Dispersion of He, H. Margenau—1021(A)
Dispersion and refractive index of nitrogen, C. E. Bennett—263, 474(A)

Optical constants and properties (continued)

- Effect of pressure, upon some optical properties, T. C. Poulter—112(A)
- Emissivities at low temperatures, Lambert's cosine law, E. R. Binkley—1687(A)
- n_d of CS₂-gasoline, L. E. Dodd—226(A)

Optical instruments

- Lens for use with the concave grating, J. B. Green—473(A)
- Prism spectrometer resolving power, J. Strong—1661
- Reflecting power and grating efficiency in the extreme ultraviolet, H. M. O'Bryan—1713(A)
- Resolving power of the concave grating, J. E. Mack, J. R. Stehn—1713(A)
- Transparency of sodium fluoride and lithium fluoride, in ultraviolet, E. H. Melvin—1230
- Ultramicroscopes, limitations and adaptability of, L. V. Foster—1715(A)

Photoelectric effect

- Angular distribution of photoelectrons in K vapor, M. A. Chaffee—1233, E. O. Lawrence, M. A. Chaffee—1718(A)
- of Ag, outgassing and temperature effects—R. P. Winch—1269
- of Au, outgassing and temperature effects, L. W. Morris—1263
- Of Cs vapor, F. W. Cooke—1707(A)
- Composite surfaces at various temperatures and potentials, D. Ramadanoff—464(A)
- And contact potential Fe and Ni, G. N. Glasoe—102(A)
- Dual work function, A. H. Warner—233(A)
- Fatigue in Co, G. B. Welch—1707(A)
- K on a Ag surface, J. J. Brady—230(A)
- Photographic images on cathodes of alkali metal photoelectric cells, A. R. Olpin, G. R. Stilwell—473(A)
- Properties of oxide cathodes, and effect of applied fields, W. S. Huxford—102(A)
- Properties of Rh, E. H. Dixon—60
- Radiation from low speed electron bombardment, F. L. Mohler, C. Boeckner—1018, 1685(A)
- Selective photoelectric effect and the selective transmission of electrons, A. R. Olpin—464(A)
- Spatial distribution of photoelectrons, J. A. Van den Akker, E. C. Watson—1631
- Temperature and fields, effects, of, D. Ramadanoff—884

Photography

- Blackening of photographic plates by positive ions, K. T. Bainbridge—1718(A)
- Latent image at low intensities, F. E. Poindexter, L. E. James—106(A)
- Time lag in the formation of the latent image, L. I. Zimmerman—106(A)

Photometry

- Intermittent exposure, B. O'Brien, E. D. O'Brien—471(A)
- Photographic photometry in the Schumann region, G. R. Harrison, P. A. Leighton—470(A)
- Variations of intensity of He lines with voltage, J. Razek—1252

Photons

- Collisions of, A. K. Das—94(L)

Plasmoidal discharges (see also Discharge of electricity in gases)

- High frequency behavior, L. Tonks—1020(A), 1458

Piezoelectric effect

- And Laue patterns of quartz, G. W. Fox, P. H. Carr—1695(A), 1622

Polar molecules

- Debye's theory, H. H. Race—430, 463(A), erratum—1371

Polarization, electrical (see Dielectric constant)**Polarization of radiation**

- Hyperfine structure of Hg 2537A, A. Ellett—216 (L), S. Mrozowski—845(L)
- Scattered by H-atoms, B. Podolsky—231(A)

Potentials, critical (see also Ionization potentials, Ionization by impact)

- Ionization of A, Ne and He by + ions, R. M. Sutton, J. C. Mouzon—229(A), 379
- Mercury vapor, C. R. Haupt—229(A), W. M. Nielsen—87(L), P. T. Smith—100(A), 808
- Of nitrogen and carbon monoxide, J. T. Tate, P. T. Smith—1705(A)

Proceedings of the American Physical Society

- Chicago Meeting, November 28 and 29, 1930—98
- Los Angeles Meeting, December 12 and 13, 1930—225
- Cleveland Meeting, December 30 and 31, 1930—453
- New York Meeting, February 26-28, 1931. Joint Meeting with the Optical Society of America—1010
- Washington Meeting, April 30, May 1 and 2, 1931—1676

Projectiles

- Air resistance, P. S. Epstein—233(A)

Quantum mechanics (see Mechanics, quantum)**Radiation**

- Of multipoles, K. F. Herzfeld—253, erratum—1673
- Properties of materials for region 20-40 μ , John Strong—1565
- Quenching of mercury resonance radiation. O. S. Duffendack—107(A)
- Selective temperature radiator, R. W. Wood—1687(A)

Radiation (continued)

Ultraviolet energy S-1 lamps in quartz, B. T. Barnes—466(A)

Radio (see **Electrical oscillations and waves**)**Radioactivity**

Luminescence, theory of, D. H. Kabakjian—1120

Raman effect

In ammonia solutions, A. Hollaender, J. W. Williams—1367(L)

Asymmetry of the C and N atoms, R. T. Dufford—1013(A)

Carbon dioxide, W. V. Houston, C. M. Lewis—227(A)

In cyclopropane and the valence properties of some organic compounds, R. C. Yates—616

Hydrogen halides as liquids and gases, E. O. Salant, A. Sandow—373

Of hydroxyl ions, J. L. Thompson, J. R. Nielsen—1669(L)

Improved technique, R. W. Wood—1022(A)

Organic halides, C. E. Cleeton, R. T. Dufford—362, 1013(A)

Rotational fine structure, E. F. Barker—330(L)

Silico-chloroform, H. C. Urey, C. A. Bradley, Jr.—843(L)

In sulphuric acid, R. M. Bell, W. R. Fredrickson—1562

Recombination

Coefficient for gaseous ions, O. Luhr, N. E. Bradbury—998

Effect on mobility, N. E. Bradbury—230(A), 1311

In mercury vapor, H. W. Webb, D. Sinclair—469(A)

Reflection of corpuscles (see **Atomic and molecular beams**)**Relativity**

Dirac's equation, tensor form, B. Podolsky—1398

Entropy of the universe, Richard C. Tolman—1639

Gravitational field produced by light, R. C. Tolman, P. Ehrenfest, B. Podolsky—602

Michelson-Morley-Miller experiment, N. Gallishohat—460(A)

Projective relativity and the quantum field, B. Hoffman—88(L)

Quantum postulates, logical relativity, W. Band—1164

Rotating fluid in the relativity theory, E. L. Akeley—109(A)

Resistance, electrical (see **Electrical conductivity and resistance**)**Scattering of electrons** (see **Electrons, scattering, Electron diffraction and Collision diameter**)**Scattering of light** (see also **Raman effect**)

Change of spectral composition, O. Halpern—112(A)

Polarization of light scattered by H-atoms, B. Podolsky—231(A)

Selection rules

And the angular momentum of light quanta, J. R. Oppenheimer—231(A)

Shot effect

Space charge and current fluctuations, E. W. Thatcher, N. H. Williams—1681(A)

Solutions

Particle size in solutions, W. P. Davey, H. B. DeVore—111(A)

Spark discharge

Diffusion of metallic vapor, H. A. Zinszer—217(L)

Fall of potential in condensed discharges, J. C. Street—1020(A)

Spark breakdown, F. G. Dunnington—1677(A)

Spectra, condensed discharges, J. W. Beams—470(A)

Spectral lines in a condensed spark, H. V. Knorr—470(A), 1611

Vacuum spark discharge, L. B. Snoddy—1678(A)

Specific heat

Of methane, P. C. Ludolph—110(A), 830

Variation (C_p) of O_2 , N_2 and H_2 with pressure, E. J. Workman—1016(A), 1345

Spectra, absorption (see also **Absorption of light**)

Of acetylene, ultraviolet, G. B. Kistiakowsky—276

Of amino acids, G. A. Anslow, M. L. Foster—1708(A)

Of BaF interpretation, A. Harvey, F. A. Jenkins—1709(A)

Of blood and its relation to rickets, R. C. Gibbs, J. R. Johnson, C. V. Shapiro—1012(A)

Of Br, W. G. Brown—1007(L)

Of CaF, A. Harvey—228(A)

Of CO_2 , fundamental vibration bands, P. E. Martin, E. F. Barker—1708(A)

Of gases from 20 to 40μ , J. Strong—1003(L) 1565

Halogen derivatives of benzene, F. S. Brackett, U. Liddel—108(A)

Hydrogen cyanide gas in the near infrared, R. M. Badger, J. L. Binder—800

Hydrogen halides in the liquid state, E. O. Salant, W. West—108(A)

In hydrogen sulphide and interpretation, H. H. Nielsen, E. F. Barker—727, H. H. Nielsen, A. D. Sprague—1183(L)

Infrared bands, asymmetric molecules, H. H. Nielsen—472(A)

Infrared bands in formaldehyde vapor, J. R. Patty, H. H. Nielsen—472(A), 1708(A)

Intensity of infrared, L. A. Matheson—1708(A)

Spectra, absorption (continued)

Of I_2 by atoms from optically dissociated molecules, L. A. Turner, E. W. Samson—1023(A)
 Of Hg vapor, J. G. Winans—107(A), 897, erratum—1371.

Of S_2 , A. Christy, S. M. Naudé—903

SO_2 , ultraviolet spectrum, W. W. Watson, A. E. Parker—1484; of CS_2 —1013(A)

Vibration spectrum of the N_2O molecule, E. K. Plyler, E. F. Barker—1709(A)

Water vapor, infrared, E. K. Plyler, W. W. Sleator—108(A), 1493, E. D. McAllister, H. J. Unger—1012(A)

Of Zn, Cd and Hg, J. G. Winans—902

Spectra, atomic (see also Hyperfine structure)

As VI, D. Borg, J. E. Mack—470(A)

Auger effect, A. G. Shenstone—1701(A)

Cb I and II, A. S. King, W. F. Meggers—226(A)

Cs II, resonance lines, O. Laporte, G. R. Miller, R. A. Sawyer—845(L)

Electrostatic interactions in (*jj*) coupling, D. R. Inglis—1702(A)

Of Ge II, C. W. Gartlein—1704(A)

He arc line 3888, structure of, R. C. Gibbs, P. G. Kruger—1559

He 10830A, components of, J. D. Hardy—1686(A)

Hg, Near-infrared, H. J. Unger—844(L)

Intensity, manganese lines, R. S. Seward—344

Of Li III, H. G. Gale, J. B. Hoag—1703(A)

O I terms, nebular and coronal lines, J. J. Hopfield—160

Order of appearance of spectral lines, H. V. Knorr—1611

Of Rb II and Cs II, O. Laporte, G. R. Miller—1703(A)

Relative intensities of Hg lines, M. J. E. Golay—821

Resonance lines of Rb II, G. R. Miller, O. Laporte, R. A. Sawyer—219(L)

Of Rhe, arc spectrum, W. F. Meggers, 219(L) 1702(A)

Of Se I, R. C. Gibbs, J. E. Ruedy—1704(A)

Of Xe II, C. J. Humphreys, T. L. de Bruin, W. F. Meggers—106(A)

Selection rules for many electron transitions, S. Goudsmit, L. Gropper—1702(A)

Structure of the arc and spark lines of N, P. G. Kruger, R. C. Gibbs—1702(A)

Theory of complex spectra II, E. U. Condon, G. H. Shortley—1014(A), 1025

Of VI, H. T. Gilroy—1704(A)

Spectra, continuous

By bombardment of gases and vapors with cath-

ode-rays, W. M. Cohn—1684(A)

Color change and the Raman spectrum, W. D. Harkins, H. E. Bowers—108(A)

Radiation from low speed electron bombardment, F. L. Mohler, C. Boeckner—1018(A), 1685(A)

From tungsten, by 800 volt electrons, L. S. Taylor—1684(A)

Spectra, general

Arc spectrum of N_2 , O. E. Anderson, K. R. More—1684(A)

Condensed discharges, J. W. Beams—470(A), H. V. Knorr—470(A) 1611

Electric and magnetic fields, effect of combined, J. S. Foster—1687(A)

Lunar ultraviolet spectrum, energy distribution in, B. O'Brien, E. D. O'Brien—1012(A)

Of Nd in solid solution, R. W. Wood—1687(A)

Oscillating arc, E. Z. Stowell—1452

Properties of materials for region 20–40 μ , John Strong—1565

Of rare earth crystals, interpretation, F. H. Spedding—777(L)

Recombination in Hg vapor, H. W. Webb, D. Sinclair—182, 469(A)

Reflection spectrum of quartz, J. D. Hardy, S. Silverman—176

Of S_2 , A. Christy, S. M. Naudé—903

Solar and lunar spectra taken in Little America, Antarctica, M. P. Hanson, E. O. Hulburt—477

Spectrographs, slit irradiation, D. C. Stockbarger, L. Burns—920

In Xe, H. W. Harkness, J. F. Heard—1687(A)

Spectra, molecular

Of bismuth chloride, analysis, P. G. Saper—1710(A)

Boron hydride bands, R. F. Paton, G. M. Almy—1710(A)

Of CaF, A. Harvey—228(A)

Of CO_2 , analysis, H. D. Smyth, T. C. Chow—1710(A)

CO bands, λ 2220 to λ 3300, H. P. Knauss—471(A)

Of CO_2 , electron impact, H. D. Smyth, T. C. Chow—1023(A)

Directed valence in polyatomic molecules, J. C. Slater—459(A), 481; L. Pauling—1185(L)

Fine structure measurements in the BeH bands, W. W. Watson, A. E. Parker—167

A-type doubling and electron configurations, R. S. Mulliken, A. Christy—1718(A)

Of germanium sulfide, C. V. Shapiro, R. C. Gibbs, J. R. Johnson—1709(A)

Halogen bands, R. S. Mulliken—1412

Intensity distribution and repulsive energy levels, J. Kaplan—1406

Spectra, molecular (continued)

- Intensities for symmetrical diatomic molecules II, E. Hutchisson—45
- Magnetic rotation spectrum of Li_2 , F. W. Loomis, R. E. Nusbaum—1712(A)
- Mass ratios from band spectra, R. T. Birge—227(A)
- Mass ratio of oxygen 18 and 16, H. D. Babcock, R. T. Birge—233(A)
- Of N_2 , O. E. Anderson, K. R. More—1684(A)
- Of NH , $\lambda 3360$ band, R. W. B. Pearse—1712(A)
- Of O_2^+ , analysis, D. S. Stevens—1711(A)
- Of O_2 and O_2^+ , electronic levels, R. S. Mulliken—1711(A)
- Persistence of molecular rotation and vibration, O. Oldenberg—194
- Perturbations and predissociation in S_2 , A. Christy, S. M. Naudé—903
- Perturbations in the He band spectrum, G. H. Dieke—1710(A)
- Rotational analysis of the S_2 bands, S. M. Naudé, A. Christy—490
- Rotational Raman effect in carbon dioxide, W. V. Houston, C. M. Lewis—227(A)
- Of scandium-, yttrium-, and lanthanum monoxides, W. F. Meggers, J. A. Wheeler—106(A)
- Of S_2 , P. Huber—471(A)
- Of SiH , interpretation of bands, R. S. Mulliken—733
- Of SO , ultraviolet band, E. V. Martin, F. A. Jenkins—226(A)
- Statistics of nuclei, P. Ehrenfest, J. R. Oppenheimer—333, J. R. Oppenheimer—232(A)
- Strontium and barium hydride, W. R. Fredrickson, A. L. Warntz—472(A)
- Temperature effect upon ultraviolet bands of ozone, O. R. Wulf, E. H. Melvin—1711(A)
- Zeeman effect in cyanogen bands, E. L. Hill—1709(A)
- Zeeman effect and uncoupling phenomena in helium bands, J. S. Millis—1005(L)

Spinor analysis

- Application to the Maxwell and Dirac equations, O. Laporte, G. E. Uhlenbeck—1022(A), 1380

Sputtering

- Color bands in films of tin, L. I. Bockstahler, C. J. Overbeck—465(A)
- Gold surfaces, H. F. Fruth—1690(A)

Stark effect

- Asymmetry, components of $H\alpha$, D. R. McRae—1688(A)
- Models showing the electron's motion, R. W. Wood—1022(A)

Structure factor

- Long chains liquid compounds, G. W. Stewart, R. W. Spangler—472(A)

- By scattering of x-rays from gases, E. O. Wollan—104(A), 862

Surface tension (see also Capillary action)

- Of Hg, M. Kernaghan—990, erratum—1674

Theories in physics

- Discrete and continuous in physics, A. Ruark—315

Thermal expansion

- Of rubber, W. W. Stiffler, P. C. Mitchell—1683(A)

Thermionic emission (see also Electrons, thermionic)

- Space charge vs. image force, R. S. Bartlett, A. T. Waterman—279

- Photoelectric and thermionic properties of Rh, E. H. Dixon—60

- Thermal fluctuations of the surface, K. H. Kingdon—89(L)

Thermionic emission of positive ions

- By iron and copper, L. L. Barnes—218(L)
- From metals, W. H. Wahlin—467(A)

Thermodynamics

- Clapeyron-Clausius equation, Extension of, J. L. Finck—1698(A)

- Equations of energy and entropy, T. C. Huang—1171

- Equilibrium, ammonia synthesis reaction, a correction, L. J. Gillespie, J. A. Beattie—655(L)

- Reciprocal relations in irreversible processes. I. L. Onsager—405

- Relativistic;—Entropy of this universe, R. C. Tolman—1639

Thermoluminescence

- Excited by exposure to radium, F. G. Wick—465(A)

Ultra-ionization potentials (see Potentials, critical and Ionization by impact)**Vacuum tubes**

- Amplification of small direct currents, L. A. DuBridge—392, 461(A)

- Starting-time of thyatrons, A. W. Hull, L. B. Snoddy—1678(A), W. B. Nottingham—1019(A)

Valence

- Directed valence in polyatomic molecules, J. C. Slater—459(A), 481; L. Pauling—1185(L)

- Orbital valency, J. H. Bartlett, Jr.—459(A), 507

van der Waals forces

- In gases, H. Margenau—1014(A), 1425, J. C. Slater, J. G. Kirkwood—682

Weight-mass ratios

- Change in mass-weight ratio, P. I. Wold, E. M. Bigsbee—460(A)

Work function (see also Thermionic emission, Photoelectric effect)

- Thoriated tungsten filament, L. B. Linford—1018(A)

X-Rays, absorption

- Absorption coefficients, absorption formulae, S. J. M. Allen—456(A)
 Change in wave-length, J. M. Cork—1555, 1696(A), D. Cooksey, C. D. Cooksey—1006(L), A. J. O'Leary, 873
 Dependence upon chemical and physical state, J. D. Hanawalt—456(A), 715
 In gases, W. W. Colvert—104(A)
 In gases of $K\alpha$ of C, E. Dershem, M. Schein—104(A) 1238
 In Hg vapor, F. M. Uber—1696(A)
 Of the $K\alpha$ line of C in various gases, E. Dershem, M. Schein—104(A), 1238

X-Rays, diffraction and scattering

- Atomic scattering power of Cu and O, G. A. Morton—1697(A)
 By bound electrons, D. P. Mitchell, A. J. O'Leary—103(A), A. J. O'Leary, 873
 Compton modified line, breadth of the, A. Hoyt, J. DuMond—1443, J. W. M. DuMond, H. A. Kirkpatrick—136, 232(A)
 Derivation of the formula for the half-width, N. Rashevsky—105(A)
 Electron distribution in argon as determined by x-ray scattering, A. H. Compton—104(A)
 Extra lines in patterns of mixtures, R. W. Drier—712
 By gases, E. O. Wollan—104(A), 862
 Liquids and structure factors, G. W. Stewart, R. D. Spangler—472(A)
 Magnetic doublet, nature of, by x-ray diffraction, G. W. Stewart—455(A)
 By simple cubic crystals, theory of, G. E. M. Jauncey, G. G. Harvey—1203, 1716(A)
 By solids, theory of, G. E. M. Jauncey—1193, 1694(A)
 Of unpolarized x-rays, G. E. M. Jauncey, G. G. Harvey—103(A), 698, erratum—1674
 Utilization of intensity data, M. L. Huggins—456(A)
 In water, G. W. Stewart—9

X-Rays, emission

- An attempt to detect axiality of x-ray emission, L. A. Pardue, L. W. McKeehan—329(L)
 Cathode-ray tube in x-ray spectroscopy, G. R. Fonda, G. D. Collins—328(L)
 Effects of cathode-ray diffusion on intensities, D. L. Webster, H. Clark, W. W. Hansen—115
 Satellites, and chemical combination, F. K. Richtmyer—457(A)
 Satellites, interpretation, R. M. Langer—457(A)

- Satellites of the x-ray line $L\alpha_1$, atomic number, E. Ramberg—457(A)
 Satellites of the x-ray line $L\beta_2$, atomic number, R. D. Richtmyer—456(A)
 Width of soft x-ray lines, W. V. Houston—1692(A)
 Widths of lines in the L-series spectrum of uranium, J. H. Williams—232(A), 1431, 1692(A)
 Width of $WK\alpha_1$, F. K. Richtmyer, S. W. Barnes—1695(A)

X-Rays, reflection and refraction

- Intensity from platinum, silver and glass, H. W. Edwards—232(A), 339
 And piezo electric effect, G. W. Fox, P. H. Carr—1622, 1695(A)
 Reflection of the $K\alpha$ line of C from quartz, E. Dershem, M. Schein—1246, 1696(A)

X-Rays, spectra and spectroscopy (see also X-Rays, emission)

- Absolute measurement of Cu and Cr K-series, J. A. Bearden—1210, 1694(A)
 Absolute measurement of the $CuL\alpha$ line, C. E. Howe, M. Allen—1694(A)
 Accessories for the Siegbahn x-ray vacuum spectrograph, F. K. Richtmyer—472(A)
 Ionization chamber method of measuring relative intensities of x-ray spectrum lines, S. K. Allison, V. J. Andrew—1717(A)
 New K-series x-ray lines, W. Duane—1017(A)
 Precision wave-length measurement with the double crystal, A. H. Compton—1694(A)
 Resolving power attainable, S. K. Allison—1695(A)
 Satellites of the $K\alpha_{1,2}$ doublet, the $K\alpha_1$ and $K\alpha_2$ lines, O. R. Ford—1695(A)

X-Rays, tubes

- Cathode-ray tube in x-ray spectroscopy, G. R. Fonda, G. B. Collins—328(L)
 Experiments with high-voltage tubes, M. A. Tuve, L. R. Hafstad, O. Dahl—469(A)
 Transparent target principle, D. E. Olshevsky—1017(A)

Zeeman effect

- Air-cooled electromagnet, I. Walerstein, A. I. May—1719(A)
 In the $^2\Sigma-^2\Sigma$ cyanogen bands, E. L. Hill—109(A)
 Hyperfine structure in thallium II and III, R. F. Bacher—226(A)
 And uncoupling phenomena in helium bands, J. S. Millis—1005(L)
